- X-rays of the hip/pelvis are usually unnecessary in patients with typical findings of meralgia paresthetica. Lumbar spine imaging can be considered if the patient has findings suggesting spinal stenosis, disk issues, or spondylolisthesis. More advanced imaging such as CT or MRI scans can be done to exclude soft tissue causes such as a tumor.
- Nerve conduction and electromyography (EMG) are rarely necessary. These studies are mainly utilized to exclude radiculopathy or lumbar plexus problems.
- Ultrasound imaging has recently been offered as an alternate diagnostic method, which reveals a swollen and hypoechoic nerve would be visualized. Additionally, it offers the benefit of serving as a means of immediate therapeutic intervention through guided injection.
- Rarely, an anesthetic nerve block injection, with or without ultrasound guidance, can be performed into the lateral femoral cutaneous nerve. Relief of the pain is confirmatory of the diagnosis of meralgia paresthetica.

TREATMENT

NONPHARMACOLOGIC THERAPY

Many patients experience sudden spontaneous resolution of their symptoms.

ACUTE GENERAL Rx

- Reassurance of the patient is vital.
- Methods to reduce compression or pressure on the nerve include avoidance of tight garments, undergarments, and belts around the waist. Wearing suspenders rather than belts can be suggested. Weight loss in obese patients, especially in the abdominal region, is also important. Correction of any leg-length discrepancy with shoe lifts can also be therapeutic.

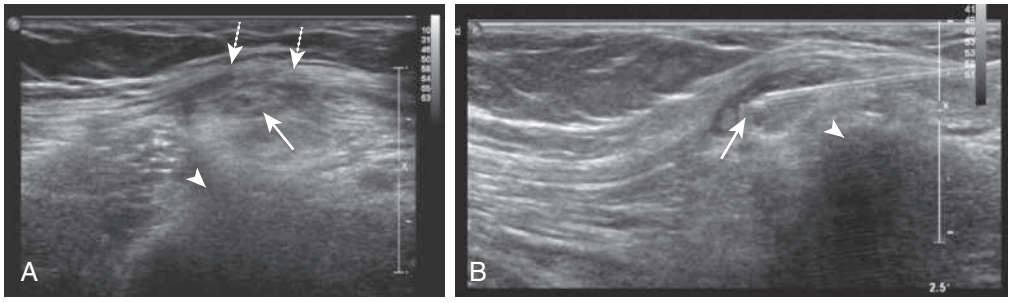

FIG. E1 Scarring of the lateral femoral cutaneous nerve causing meralgia paresthetica. A, Ultrasound image at the level of the anterior superior iliac spine *(arrowhead)* shows the lateral femoral cutaneous nerve *(dashed arrows)* surrounded by scar tissue *(solid arrow).* **B,** Ultrasound image shows steroid and anesthetic injection with the needle tip inside the scar *(solid arrow).* (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2014, WB Saunders.)

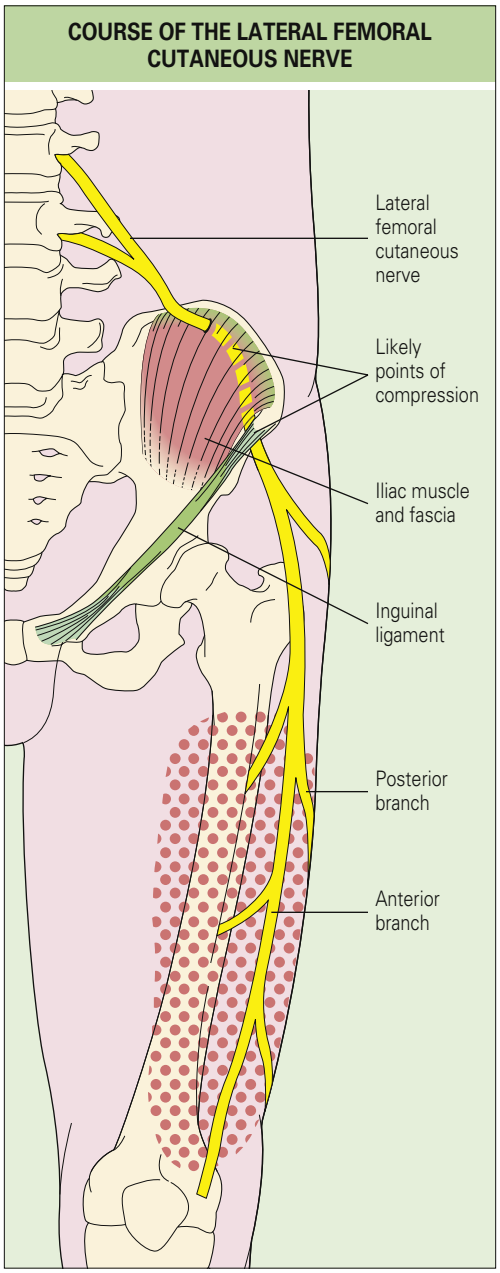

FIG. E2 The potential for entrapment of the lateral femoral cutaneous nerve can be seen by its course just under the inguinal ligament and medial to the anterior superior iliac spine. (From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.)

Parisi TJ et al: Meralgia paresthetica: relation to obesity, advanced age, and diabetes mellitus, *Neurology* 77(16):1538-1542, 2011.

CHRONIC Rx

- Persistent symptoms after 1 to 2 mo despite conservative approach may warrant verification of diagnosis through reexamination of affected area, repeat questioning, and possibly other studies.
- Gabapentin, amitriptyline, phenytoin, and carbamazepine may prove beneficial in reducing the associated neuropathic pain. However, in the majority of patients they are not beneficial.
- Lidocaine patches and titanium dioxide patches can be utilized as additional modes of treatment for more refractory cases.
- Physical therapy including stretching and massage, moist heat, and low-intensity phonophoresis can play a large role in the management of pain.
- Consultation with an anesthesia specialist or interventional radiologist for local nerve blockade can be done. Glucocorticoid or local anesthetic, or a mixture of both, can be injected into the appropriate region for temporary relief.
- A recent small case series showed that ultrasound-guided neurolysis with 50% alcohol can be used for refractory meralgia paresthetica to provide pain relief and can help avoid surgical treatment.
- Surgical treatment—either decompression, removal of the nerve, or cutting of the nerve—have provided benefit to patients in refractory cases. Predictors of good surgical results include presence of an abnormal electromyographic (EMG) study before surgery and immediate relief of symptoms after the blocking of the lateral femoral cutaneous nerve.
- A few reports have mentioned the utility of radiofrequency nerve ablation in treating the condition, but this has not been studied adequately.

DISPOSITION

This is a self-limited, nonthreatening condition in most patients. Conservative measures are enough for >90% of patients, but recurrence of symptoms is common.

REFERRAL

- Patients with meralgia paresthetica can often be easily managed by the primary care physician.
- Referral to anesthesiologist, interventional radiologist, or neurosurgeon may be indicated in refractory cases.

AUTHOR: **Jacob Modest, MD**

Mesenteric Adenitis

BASIC INFORMATION

DEFINITION

Acute mesenteric lymphadenitis is a syndrome of acute right lower quadrant abdominal pain associated with mesenteric lymph node enlargement and a normal appendix.

SYNONYMS

Acute mesenteric lymphadenitis
Mesenteric lymphadenitis

ICD-10CM CODE
I88.0 Nonspecific mesenteric lymphadenitis

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence unknown
- Affects mostly children (<18 yr) with no sex preference
- When *Yersinia* enterocolitis is the cause, boys are more frequently involved

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Abdominal pain of variable severity (mild ache to severe colic) beginning in upper abdomen or right lower quadrant; eventually localizes in the right side but not in a precise location (unlike appendicitis)
- In *Yersinia* infection outbreaks (see Table E1), symptoms include abdominal pain (84%), diarrhea (78%), fever (43%), anorexia (22%), nausea (13%), and vomiting (8%)
- Physical findings:
  1. Other lymphadenopathy (20% of cases)
  2. Right lower quadrant tenderness (site of maximal tenderness may vary from one examination to the next)
  3. Guarding (rare)
  4. Mild fever

ETIOLOGY & PATHOGENESIS

- Reactive hyperplasia of lymph nodes that drain the ileocecal region, similar to that seen in inflammatory or allergic conditions. One study reported that approximately two thirds of cases are secondary (reactive) and one third are primary (no demonstrable associated inflammatory process).
- *Yersinia enterocolitica, Y. pseudotuberculosis, Salmonella* species, *Escherichia coli,* and streptococci have been implicated in mesenteric adenitis. Clinical manifestations of yersiniosis are described in Table E2.

DIAGNOSIS

In general, the diagnosis is made on exploration of the abdomen of a patient suspected of having acute appendicitis. On examination the appendix appears normal, and enlarged mesenteric lymph nodes are noted. Excision of an enlarged lymph node with culture and nodal histology may provide information regarding the etiology but is not routinely used.

DIFFERENTIAL DIAGNOSIS

- Acute appendicitis (5% to 10% of patients admitted to hospitals with a diagnosis of appendicitis are discharged with a diagnosis of mesenteric adenitis)
- Crohn disease

Section II describes the differential diagnosis of right lower quadrant abdominal pain.

LABORATORY TESTS

- Complete blood count may show leukocytosis.
- Abdominal sonography and CT scan with IV and oral contrast (Fig. E1) may be useful.
- Laparotomy if appendicitis is suspected.

PROGNOSIS

Recurrent bouts are common; therefore if laparotomy is performed and a normal appendix is found, it should be removed.

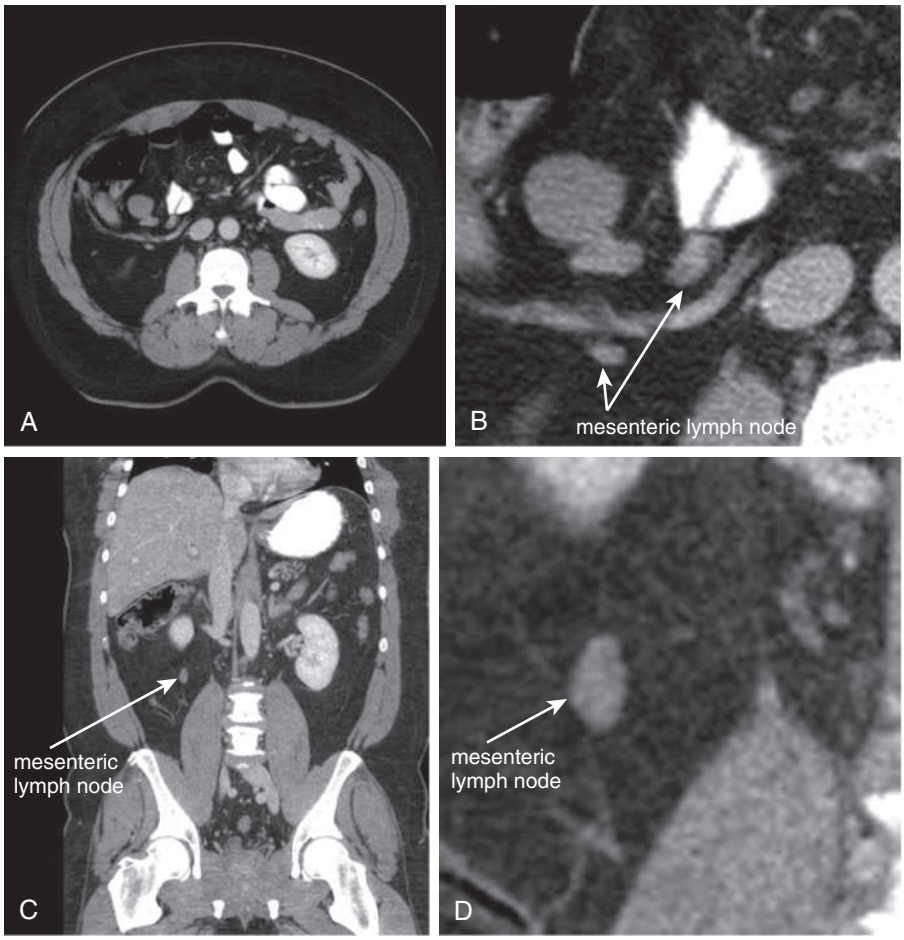

FIG. E1 Mesenteric adenitis, computed tomography (CT) with intravenous and oral contrast, soft-tissue window. Mesenteric adenitis can mimic appendicitis in its clinical presentation. Enlarged lymph nodes are visible on CT. Lymph nodes have soft-tissue density and appear as discrete, rounded structures. On a single image they may appear similar to blood vessels or to the appendix, but on inspection of adjacent images it becomes clear that lymph nodes are rounded, not tubular like a blood vessel or the appendix. **A,** Axial image. **B,** Close-up from **A. C,** Coronal reconstruction. **D,** Close-up from **C.** (From Broder JS: *Diagnostic imaging for the emergency physician,* Philadelphia, 2011, WB Saunders.)

Mesenteric Venous Thrombosis

BASIC INFORMATION

DEFINITION

Mesenteric venous thrombosis (MVT) is a thrombotic occlusion of the mesenteric venous system involving major trunks or smaller branches and can lead to intestinal infarction in its acute form.

SYNONYM

MVT

ICD-10CM CODES

K55.0 Acute vascular disorders of intestine
K55.1 Chronic vascular disorders of intestine

EPIDEMIOLOGY & DEMOGRAPHICS

Between 5% and 15% of patients with acute mesenteric ischemia has MVT. MVT is slightly more common in men than women. The typical age of occurrence is 50 to 60 yr. Table E1 summarizes the incidence of ischemic bowel disease.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

ACUTE MVT:

- Symptoms: Abdominal pain in 90% of patients, typically out of proportion to the physical findings. Nausea and vomiting occur in 50% and gastrointestinal (GI) bleeding occurs in 50% (occult) and 15% (gross).
- Physical findings:
  1. Early: Abdominal tenderness, decreased bowel sounds, abdominal distention
  2. Later: Guarding and rebound tenderness, fever, septic shock

SUBACUTE MVT:

- Symptoms: Nonspecific abdominal pain for wk or mo
- Physical findings: None

CHRONIC MVT:

- Symptoms: Typically asymptomatic, tends to present with complications of portal hypertension (hemorrhage from bleeding varices, ascites) due to concomitant portal vein or splenic vein thrombosis.
- Physical findings: None other than signs of portal hypertension if the portal/splenic veins are also involved.

ETIOLOGY & PATHOGENESIS

HYPERCOAGULABLE STATES:

- Personal or family history of thrombophilia or personal history of thromboembolism
- Neoplasms
- Antithrombin III, protein C, protein S deficiencies or activated protein C resistance
- Lupus anticoagulant (antiphospholipid antibody syndrome)
- Factor V Leiden or prothrombin G20210A mutations
- Oral contraceptive use, pregnancy
- Myeloproliferative disorders (polycythemia vera, essential thrombocytosis)
- Paroxysmal nocturnal hemoglobinuria

TABLE E1 Incidence of Ischemic Bowel Diseases

Disease	Incidence (%)*
Superior mesenteric artery (SMA) embolism: • The SMA is susceptible to embolism because of large vessel caliber and a narrow angle of departure from the aorta. • The proximal SMA is most commonly obstructed within 6-8 cm of the aorta	50
Nonocclusive ischemia	25
SMA thrombosis	20
Mesenteric venous thrombosis	5

*Percentage of all cases of acute mesenteric ischemia.
From Adams JG et al: *Emergency medicine, clinical essentials,* ed 2, Philadelphia, 2013, Elsevier.

BOX E1 Factors Associated with Mesenteric Venous Thrombosis

Hypercoagulable states
  Polycythemia vera
  Sickle cell disease
  Antithrombin III deficiency
  Protein C or S deficiency
  Malignancy
  Myeloproliferative disorders
  Estrogen therapy, oral contraceptive pills
  Pregnancy
Inflammatory conditions
  Pancreatitis
  Diverticulitis
  Appendicitis
  Cholangitis
Trauma
  Operative venous injury
  Postsplenectomy
  Blunt or abdominal trauma
  Miscellaneous
  Congestive heart failure
  Renal failure
  Decompression sickness
Portal hypertension

From Marx JA et al: *Rosen's emergency medicine,* ed 8, Philadelphia, 2014, WB Saunders.

PORTAL HYPERTENSION:

- Cirrhosis

INFLAMMATION:

- Pancreatitis
- Peritonitis (e.g., appendicitis, diverticulitis, perforated viscus)
- Inflammatory bowel disease
- Pelvic or intraabdominal abscess
- Intraabdominal cancer

POSTOPERATIVE STATE OR TRAUMA:

- Blunt abdominal trauma
- Postoperative states (abdominal surgery)
- Box E1 summarizes factors associated with mesenteric venous thrombosis

Thrombosis may begin in small mesenteric branches (e.g., in hypercoagulable states) and propagate to the major venous mesenteric trunks or begin in large veins (e.g., in cirrhosis, intraabdominal cancer, surgery) and extend distally. If collateral drainage is inadequate, the intestine becomes congested, edematous, cyanotic, and hemorrhagic and eventually may infarct.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

All other causes of abdominal pain (e.g., peritonitis, intestinal obstruction, pancreatitis, peptic ulcer disease, gastritis, inflammatory bowel disease, perforated viscus) are also to be considered in the differential diagnosis.

WORKUP

Laboratory tests and imaging studies

LABORATORY TESTS

- Complete blood count: Leukocytosis
- Electrolytes: Metabolic acidosis (lactic) indicates bowel infarction
- Tests for hypercoagulable states

IMAGING STUDIES

- Computed tomography (CT) with and without oral and IV contrast (Fig. E1) is a good initial screening study due to widespread availability and the ability to detect sequelae of MVT (such as intestinal ischemia or infarction).
- If CT with and without oral and IV contrast does not demonstrate MVT and the clinical suspicion is high, computed tomographic angiography (CTA) is another imaging modality with higher sensitivity but more use of contrast material. Use of two-phase imaging improves sensitivity for venous thrombosis.
- Magnetic resonance angiography/venography (MRA/MRV) can also be used; it avoids the risk of radiation and contrast material but takes longer and may be limited due to motion artifact.

TREATMENT

- Acute and subacute MVT: Anticoagulation with unfractionated heparin or low-molecular-weight heparin with eventual transition to a vitamin K antagonist or novel oral anticoagulant for 3 to 6 mo, or longer if a hypercoagulable state has been identified. When medical treatment is unsuccessful, options include transhepatic and percutaneous mechanical thrombectomy, intravascular catheter-directed thrombolysis, and open intraarterial thrombolysis.

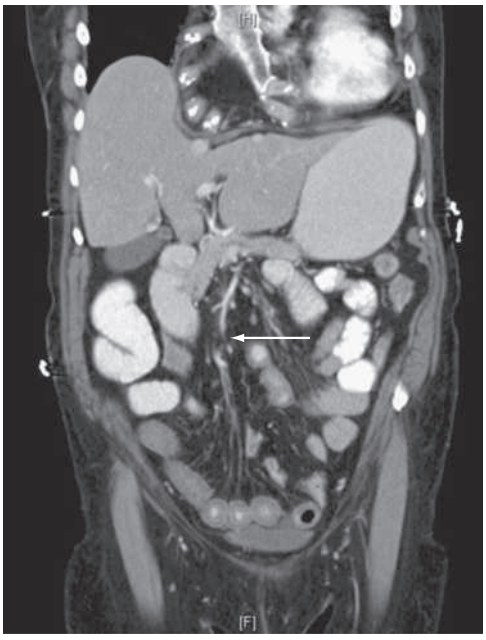

FIG. E1 Computed tomography after administration of oral and intravenous contrast in a patient with an embolism to the superior mesenteric artery and ischemia of the small bowel and right colon. The arrow points to the embolus in the superior mesenteric artery. (From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.)

- Intravenous fluid administration (due to relative hypovolemia from bowel wall edema), bowel rest and decompression if ileus forms.
- Consider prophylactic antibiotics to reduce the incidence of bacterial translocation.
- Laparotomy if intestinal infarction is suspected.

CHRONIC MVT

- Anticoagulation should be considered but is a decision specific to each individual patient.
- If anticoagulation is pursued, ensure potential bleeding complications (esophageal varices) have been identified and treated.
- If varices are present, initiate beta blockade, similar to cirrhosis-related portal hypertension.

PROGNOSIS

- Mortality rate of acute MVT: With prompt diagnosis and anticoagulation, 10% to 20%. The presence of intestinal infarction is a poor prognostic sign for overall mortality.
- Recurrence rate: 15% to 25%.

SUGGESTED READING

Clair DG: Beach JM: mesenteric ischemia, *N Engl J Med* 374:959-968, 2016.

Mesothelioma, Malignant PTG

BASIC INFORMATION

DEFINITION

Malignant mesothelioma is a neoplasm originating from the mesothelial surfaces of the pleural (80%) or peritoneal cavities (20%). The three major histologic subtypes are epithelial (most common), sarcomatous, and mixed (epithelial/sarcomatous).

SYNONYM

Malignant mesothelioma

ICD-10CM CODES

C45.0 Mesothelioma of pleura
C45.1 Mesothelioma of peritoneum
C45.2 Mesothelioma of pericardium
C45.7 Mesothelioma of other sites
C45.9 Mesothelioma, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- Associated with asbestos exposure (all fiber types) and has a latency of 20 to 40 yr.
- About 3000 new cases are diagnosed in the U.S. annually.
- More common in men (5:1) as a result of workplace asbestos exposure; however, even family members of workers exposed to asbestos have a higher risk due to cleaning of contaminated clothes.
- Incidence in the U.S. has leveled off due to lack of asbestos use and mining.
- Incidence of mesothelioma increases with age; median age at presentation is >70 yr.
- More than 8 million persons in the U.S. are currently at risk for mesothelioma because of prior asbestos exposure.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Dyspnea
- Nonpleuritic chest pain
- Fever, weight loss, sweats, fatigue, loss of appetite
- Dysphagia, superior vena cava syndrome, Horner syndrome in advanced stages
- Auscultation may reveal unilateral loss of breath sounds
- Dullness on percussion may be present

ETIOLOGY

- Asbestos exposure (>70% of patients).
- Other reported potentially causal factors include prior radiation therapy and extravasated thorotrast, zeolite, and erionite fibers.
- Mutations of BRCA1-associated protein 1 (BAP1) cyclin-dependent kinase inhibitor 2A gene *(CDKN2A)* have been causally linked to development of mesothelioma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Metastatic adenocarcinomas (from lung, breast, ovary, kidney, stomach, prostate)

WORKUP

- Staging evaluation (Box 1) includes complete history (including occupational history), physical examination, and testing to determine potential operability (CT, bone scan, pulmonary function tests [PFTs]).
- Thoracoscopy, pleuroscopy, and open-lung biopsy are useful in obtaining adequate tissue samples for diagnosis.
- Pulmonary function tests.
- PET-CT scan (Figs. E1 and E2) is performed only in patients considered candidates for surgery to determine resectability.
- Staging: The TNM system categorizes mesothelioma in stages I to IV similar to that used for non–small cell lung cancer.

LABORATORY TESTS

- Diagnostic thoracentesis is generally insufficient for diagnosis because pleural effusions may only reveal atypical mesothelial cells.
- Immunohistochemistry is useful to distinguish adenocarcinoma from epithelial malignant mesothelioma (mesotheliomas are generally carcinoembryonic antigen negative and cytokeratin positive).
- Thrombocytosis and anemia may be found on initial laboratory evaluation.
- Serum osteopontin levels (when available) can also be used to distinguish persons with exposure to asbestos who do not have cancer from those with exposure to asbestos who have pleural mesothelioma.

BOX 1 International Mesothelioma Interest Group (IMIG) Staging System

T: Primary Tumor and Extent

T_1:
a. Tumor limited to ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; no involvement of the visceral pleura
b. Tumor involving the ipsilateral parietal pleura, including mediastinal and diaphragmatic pleura; scattered foci or tumor also involving the visceral pleura

T_2 Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic pleura); scattered foci or tumor also involving the visceral pleura:
a. Involvement of diaphragmatic muscle
b. Confluent visceral pleura (including the fissures) or extension of tumor from visceral pleura into the underlying pulmonary parenchyma

T_3 Locally advanced but potentially resectable tumor; tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
a. Involvement of the endothoracic fascia
b. Extension into mediastinal fat
c. Solitary, complete resectable focus or tumor extending into the soft tissues of the chest wall
d. Nontransmural involvement of the pericardium

T_4 Locally advanced, technically nonresectable tumor; tumor involving all the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features:
a. Diffuse extension or multifocal mass of tumor in the chest wall, with or without associated rib destruction
b. Direct transdiaphragmatic extension of the tumor to the peritoneum
c. Direct extension of tumor to the contralateral pleura
d. Direct extension of tumor to one or more mediastinal organs
e. Direct extension of tumor into the spine
f. Tumor extending through the internal surface of the pericardium with or without a pericardial effusion or tumor involving the myocardium

N: Lymph Nodes

N_x Regional lymph nodes cannot be assessed
N_0 No regional lymph node metastases
N_1 Metastases in ipsilateral bronchopulmonary or hilar lymph nodes
N_2 Metastases in the subcarinal or the ipsilateral mediastinal lymph nodes, including the ipsilateral internal mammary nodes
N_3 Metastases in contralateral mediastinal, contralateral internal mammary, ipsilateral, or contralateral supraclavicular scalene lymph nodes

M: Metastases

M_x Presence of distant metastases cannot be assessed
M_0 No (known) metastasis
M_1 Distant metastasis present

Stage Grouping

I.
a. $T_{1a}N_0M_0$
b. $T_{1b}N_0M_0$
II. $T_2N_0M_0$
III. Any T_3M_0, any N_1M_0, any N_2M_0
IV. Any T_4, any N_3, any M_1

From Sellke FW et al: *Sabiston & Spencer surgery of the chest,* ed 9, Philadelphia, 2016, Elsevier.

BOX 2 Therapeutic Options for Malignant Pleural Mesothelioma

Single-Modality Therapy
- Debulking surgery (pleurectomy/decortication or extrapleural pneumonectomy)
- Radiation (external beam, brachytherapy)
- Chemotherapy (single- or double-agent approach: Doxorubicin, cyclophosphamide, cisplatinum; gemcitabine, pemetrexed, and cisplatin)

Multimodality Therapy
- Surgery and adjuvant radiation
- Surgery and adjuvant chemotherapy
- Surgery and adjuvant chemoradiotherapy

Innovative Therapies under Investigation
- Intracavitary lavage with hyperthermic chemotherapy
- Photodynamic therapy
- Gene therapy
- Angiogenesis
- Immunogenic therapy

From Sellke FW et al: *Sabiston & Spencer surgery of the chest,* ed 9, Philadelphia, 2016, Elsevier.

IMAGING STUDIES

- Chest radiographs may reveal pleural plaques (Fig. E3) or calcifications in the diaphragm.
- CT scans of the chest and abdomen, bone scan, and PET scan are used to assess the stage of disease.

Rx TREATMENT

GENERAL Rx

- Box 2 summarizes therapeutic options for malignant pleural mesothelioma.
- Operable patient (epithelial type, no positive nodes, confined to pleura, adequate PFTs): The two surgical techniques for therapeutic intervention are decortication (pleurectomy) and extrapleural pneumonectomy. Postoperative chemotherapy with cisplatin and pemetrexed and subsequent external-beam radiation are used with limited success.
- Inoperable patient (elderly patient, extensive disease, sarcomatous or mixed histology type, poor PFTs): Chemotherapy is administered to improve survival; supportive care is a standard option. Combined modality therapies (radiation therapy, chemotherapy, and biologics) have also been used to reduce both local and distant recurrences. First-line chemotherapy options include the combination of cisplatin and pemetrexed with or without additional bevacizumab (antiangiogenic agent).
- Patients with progressive cancer after initial chemotherapy can often be treated with single-agent chemotherapy such as gemcitabine or vinorelbine.
- Recent data have shown improvement in survival with use of immune checkpoint inhibitors targeting the programmed death-1 (PD-1) pathway such as pembrolizumab and nivolumab with or without ipilimumab.
- Intrapleural instillation of cisplatin or biologics (e.g., interferons, interleukin-2) is generally limited to very early disease because it can only penetrate a very limited depth of the tumor and there is a propensity of the pleural space to become progressively obliterated with advancing disease.
- Radiation therapy is often used for palliation of local chest pain.
- Obliteration of the pleural space (pleurodesis) with instillation of talc or tetracycline into the pleural cavity is done in the treatment of recurrent symptomatic pleural effusions.
- Several biomarkers have been evaluated extensively in mesothelioma management. Serum mesothelin is not sensitive or specific for diagnostic purposes, but serial measurements during chemotherapy can be useful as a monitoring tool. Recent data reveal that plasma fibulin-3 levels can distinguish healthy persons with exposure to asbestos from patients with mesothelioma. In conjunction with effusion fibulin-3 levels, plasma fibulin-3 levels can further differentiate mesothelioma effusions from other malignant and benign effusions.

DISPOSITION

The overall prognosis of malignant mesothelioma is dismal, with a median survival of 6 to 8 mo. Survival is better for patients with the epithelial form, although overall median survival is approximately still 1 yr.

PEARLS & CONSIDERATIONS

- Patients with early disease should be referred to treatment centers specializing in multidisciplinary therapy before attempts are made to obliterate the pleural space with pleurodesis.
- Patients with advanced or resected disease should be treated with appropriate combination chemotherapy as listed previously.

BASIC INFORMATION

DEFINITION

Metabolic syndrome refers to a constellation of risk factors for development of cardiovascular disease and type 2 diabetes mellitus. Hyperglycemia, dyslipidemia, abdominal obesity, and hypertension are critical components of metabolic syndrome. Over the yrs, many definitions of the syndrome have been proposed and debated (see Table E1). In 2009, a consensus statement defined "metabolic syndrome" as the presence of any three of the following criteria[1]:

- Abdominal waist circumference >94 cm (37 in) in men and >80 cm (31 in) in women (the use of population- and country-specific definitions is suggested; However, until better data are available, The International Diabetes Federation [IDF] recommends using these cutoffs)
- Serum hypertriglyceridemia ≥150 mg/dl (1.7 mmol/L) or drug treatment for elevated triglycerides
- Serum high-density lipoprotein (HDL) cholesterol <40 mg/dl (1 mmol/L) in men and <50 mg/dl (1.3 mmol/L) in women or drug treatment for low HDL-C
- Blood pressure ≥130/85 mm Hg or drug treatment for elevated blood pressure
- Fasting glucose ≥100 mg/dl (5.6 mmol/L) or drug treatment for elevated blood glucose

SYNONYMS

Syndrome X
Insulin resistance syndrome
Obesity dyslipidemia syndrome

ICD-10CM CODE
E88.81 Metabolic syndrome

EPIDEMIOLOGY & DEMOGRAPHICS

- Affects close to 25% of U.S. adults.
- Prevalence increases with age, affecting more than 40% of individuals >60 yr.
- Increasing prevalence among women, especially in the African American and Mexican American populations.
- Prevalence increases with weight. Metabolic syndrome is noted in 5% of normal weight, 22% of overweight, and 60% of obese individuals.
- Other risk factors include low socioeconomic status, lack of physical activity, high-carbohydrate diet, alcohol intake, smoking, genetic predisposition, use of atypical antipsychotics, and postmenopausal status.

CLINICAL PRESENTATION

- Obesity, hypertension, dyslipidemia, and hyperglycemia as defined.
  1. Blood pressure: ≥130/85 mm Hg
  2. Abdominal obesity with waist circumference: >94 cm (37 in) in men and >80 cm (31 in) in women
  3. Triglycerides: ≥150 mg/dl (1.7 mmol/L)
  4. HDL: <40 mg/dl (1 mmol/L) in men and <50 mg/dl (1.3 mmol/L) in women
  5. High fasting glucose: ≥100 mg/dl (5.6 mmol/L)
- Patients with metabolic syndrome are at twice the risk of developing cardiovascular disease and have a sevenfold increase in risk for type 2 diabetes and a one-point-fivefold increase in all-cause mortality compared to patients without the syndrome. Other complications include cognitive decline in the elderly, fatty liver disease, polycystic ovary syndrome, obstructive sleep apnea, gout, and chronic kidney disease.
- Focus history on symptoms of diabetes and its complications, obesity and its complications, coronary artery disease (angina), and polycystic ovary syndrome.
- Complete physical examination, including height, weight, waist circumference, and blood pressure.

ETIOLOGY

- Genetic and environmental factors associated with obesity increase the risk of developing metabolic syndrome.
- Abdominal obesity is associated with insulin resistance and hyperinsulinemia.
- Insulin resistance results in ineffective glucose utilization, eventually leading to type 2 diabetes mellitus.
- Hyperinsulinemia and inflammatory markers/cytokines play an important role in development of abnormal lipid profile, hypertension, and vascular endothelial dysfunction, which can lead to the development of atherosclerotic cardiovascular disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of weight gain or obesity (Cushing syndrome, hypothyroidism)
- Other causes of hyperlipidemia (familial hyperlipidemia, hypothyroidism)
- Other causes of hypertension (Cushing syndrome, hyperaldosteronism)
- Other forms of diabetes (type 1)

LABORATORY TESTS

- Fasting lipid profile (total cholesterol, low-density lipoprotein [LDL] cholesterol, HDL cholesterol, and triglycerides)
- Fasting glucose

TREATMENT

NONPHARMACOLOGIC THERAPY

- Lifestyle modification:
  1. Dietary modifications aimed at weight loss. The American Heart Association (AHA) recommendations include:
     a. Consuming vegetables and fruits
     b. Eating whole grains and high-fiber foods (≥30 g/day)
     c. Eating fish twice weekly
     d. Consuming lean animal and vegetable proteins
     e. Reducing intake of sugary beverages
     f. Minimizing sugar and sodium intake
     g. Maintaining moderate to no alcohol intake
     h. Consuming 50% to 55% of calories from carbohydrates, 15% to 20% of calories from protein, and 30% to 35% of calories from fat
     i. Limiting saturated fat to less than 7% of energy, trans fat to less than 1% of energy, and cholesterol to less than 300 mg/day
  2. Physical activity of moderate intensity (i.e., brisk walking): 30 min daily
  3. Smoking cessation
- Consider bariatric surgery in the management of obesity:
  1. Body mass index (BMI) ≥40 kg/m^2 in patients who have not responded to diet and exercise (with or without drug therapy).
  2. Individuals with BMI >35 kg/m^2 and comorbidities (hypertension, impaired glucose tolerance, diabetes mellitus, dyslipidemia, sleep apnea) are also potential surgical candidates.

TABLE E1 Common Definitions for Metabolic Syndrome

Criterion	NCEP ATP III (3 or more criteria)
Abdominal obesity	Waist circumference
Men	>40 inches (>102 cm)
Women	>35 inches (>88 cm)
Hypertriglyceridemia	>150 mg/dl (≥1.7 mmol/L)
Low HDL	
Men	<40 mg/dl (<1.03 mmol/L)
Women	<50 mg/dl (<1.30 mmol/L)
Hypertension	≥130/85 mm Hg or on antihypertensive medication
Impaired fasting glucose or diabetes	>100 mg/dl (5.6 mmol/L) or taking insulin or hypoglycemic medication

ATP, Adult Treatment Panel; *HDL,* high-density lipoprotein; *NCEP,* National Cholesterol Education Program. From Floege J et al: *Comprehensive clinical nephrology,* ed 4, Philadelphia, 2010, WB Saunders.

[1]Alberti KG et al: Harmonizing the metabolic syndrome: a joint interim statement of the International Diabetes Federation Task Force on Epidemiology and Prevention; National Heart, Lung, and Blood Institute; American Heart Association; World Heart Federation; International Atherosclerosis Society; and International Association for the Study of Obesity,. *Circulation* 120:1640-5, 2009.

ACUTE GENERAL Rx

- Treat obesity (see "Obesity"): Pharmacologic treatment: Consider orlistat and other approved agents (e.g., liraglutide, topiramate/phentermine, bupropion/naltrexone, lorcaserin) in patients who have not responded to diet and exercise if BMI >30 kg/m^2 or a BMI of 27 to 30 kg/m^2 with comorbid conditions. Drug therapy still needs to be in conjunction with diet and exercise.
- Treat hypertension (see "Hypertension"): Systolic blood pressures >130/85 mm Hg: Consider angiotensin-converting enzyme inhibitors or angiotensin II receptor blocker as first-line therapy.
- Treat hyperlipidemia: The 2018 Guideline on the Management of Blood Cholesterol from the American College of Cardiology and American Heart Association (ACC/AHA) specifies four groups that may require statin therapy[2] (potential statin side effects will need to be discussed with the patient prior to any initiation):
  1. Patients with atherosclerotic cardiovascular disease (ASCVD) should be started on high-intensity statin therapy.
  2. Patients with LDL-C levels of ≥190 mg/dl should be started on high-intensity statin therapy.
  3. Patients with diabetes, age 40 to 75, with LDL-C >70 mg/dl should be started on moderate-intensity statin therapy.
  4. Patients without diabetes, age 40 to 75 with LDL-C levels of 70 to 190 mg/dl, and a 10-yr ASCVD risk of 7.5% or higher as determined by the ACC/AHA Pooled Cohort Equations.
- Treat diabetes:
  1. Goal HbA1c determined in an individualized fashion based on age and comorbidities; ACP recommends target of 7.0 to 8.0% for most patients
  2. Metformin as first-line therapy to improve insulin sensitivity provided no contraindications
- Treat cardiovascular risk factors:
  1. Consider aspirin. Aspirin should be started in patients with metabolic syndrome and an intermediate or elevated Framingham cardiovascular risk, if there are no contraindications.
  2. Risk can be lowered with weight loss, exercise, smoking cessation, blood pressure control, diabetes management, and treatment of hyperlipidemia.

CHRONIC Rx

- Encourage lifestyle modification as discussed previously.
- Pharmacologic and surgical management to maintain therapeutic goals described previously.

DISPOSITION

Weight loss can prevent disease progression. Appropriate treatment of obesity, hypertension, hyperlipidemia, and diabetes can improve morbidity and mortality rates.

REFERRAL

- To nutritionist for dietary counseling
- To weight loss and exercise programs
- To endocrinologist if difficulty reaching therapeutic goal and also to consider weight loss pharmacotherapy
- To bariatric surgeon if patient meets surgical criteria (as noted previously)

PEARLS & CONSIDERATIONS

PREVENTION

- Weight loss is essential for the prevention and treatment of metabolic syndrome.
- Recommend dietary modifications and moderate physical activity.
- Consider pharmacologic and surgical options in select individuals (as noted previously).
- Participating in resistance exercise, even less than 1 hour per wk, is associated with lower risk of developing metabolic syndrome, independent of aerobic exercise. Health professionals should recommend that patients perform resistance exercise along with aerobic exercise to reduce risk of metabolic syndrome.[3]

BASIC INFORMATION

DEFINITION

A symptom of various pathologies causing localized pain to the forefoot, specifically beneath metatarsal heads 2, 3, and 4.

ICD-10CM CODES

M77.40 Metatarsalgia, unspecified foot
M77.41 Metatarsalgia, right foot
M77.42 Metatarsalgia, left foot

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Pain beneath metatarsals 2, 3, and/or 4
- Callus formation to plantar metatarsal head(s) (Fig. E1)
- Hallux rigidus/bunion deformity
- Pain during midstance or heel strike phases of gait
- Fat pad atrophy
- Obesity, recent weight gain, or increase/change in type of activity

ETIOLOGY

Primary metatarsalgia: Anatomic abnormalities/variants that alter the weight-bearing metatarsal parabola

- Long or plantar-flexed metatarsal, most commonly number 2
- Cavus foot type
- Equinus/pseudoequinus
- Fractures/surgery

Secondary metatarsalgia: Changes in the lesser metatarsals and/or adjacent first and fifth rays that lead to acquired changes in the anatomic and biomechanical function of the foot.

- Hallux limitus/rigidus, which tends to transfer pressure to the lesser metatarsal heads
- Hammertoe deformity, which is theorized to allow distal shifting of the plantar fat pad
- Inflammatory arthropathy
- Lesser metatarsophalangeal joint instability
- Lesser metatarsophalangeal joint synovitis
- Fat pad atrophy
- Increased forefoot pressures as seen with equinus and neuropathy
- Referred pain due to interdigital neuroma, tarsal tunnel syndrome, spinal lesions

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Morton neuroma, most commonly of the third interspace
- Foreign body
- Metatarsal fracture, stress or traumatic in nature
- Freiberg infarction, most commonly of second metatarsal
- Plantar plate rupture
- Metatarsophalangeal joint capsulitis
- Arthritis
- Limb length discrepancy leading to unilateral forefoot overload
- Equinus deformity, which leads to forefoot overloading
- Neuropathy or peripheral vascular disease

WORKUP

- It is important to remember that metatarsalgia is a symptom of one or more anatomic and/or functional abnormalities. It is important to find the underlying etiology of the pain and to treat it directly.
- Start with a general evaluation of foot type and location of pain.
- Callus patterns are a window into the mechanical function of the foot and should be noted (see Fig. E1).
- Evaluate for equinus and be sure to make note of any first ray pathology including bunion and hallux rigidus deformities.

LABORATORY TESTS

As indicated to evaluate for rheumatologic disease

IMAGING STUDIES

- X-rays (standing dorsoplantar view and lateral view): Evaluate position and length of metatarsals, rule out fracture, tumor, avascular necrosis, arthritic process/joint disease.
- MRI: Evaluate for any plantar plate injury, capsular injury, tendon rupture, or neuroma.
- Bone scan: If stress fracture suspected (may take 2 wk to show up on x-ray).

TREATMENT

Proper supportive shoe gear is essential for pedal health. Treatment of the underlying problem is paramount in the extended relief of metatarsalgia. Evaluation and treatment of any first ray pathology should not be overlooked. Relative rest and offloading should also be discussed.

Dynamic metatarsal cushioning consists of a Plastazote insert reinforced with a less compressible foam layer, which supports the entire arch and midfoot. This combination proves to provide a significant reduction in forefoot pressures and is an excellent option for a more sedentary adult. Functional orthosis aims to reestablish proper biomechanics leading to reduction of pressure points and an improved biomechanical gait. These custom devices are ideal for a more ambulatory patient.

Other treatments include:

- Silicone padding provides symptomatic relief and works well for fat pad atrophy.
- Moleskin or padding will reduce frictional forces without adding bulk for long-term use.
- Custom orthotics address functional or structural etiology.
- Heel lift or shoes with short heel or wedge are effective when equinus is etiology.
- Rocker-bottom shoes reduce pressure at metatarsal heads; they are indicated mostly for diabetics and for limited ankle motion.
- Nonsteroidal antiinflammatory drugs.
- Intraarticular injection in cases of primary arthritic process; however, these should be limited due to increased risk of plantar plate rupture.

DISPOSITION

Varies depending on etiology

REFERRAL

Referral to podiatric or foot/ankle orthopedic surgeon is highly recommended for this diagnosis due to complexity of differential diagnosis and necessity of early diagnosis. Specialized casting, orthotics, or surgical evaluations are frequently necessary.

Methanol and Ethylene Glycol Poisoning PTG

BASIC INFORMATION

DEFINITION

An accidental or intentional ingestion of 1 g per kg methanol or ethylene glycol is considered lethal, although even small amounts can be toxic. Inhalational and dermal exposures rarely cause toxicity.

SYNONYMS

Toxic alcohols
Moonshine
Wood alcohol
Antifreeze

ICD-10CM CODES	
T51.8	Toxic effect of alcohols
T51.1X1	Toxic effect of methanol
T51.1X2	Toxic effect of methanol, intentional self-harm
T52.8X1	Ethylene glycol poisoning

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- In 2016, the American Association of Poison Control Centers reported 6,508 single-exposure cases of ethylene glycol poisoning and 1,853 of methanol poisoning.
- Most cases are reported in adults and predominantly in men.
- Accidental exposure is common in children, while alcoholism, polysubstance abuse, depression, and suicide are seen in adults.
- Suicide attempts involving toxic alcohols frequently involve the ingestion of multiple substances.
- Outbreaks or epidemic poisoning with methanol is frequently the result of bootleg distillation or counterfeit alcohol.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Clinical manifestations depend on the quantity of ingestion, duration of time since ingestion, and whether co-ingestion of other substances occurs.
- Early ingestion of either substance causes CNS depression, nausea, and vomiting; inebriation can mimic ethanol ingestion. Late effects include progressive CNS dysfunction, including seizure and coma, as well as respiratory and cardiopulmonary failure.
- Visual symptoms ranging from blurry or snowy vision to complete visual loss and findings of papillary edema and, later, optic atrophy, fixed and dilated pupils, retinal hyperemia, and a Parkinson-like syndrome are indicative of methanol poisoning. Other CNS effects are hemorrhage and white matter lesions in the putamen, subcortical structures, brainstem, and cerebellum.
- Oliguria, hematuria, calcium oxalate crystalluria, tetany, cranial nerve palsy, and acute kidney injury suggest ethylene glycol toxicity.
- Abdominal pain may result from exposure to either substance, while methanol can cause acute pancreatitis.
- Kussmaul respirations (rapid, labored breathing) may be evident with severe acidosis.

PATHOPHYSIOLOGY

- Toxicity of these alcohols is related to their metabolites rather than the parent compound.
- Lethal dose for methanol is >15 to 30 ml and >1 to 1.5 ml/kg for ethylene glycol.
- Sequential metabolism by alcohol and aldehyde dehydrogenases converts methanol to formaldehyde and then formic acid, while ethylene glycol is converted to glycoaldehyde, glycolic acid, and then oxalate.
- Fig. E1 depicts the pathways involved in methanol metabolism.
- While methanol metabolites primarily cause retinal injury, ethylene glycol metabolites produce renal tubular injury and calcium oxalate stones.
  1. Formaldehyde binds to tissue proteins and is likely the major toxin in methanol poisoning involving necrosis of retinal and optic neurons and the basal ganglia (putamen). Formic acid, the acid produced in the largest quantity, inhibits cytochrome oxidase, preventing oxygen utilization by mitochondria and causing further organ dysfunction. Leukotriene has been implicated in the inflammation and neurotoxicity characteristic of acute methanol poisoning.
  2. Glycoaldehyde may be the major nephrotoxin, while glycolic acid is the acid produced in the largest quantity in ethylene glycol poisoning, with a small quantity converted to oxalic acid by lactate dehydrogenase. Oxalate then forms calcium oxalate crystals, which are deposited in the renal parenchyma, cerebral blood vessels, and meninges, causing hypocalcemic tetany.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of a high anion gap metabolic acidosis include lactic acidosis, diabetic and alcoholic ketoacidosis, kidney failure (acute and chronic), early toluene toxicity, and salicylate intoxication. Of note, L-lactate may be elevated in methanol toxicity due to cytochrome oxidase inhibition by formic acid and an increase of the NADH:NAD^+ ratio that is driven by methanol metabolism.
- Elevated plasma osmolal gap may be encountered in ethyl alcohol or isopropyl alcohol ingestion.

EVALUATION AND WORKUP

- Diagnosis depends on history, clinical presentation, and laboratory abnormalities.
- High anion gap metabolic acidosis (AG >12 mEq/L) with elevated plasma osmolal gap (>10 mOsm/kg; usually >25 mOsm/Kg) in an appropriate clinical setting should raise the suspicion of methanol or ethylene glycol ingestion.
- In either intoxication, an osmolal gap will initially be positive, but as the parent compound is converted to its metabolites, the osmolal gap will normalize and the serum anion gap will increase.
- Serum methanol and ethylene glycol levels are elevated in their respective ingestions.
- Acute kidney injury, hypocalcemia with prolonged QT interval, and calcium oxalate crystalluria are seen with ethylene glycol toxicity.
- Metabolic acidosis in the absence of acute kidney injury suggests methanol toxicity; that is, ethylene glycol is more often associated with acute kidney injury.
- Wood's light uses ultraviolet light to detect urinary presence of fluorescein, which is contained in some ethylene glycol preparations. Fluorescence lacks sensitivity and specificity. Therefore, fluorescence is not considered a reliable clinical tool.

LABORATORY TESTS

- Calculation of the anion gap and serum osmolal gap
  1. Anion gap determination: Electrolytes and albumin
  2. Osmolal gap determination: Measured and calculated serum osmolalities (sodium, BUN, glucose, ± ethanol)
- Arterial blood gas analysis, lactate, calcium, and creatine kinase
- Creatinine and urinalysis to evaluate presence of tubular injury and calcium oxalate crystals
- ECG to evaluate QT interval
- Toxicology screen with quantification: Acetaminophen, salicylate, ethanol, methanol, ethylene glycol, and isopropyl alcohol

TREATMENT

High index of suspicion and immediate recognition with early treatment remain crucial to reduce mortality. Box 1 describes common commercial products that may contain ethylene glycol.

NONPHARMACOLOGIC THERAPY

- Cardiorespiratory support as required.
- Rapid (within 60 min) gastric decontamination (charcoal and/or gastric lavage). Later intervention is not beneficial due to rapid and complete invasion (methanol).
- Induction of vomiting is contraindicated even in conscious patients given the risks

BOX 1 Common Commercial Products That May Contain Ethylene Glycol

Paints and lacquers
Polishes and detergents
Inks
Cosmetics
Hydraulic brake fluids
Solar collector fluids
Car wash fluids

Data are from Kruse JA: Methanol, ethylene glycol, and related intoxications. In Carlson RW, Geheb MA (eds): *Principles and practice of medical intensive care,* Philadelphia, 1993, WB Saunders.

of development of central nervous system depression in these patients.

ACUTE GENERAL Rx

- Principles of therapy include prevention of formation of toxic metabolites, correction of acidosis, and toxin removal.
- Intravenous isotonic fluids can facilitate urinary excretion of volatile alcohol and its metabolites; when acidosis is present (pH <7.3), isotonic bicarbonate should be used because reversal of acidosis helps prevent end-organ damage from toxic metabolites (target pH: 7.35 to 7.45).
- Ethanol, a competitive substrate, and fomepizole (4-methylpyrazole or 4-MP), a competitive inhibitor of alcohol dehydrogenase, prevent formation of toxic metabolites of ethylene glycol and methanol.
- Fomepizole is preferred over ethanol given the increased incidence of GI and CNS adverse events with ethanol administration, greater inhibition of alcohol dehydrogenase, and easier administration. Cost and availability of fomepizole may influence the decision to administer this agent vs. ethanol.
- Ethanol: Dosing:
  1. Target ethanol concentration is 100 to 200 mg/dl and requires close monitoring.
  2. Loading dose: 800 mg/kg in a 10% solution of 5% dextrose in water will raise serum ethanol by 100 mg/dl.
  3. Maintenance dose: Infusion of 80 to 160 mg/kg/hr based on blood concentrations.
  4. Comment on dosing adjustment in patients receiving concomitant dialysis.
- Fomepizole: Indications for use:
  1. Plasma concentration of methanol or ethylene glycol >20 mg/dl OR
  2. Documented ingestion with an osmolal gap >10 mOsm/kg OR
  3. Suspected ingestion with at least two of the following criteria:
     a. Arterial pH <7.3
     b. Serum bicarbonate <20 mEq/L
     c. Osmolal gap >10 mOsm/L
     d. Urinary oxalate crystals in the case of ethylene glycol toxicity
- Fomepizole (4-methylpyrazole): Dosing:
  1. Loading dose: 15 mg/kg body weight
  2. Maintenance dose: 10 mg/kg body weight every 12 hr for 4 doses, then 15 mg/kg every 12 hr (if blood levels do not reach goal by 48 hr)
  3. During hemodialysis: Add 1 to 1.5 mg/kg/hr, or repeat loading dose every 4 hr
- The half-lives of ethylene glycol and methanol increase with ethanol or fomepizole.
- The half-life of methanol metabolism during treatment with fomepizole is as much as 87 hr. Treatment with fomepizole alone is not recommended, and hemodialysis should be considered to prevent a prolonged requirement for intensive care.
- In contrast, the observed half-life of ethylene glycol with use of fomepizole is only around 17 hours. Ethylene glycol poisoning (even with levels greater than 50 mg/dl) in patients without kidney injury or acidosis can be managed with fomepizole alone, and without hemodialysis.
- Hemodialysis is indicated for likely or confirmed methanol poisoning in the setting of any of the following: New vision or neurologic deficit (particularly seizure or coma); metabolic acidosis or acidemia with pH ≤7.15; elevated anion gap >24 mmol/L; methanol concentration >70 mg/dl (or 21.8 mmol/L) in the context of fomepizole, or >50 mg/dl (or 15.6 mmol/L) in the absence of an ADH blocker.
- Hemodialysis is indicated for likely or confirmed ethylene glycol poisoning in the setting of any of the following: Acute kidney injury; anion gap metabolic acidosis; EG level >50mg/dl (see earlier regarding use of fomepizole when elevated levels without acidosis or acute kidney injury are present).
- Hemodialysis also should be considered in patients with poisoning and electrolyte imbalances refractory to pharmacologic treatments, or hemodynamic instability.
- Average duration of dialysis in studies was 8.4 ± 3.2 hr.
  1. Treatment with medications and/or hemodialysis is continued until the methanol or ethylene glycol concentration is <20 mg/dl.
  2. Intermittent hemodialysis is the preferred modality of dialysis, as continuous renal replacement therapy (CRRT) alone is ineffective in achieving rapid clearance of methanol and ethylene glycol. In the treatment of a mass outbreak of methanol poisoning, acidemia correction was faster with intermittent hemodialysis than CRRT.
  3. CRRT is an acceptable alternative when intermittent hemodialysis is not available.
  4. If blood concentration levels are not available, start by conducting an 8-hr intermittent hemodialysis session followed by 18 hr of continuous renal replacement therapy; adjust therapy afterward as clinically indicated.
  5. Do not use heparin with dialysis, as heparin may increase the risk for cerebral hemorrhage.

ADJUNCTIVE Rx

- In ethylene glycol poisoning, thiamine (100 mg IV q6h) and pyridoxine (100 mg IV daily) may decrease oxalic acid formation and direct metabolism to less toxic metabolites.
- In methanol poisoning, folinic acid doses (50 mg IV every 6 hr) may increase formic acid metabolism to CO_2 and H_2O. Correct electrolyte abnormalities (hypocalcemia, etc.).
- Treat seizures.

DISPOSITION

Transfer to a hospital with an intensive care unit and hemodialysis capabilities should be carried out early in the course of intoxication.

REFERRAL

- Regional poison center (toxicologist) and nephrology recommended to avoid treatment delays
- Ophthalmology for patients with visual symptoms
- Psychiatry if depression and suicidal ideation are present
- Detoxification centers for patients with substance abuse

PROGNOSIS

- Coma or seizures at presentation and prolonged severe acidosis correlate with increased mortality
- High osmolal gap and high anion gap acidosis associated with high mortality
- Hyperglycemia may correlate with worse prognosis in methanol poisoning

PEARLS & CONSIDERATIONS

- Profound plasma osmolal gap or anion gap metabolic acidosis should raise suspicion for ethylene glycol and/or methanol ingestion. A high index of suspicion and early treatment are crucial to reducing mortality. The metabolites of methanol and ethylene glycol produce the clinical toxidrome.
- Complaints of visual blurring, central scotomata, and blindness are consistent with methanol poisoning.
- Calcium oxalate crystalluria, oliguria, hematuria, and acute kidney injury are consistent with ethylene glycol poisoning.
- Fomepizole is preferred to ethanol due to complications associated with ethanol use.
- Emergent hemodialysis is indicated with end organ damage and/or severe metabolic acidosis.
- Elevated osmolal gap and anion gap metabolic acidosis may occur rarely with other toxic alcohols such as diethylene glycol and propylene glycol.

Methicillin-Resistant *Staphylococcus aureus* (MRSA) PTG

BASIC INFORMATION

DEFINITION

Methicillin-resistant *Staphylococcus aureus* (MRSA) is a common bacterial pathogen with resistance to many antibiotics. It is defined as an *S. aureus* that shows a minimum inhibitory concentration (MIC) of greater than or equal to 4 mcg/ml to oxacillin. There are two types of MRSA:

- HA-MRSA: Hospital-acquired MRSA, usually multidrug resistant
- CA-MRSA: Community-acquired MRSA; an emerging pathogen, usually acquired outside of the hospital setting; resistance may differ from HA-MRSA and is generally susceptible to more antibiotics than HA-MRSA

SYNONYMS

Multidrug-resistant *Staphylococcus aureus*
Oxacillin-resistant *Staphylococcus aureus*

ICD-10CM CODES

A41.02	Sepsis due to Methicillin resistant *Staphylococcus aureus*
A49.02	Methicillin resistant *Staphylococcus aureus* infection, unspecified site
B95.62	Methicillin resistant *Staphylococcus aureus* infection as the cause of diseases classified elsewhere
J15.212	Pneumonia due to Methicillin resistant *Staphylococcus aureus*
Z22.322	Carrier or suspected carrier of Methicillin resistant *Staphylococcus aureus*
Z86.14	Personal history of Methicillin resistant *Staphylococcus aureus* infection

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 1:3000
PEAK INCIDENCE: Occurs yr-round; may peak during summer and fall mos for CA-MRSA.
PREVALENCE: The national rate of MRSA colonization or infection is 46.3 per 10,000 inpatients. Hospital prevalence rate of MRSA is as high as 60% in hospitals, which means that 60% of *S. aureus* strains in that hospital will be MRSA.
PREDOMINANT AGE AND SEX: All ages and both sexes
RISK FACTORS:

- HA-MRSA: Hospitalization, invasive medical device, residing in long-term nursing facility
- CA-MRSA: Initially seen in young men engaged in athletic activities and in gyms, prisons, military barracks, etc., but has now spread to the entire age spectrum including neonates and the elderly

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- CA-MRSA: Can present with skin infection, associated with opening in the skin; red bump, pustule, or boil; erythema, swelling; edema, often fluctuant and very painful
- HA-MRSA: Bacteremia; infection associated with intravenous device:
  1. Catheters: Pneumonia
  2. Skin: Cellulitis
  3. Bone: Osteomyelitis
  4. Endocarditis
  5. Abscesses: Skin or organ
  6. Pneumonia: Nosocomial

ETIOLOGY

- CA-MRSA: The most prevalent strain in the U.S. on pulse field electrophoresis (PFGE) is called USA 300.
  1. CA-MRSA: Common cause of skin and soft-tissue infections seen in the emergency room. It can, however, also cause necrotizing pneumonia, sepsis, osteomyelitis, etc.
  2. Virulence factors particular to CA-MRSA: Panton-Valentine leukocidin (PVL) toxin, alpha-hemolysin toxin, phenol-soluble modulins, etc., that enhance ability to cause infection.
- HA-MRSA: Most strains on PFGE are USA 100 or USA 200 and tend to have multidrug resistance. Patients with HA-MRSA infection have higher mortality and morbidity than patients with a methicillin-sensitive *S. aureus* (MSSA) infection.
- By definition, all MRSA strains carry the *mecA* gene, which confers resistance to all beta-lactam antibiotics, including cephalosporins and carbapenems.

DIAGNOSIS

LABORATORY TESTS

- Rapid detection methods for MRSA:
  1. Rapid culture methods: Chromogenic agar, which uses a culture media that changes color if *Staphylococcus aureus* is present and then has antibiotics incorporated into media that only allows MRSA strains to grow. This allows for early detection of MRSA in 24 to 48 hr.
  2. Molecular methods that target gene sequences of the bacteria: PCR and gene probe hybridization. Examples include IDI-MRSA, Genotype MRSA direct and Gene Expert MRSA assay. The sensitivity and specificity of these assays compared to traditional cultures range from 90% to 98% and from 91% to 99%, respectively.
- PFGE is usually done only for epidemiologic or outbreak purposes.

IMAGING STUDIES

- Radiographs or computed tomography scan of suspected organ
- Echocardiogram: All adult patients with *S. aureus* bacteremia should undergo echocardiography

TREATMENT

- CA-MRSA: Oral antibiotics that may be effective include trimethoprim-sulfamethoxazole, doxycycline, minocycline, or clindamycin; linezolid and tedizolid are other options but are very expensive
- HA-MRSA: Intravenous antibiotics, vancomycin, linezolid, tedizolid, daptomycin, tigecycline, and newer agent eravacycline

ACUTE GENERAL Rx

- Trimethoprim-sulfamethoxazole, one double-strength tablet PO bid, is useful in cases of CA-MRSA since 95% of community-acquired MRSA strains are susceptible to it in vitro. Other agents that can be used for CA-MRSA include:
  1. Clindamycin: 300 to 450 mg q6h to q8h also inhibits toxin production. If strain tests sensitive to clindamycin but resistant to erythromycin, then a D test must be done to ensure there will not be inducible resistance while on therapy with the clindamycin.
  2. Doxycycline: 100 mg PO q12h and minocycline also have some activity against MRSA.
  3. Rifampin: Never used alone but can be used with one of the other oral agents.
- Vancomycin 15 to 20 mg/kg IV q8 to 12h is the mainstay of parenteral therapy for MRSA infections. There is an increasing concern of MRSA strains developing tolerance to vancomycin, requiring higher doses to achieve eradication. True vancomycin-resistant strains (MIC ≥32 mg/L) remain rare. Vancomycin trough levels of at least 15 to 20 mcg/ml are recommended to treat MRSA infections.
- Linezolid 600 mg PO or IV bid is a synthetic oxazolidinone FDA-approved for MRSA skin and soft tissue infections and pneumonia. It has been shown to be more effective than vancomycin for MRSA pneumonia. A similar agent, tedizolid (200 mg IV or PO for 6 days), is approved for skin and soft tissue infections. These agents are much more expensive than vancomycin.
- Daptomycin: 4 mg/kg/day to 6 mg/kg/day IV is approved for skin and soft tissue infections, bacteremia, and right-sided endocarditis but should not be used for pneumonia as it is inactivated by pulmonary surfactant.
- Tigecycline: 100 mg IV load, then 50 mg IV q12h, is approved for MRSA skin and soft tissue infections and intraabdominal abscess.
- Eravacycline, a derivative of tetracycline, does cover MRSA, VRE, and resistant GNRs but currently is approved only for complicated intraabdominal infections.
- Ceftaroline is a fifth-generation cephalosporin, also effective against MRSA but only skin and soft-tissue infections, not pneumonia: 600 mg IV q12h.
- Newer glycopeptide agents: Dalbavancin (1000 mg IV followed by 500 mg IV a wk later for complicated skin and soft tissue infections) and telavancin (10 mg/kg IV daily for 7 to 14 days) to treat skin infections or pneumonia; these are expensive alternatives to vancomycin.

CHRONIC Rx

- Patients with MRSA colonization may have reexposure or may be unable to eradicate colonized state.
- Oral agents used to attempt eradication of nasal colonization of MRSA are rifampin, tetracycline, and minocycline.

- Topical agents used in an attempt to eradicate MRSA nares carriage include mupirocin nasal ointment 2% applied bid ×5 days. If mupirocin resistant, can use bacitracin or polymyxin.
- There are protocols for using an antiseptic on skin, such as chlorhexidine, along with mupirocin nasal ointment to eradicate MRSA carriage from the body. Postdischarge MRSA decolonization with chlorhexidine and mupirocin results in a 30% lower risk for MRSA infection than education alone.

Microangiopathic Hemolytic Anemia

BASIC INFORMATION

DEFINITION

Microangiopathic hemolytic anemia (MAHA) is used to describe any nonautoimmune hemolytic anemia that results in red blood cell fragmentation associated with small vessel disease. Several diseases, including thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation (DIC), hemolytic-uremic syndrome (HUS), atypical hemolytic-uremic syndrome (aHUS), hemolysis, elevated liver enzymes, and low platelets syndrome of pregnancy (HELLP), and malignant hypertension, are associated with MAHA.

SYNONYMS

MAHA
Thrombotic microangiopathy (TMA)
Mechanical hemolytic anemias
Nonautoimmune hemolytic anemias
Fragmentation hemolytic anemia

ICD-10CM CODE
D59.4 Other non-autoimmune hemolytic anemias

EPIDEMIOLOGY & DEMOGRAPHICS

- TTP: Increased incidence in women and African Americans
- Typical HUS:
  1. Associated with *E. coli* O157:H7 in 80% of cases.
  2. Person-person transmission is implicated.
  3. Children are more commonly affected than adults.
- Atypical HUS:
  1. Diarrhea is not a presenting feature.
  2. Adults are more commonly affected.
- DIC:
  1. Always secondary to underlying causes, including sepsis, trauma, malignancy, surgery, or obstetrical complications.
  2. DIC can occur in about 20% of acute leukemias.
- HELLP syndrome:
  1. Occurs in 10% to 20% of pregnancies with preeclampsia.
  2. Develops between 28 and 36 wks of gestation.
  3. Can also present after delivery of fetus in 30% cases.
- Malignant hypertension: MAHA complicates about 25% of malignant hypertension cases.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Mucosal pallor
- Fatigue
- Acute onset of generalized weakness
- Jaundiced skin
- Icteric sclera
- Dark-colored urine

ETIOLOGY

TTP	Idiopathic or familial deficiency of ADAMTS13 Acquired antibodies against ADAMTS13
Typical HUS	Shiga toxin–producing enterohemorrhagic *E. coli* O157:H7
Atypical HUS	Inherited disorders of complement regulation
DIC	Secondary to multiple causes resulting in subendothelial tissue factor exposure and subsequent activation of coagulation cascade
HELLP syndrome	Mechanism not clearly identified, but endothelial injury from hypertension associated with preeclampsia has been implicated
Malignant hypertension	Endothelial damage

DIAGNOSIS

Pathognomonic findings in MAHA include anemia consistent with an intravascular hemolytic picture, including schistocytes (Fig. 1) on peripheral blood smear, elevated lactate dehydrogenase (LDH), increased indirect bilirubin, decreased serum haptoglobin, increased urinary urobilinogen, along with an elevated reticulocyte count and negative Coombs test.

DIFFERENTIAL DIAGNOSIS

- Immune-mediated hemolysis (positive Coombs test):
  1. Autoimmune hemolytic anemia
  2. Paroxysmal nocturnal hemoglobinuria
  3. Cold agglutinin disease
- Infections affecting red blood count (RBC):
  1. Malaria
  2. Babesiosis
  3. Bartonellosis
- Hemolysis due to mechanical stress or oxidative injury:
  1. G6PD deficiency
  2. Runner's anemia or march hemoglobinuria
- Extravascular hemolysis:
  1. Intrinsic RBC defects
  2. Liver disease
  3. Hypersplenism

WORKUP

- Peripheral blood smear showing schistocytes.
- Laboratory workup including CBC, liver function tests, LDH, haptoglobin, reticulocyte count, Coombs test, and urine analysis.
- MAHA and thrombocytopenia are sufficient to make a diagnosis of TTP or HUS; the classic "pentad" of fever, neurologic abnormalities, and renal failure is no longer necessary.
- In DIC, activated partial thromboplastin time and prothrombin time are prolonged, along with decreased fibrinogen levels and increased fibrin degradation products (including D-dimer).
- Blood pressure is greater than 180/120 mm Hg in malignant hypertension and usually associated with acute kidney injury (including hematuria and proteinuria).
- Additional specific tests:
  1. ADAMTS13 activity assay: Decreased activity is associated with idiopathic TTP, and ADAMTS13-directed antibodies are associated with secondary TTP.
  2. Stool culture for shiga toxin–producing *E. coli* in typical HUS.
  3. Although gold standard, renal biopsy is often not required for diagnosis of malignant hypertension.

TREATMENT

If specific etiology of MAHA is not readily identified, plasma exchange therapy should be instituted immediately, in presence of thrombocytopenia and appropriate clinical picture.

- TTP:
  1. Emergent plasma exchange (PEX) to remove unusually large von Willebrand factor (vWF) multimers and autoantibodies directed against ADAMTS13.
  2. Platelet transfusions reserved only for bleeding patients.
  3. If needed, PEX can be increased from once a day to twice daily, along with concomitant use of corticosteroids.
  4. Patients nonresponsive to PEX can be treated with second-line rituximab with or without cyclophosphamide.
- Typical HUS: Supportive care, including hemodialysis, for severe acute kidney injury and hypertension management

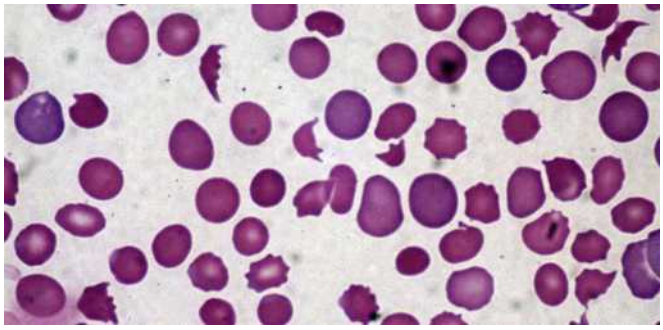

FIG. 1 Peripheral blood smear depicting schistocytes or fragmented red blood count.

- Atypical HUS: Eculizumab has been shown to be more effective than PEX. Eculizumab is an expensive drug, and current manufacturer recommendations include lifelong use, which can be cumbersome. Research is ongoing looking into shorter courses of treatments and outcomes.
- DIC:
  1. Treatment of underlying cause corrects the coagulopathy.
  2. Supportive care, including hemodynamic support and antimicrobial therapy, as indicated.
  3. Activated protein C (APC) is FDA approved for DIC complicated by sepsis.
- HELLP syndrome:
  1. Emergent delivery of fetus if more than 34 wk into gestation, preferably vaginal delivery.
  2. If less than 34 wks' gestation, corticosteroids are recommended for expediting fetal lung maturation and delivery, but not beneficial to the mother.
- Malignant hypertension:
  1. Control blood pressure with medical therapy as indicated.
  2. Care should be taken to avoid rapid lowering of systolic blood pressure, which can lead to ischemia or hyperperfusion syndrome.

MONITORING & FOLLOW-UP

Serial laboratory monitoring of CBC, LDH, and presence of schistocytes on peripheral smear is required to asses MAHA disease activity.

- TTP:
  1. Idiopathic TTP has a relapse rate of 18%, which can happen up to 10 yr from initial presentation.
  2. Serial measurements of ADAMTS13 activity may have predictive value in assessing risk of relapse.
- Typical HUS: Full recovery of renal function, baseline neurologic status, and resolution of diarrhea
- DIC: With adequate management of underlying cause, coagulopathy associated with DIC is reversible.
- HELLP syndrome:
  1. MAHA, thrombocytopenia, and liver injury are resolved within 48 hours after fetal delivery.
  2. Patients should be monitored for at least 2 days, with laboratory workup including CBC, LDH, and liver function.
- Malignant hypertension:
  1. Early adequate blood pressure control can reverse acute kidney injury.
  2. Patients can be discharged from the hospital after achieving adequate blood pressure control on an oral regimen.

PROGNOSIS

- TTP:
  1. If untreated, TTP has a high mortality rate of 90%.
  2. With PEX, mortality rate in idiopathic TTP is 15% and up to 59% in nonidiopathic TTP.
- Typical HUS:
  1. Typical HUS has a mortality rate of 5%, and younger children have better prognosis compared with adults.
  2. Central nervous system involvement or other extrarenal manifestations portend poor outcomes.
- Atypical HUS:
  1. Mortality ranges between 15% and 25%.
  2. Adults have poor prognosis compared with children.
  3. At 1-yr mark, about 25% of all patients have chronic renal failure.
- DIC:
  1. Prognosis of DIC depends on the severity of coagulopathy and underlying condition.
  2. DIC has been shown to be an independent predictor of mortality in sepsis and trauma, increasing the risk of death by a factor of 1.5 to 2.
- HELLP:
  1. Increased risk of preeclampsia in future pregnancies.
  2. Recurrence of HELLP with subsequent pregnancies is about 5%.
- Malignant hypertension:
  1. 10-yr overall survival is approximately 50%.
  2. MAHA in malignant hypertension predicts an increased likelihood of need for future hemodialysis.

REFERRAL

- Hematologist
- Nephrologist
- Neurologist
- Obstetrician

PEARLS & CONSIDERATIONS

- MAHA is not an individual clinical entity by itself, but rather includes many causes with different pathologic mechanisms, with a common phenomenon of small-vessel disease causing intravascular hemolysis.
- Presence of anemia with schistocytes and thrombocytopenia are key features in recognizing MAHA.
- If the etiology of MAHA is not readily apparent on initial evaluation, PEX must be immediately instituted for presumed TTP because it has a very high mortality rate of 90% if untreated.

Microscopic Colitis (Lymphocytic Colitis) ALG

BASIC INFORMATION

DEFINITION

Microscopic colitis (MC), also known as lymphocytic colitis, is an inflammatory condition of the colon that most often presents as chronic watery diarrhea. Although clinically similar, lymphocytic colitis and collagenous colitis represent two histopathologic subtypes of microscopic colitis.

SYNONYMS

Lymphocytic colitis
Collagenous colitis
MC

ICD-10CM CODES

K52.839	Microscopic colitis
K52.838	Other microscopic colitis
K52.832	Lymphocytic colitis
K52.831	Collagenous colitis
K52.9	Colitis, nonspecific

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Incidence of microscopic colitis is 24 to 103 in 100,000 person-yr.
PEAK INCIDENCE: Most cases of microscopic colitis are diagnosed in patients 60 to 70 yr of age.
PREVALENCE: Approximately 7.5% of patients who undergo workup for chronic watery diarrhea are diagnosed with MC.
PREDOMINANT AGE AND SEX: Microscopic colitis, more specifically the collagenous variant, is often diagnosed later in life (>65 yr) and most commonly affects females.
GENETICS: It is unclear how important specific genetic polymorphisms are in the pathophysiology of MC. However, a recent study described genetic similarities in human leukocyte antigen (HLA) genes for patients with microscopic colitis when compared with patients with Crohn disease.
RISK FACTORS:

- Increased age
- Smoking: One study demonstrated that patients who smoke are diagnosed with MC an average of 10 yr earlier than their nonsmoker counterparts
- Autoimmune disorders such as rheumatoid arthritis, thyroid disease, type 1 diabetes
- Celiac disease
- Medications: NSAIDs, proton pump inhibitors (PPIs), selective serotonin reuptake inhibitors (SSRIs), HMG-COA reductase inhibitors (statins)

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most often presents with chronic watery diarrhea (>3 BM daily). Classically, patients with microscopic colitis will experience nocturnal bowel movements.
- Other symptoms include abdominal pain, fecal incontinence, urgency, and less commonly, weight loss.
- Melena and hematochezia are not hallmarks of this disease.

ETIOLOGY

- The pathophysiology of MC remains unclear. Some studies suggest that colonic inflammation promotes a breakdown in electrolyte transport, leading to a combined osmotic and secretory diarrhea. Luminal agents including dietary items, bacterial flora, and medications may influence inflammation.
- Serotonin signaling also may play an important role in the development of MC as patients with a specific polymorphism in a serotonin receptor show a higher incidence of the disease.
- Microbiome studies show dysregulation and decreased bacterial diversity in patients with microscopic colitis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Irritable bowel syndrome (IBS)
- Inflammatory bowel disease (IBD)
- Ischemic colitis
- Infectious colitis (*C. difficile, E. coli, Giardia, Cryptosporidium, Entamoeba histolytica)*
- Pancreatic insufficiency
- Celiac sprue
- Intestinal lymphoma
- Carcinoid tumor
- Diverticulitis
- Small intestine bacterial overgrowth

WORKUP

- Given the breadth of causes of watery diarrhea, the diagnostic workup is largely guided by history.
- Infectious causes of symptoms should be ruled out first, particularly if the patient has specific risk factors including recent travel, consumption of untreated water, or recent antibiotic use or hospitalization.
- A careful history may elucidate specific dietary triggers such as lactose intolerance.
- Celiac disease is often comorbid with MC and should be ruled out in all patients with chronic watery diarrhea.

LABORATORY TESTS

- CBC
- Hepatic function panel
- Electrolyte panel
- *C. difficile* stool PCR
- If the patient has been exposed to untreated drinking water, testing for giardia, cryptosporidium, and *E. histolytica* is indicated
- IgA tissue transglutaminase
- Consider fecal elastase if history is concerning for pancreatic insufficiency
- Fecal calprotectin: Unclear diagnostic benefit

IMAGING STUDIES

- MC is both a clinical and histopathologic diagnosis.
- Abdominal imaging is not helpful in diagnosing MC but may be warranted in patients with severe abdominal pain, evidence of obstruction, or a clinical history suggestive of infectious colitis or diverticulitis. Perforation is a rare complication of MC.
- Colonoscopy is a necessary part of MC diagnosis. On gross endoscopic examination, the colonic mucosa most often appears normal. Nonspecific findings such as erythema or mucosal cracking can be observed in a rare subset of patients.
- Obtaining multiple biopsies of each part of the large colon is foundational for endoscopic evaluation and maximizes diagnostic sensitivity. Lymphocytic colitis and collagenous colitis represent two histologic subtypes of MC. Lymphocytic colitis is marked by >20 intraepithelial lymphocytes to 100 surface epithelial cells in the presence of normal colonic mucosa. Collagenous colitis is characterized by increased intraepithelial lymphocytes and a thickened (>1 mm) subepithelial collagen band in the setting of normal colonic mucosa.

TREATMENT

There is no evidence to suggest that MC increases one's risk of colorectal cancer, nor is it believed to portend increased mortality. However, treatment is important to limit the significant burden on quality of life and healthcare costs. Both histopathologic subtypes of MC are clinically similar and managed using the same modalities. A treatment algorithm for collagenous and lymphocytic colitis is shown in Fig. 1.

NONPHARMACOLOGIC THERAPY

- The first step in management is to withdraw any medications that can provoke disease activity.
  1. NSAIDs are most notably associated with microscopic colitis and should be withheld.
  2. Other medications that may be associated with microscopic colitis include SSRIs, PPIs, statins, and bisphosphonates. Many of these medications are both common and effective, and a careful consideration of risk vs. benefit should occur before withdrawal.
- Smoking cessation.

ACUTE GENERAL Rx

- Antidiarrheal agents including loperamide can be used in patients with mild symptoms. Nighttime dosing of these meds may curb nocturnal diarrhea.
- Budesonide (see Table 1) Shown to be the most effective first-line induction therapy and is often given for up to 8 wk.
  1. Induction therapy dose: 9 mg once daily for 6 to 8 wk.
  2. Maintenance therapy dose: Administer in patients who relapse after completion of induction course. 6 mg daily tapered to lowest effective dose for duration of 6 to 12 mo OR alternating 3 mg and 6 mg daily dose for 12 mo.
- Mesalamine (see Table 1): Although several studies demonstrate that it is less effective than budesonide, mesalamine 3 mg PO once daily also can be used for induction therapy.
- Bismuth salicylate (see Table 1): For those with contraindications to budesonide and

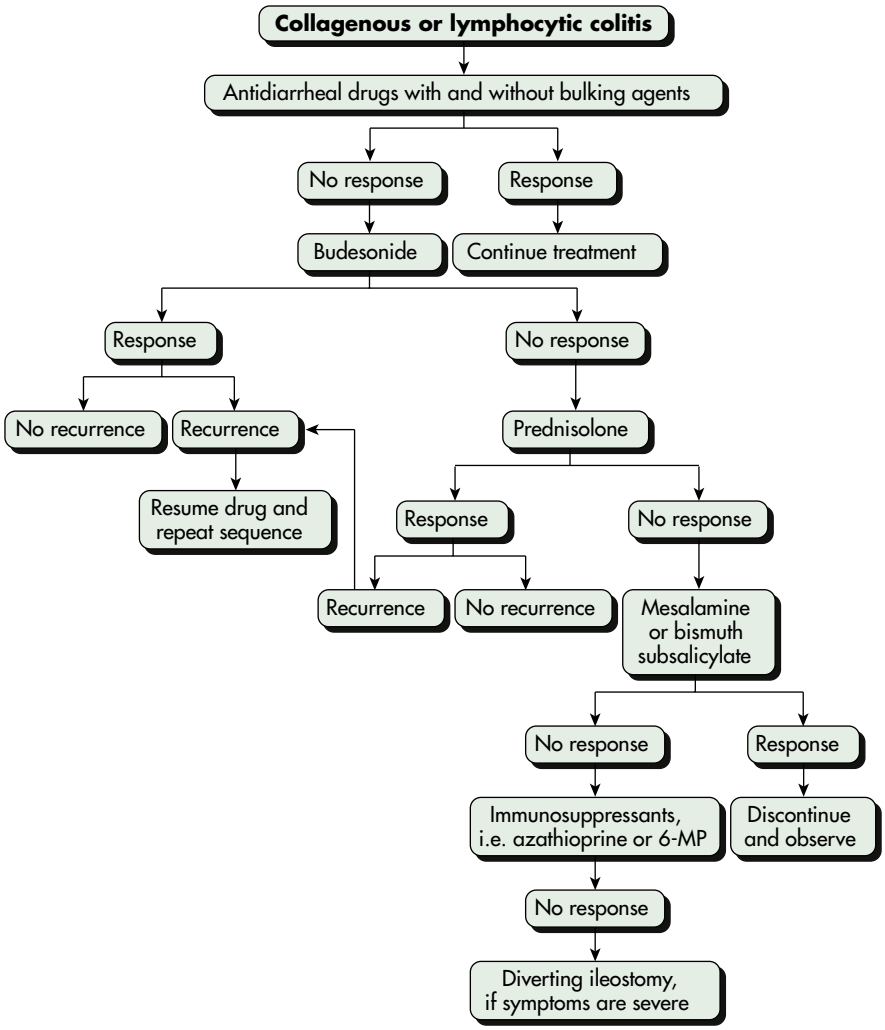

FIG. 1 Algorithm for the treatment of collagenous or lymphocytic colitis. *6-MP,* 6-Mercaptopurine. (From Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease,* ed 10, Philadelphia, 2016, Elsevier.)

TABLE 1 Treatment Regimens for Lymphocytic Colitis

Medication	Induction	Maintenance
Budesonide	9 mg once daily for 6-8 wk	6 mg daily tapered to lowest effective dose for duration of 6-12 mo* OR Alternating 3 mg and 6 mg daily dose for 12 mo
Mesalamine	3 mg PO once daily†	Not studied as a maintenance therapy
Bismuth subsalicylate	Nine 262-mg tablets daily, divided into three doses	Not studied as a maintenance therapy

*Administer in patients who relapse after completion of induction course.
†Shown to be inferior to budesonide in head-to-head randomized clinical trials.

mesalamine, bismuth salicylate is another medication shown to be superior to watchful waiting in patients with mild symptomatic disease. The dose of bismuth salicylate is nine 262 mg tablets daily, divided into three doses.

- Bile acid sequestrants: There are limited data to suggest that bile acid sequestrants such as cholestyramine may be useful as single-agent or adjuvant induction therapy in patients with mild symptoms.
- Immune modulators: Although limited supporting evidence exists for their use, immune modulators such as azathioprine, vedolizumab, and anti-TNF-alpha inhibitors may also have a role for induction therapy in budesonide refractory disease.
- There is no role for systemic steroids such as prednisone in the treatment of microscopic colitis.
- Rarely, patients require surgical intervention with colonic diversion.

CHRONIC Rx

Approximately two thirds of patients with microscopic colitis experience relapsed disease and require maintenance therapy. Budesonide is the most studied maintenance agent that can be administered for up to 12 mo at doses lower than those used for induction. For less severe disease, patients also can continue using bismuth salicylate or cholestyramine.

COMPLEMENTARY & ALTERNATIVE MEDICINE

It is unclear whether probiotics provide benefit.

DISPOSITION

Symptoms associated with MC are often episodic. While induction therapy is highly effective, 66% of patients in remission will experience a subsequent disease flare.

REFERRAL

- Gastroenterology referral should be offered to patients with long standing chronic diarrhea whose workups have ruled out acute infectious causes.

- Nutrition referrals also may be helpful in patients with severe symptoms such as weight loss.

PEARLS & CONSIDERATIONS

COMMENTS

- MC poses a significant burden on patient quality of life and is often under-recognized.
- Chronic watery diarrhea in the older adult, particularly with nighttime symptoms, should prompt the provider to consider MC. Identification of MC through clinical history and endoscopic evaluation should not be delayed as induction therapy is highly effective at improving disease morbidity.
- Budesonide remains the most effective mainstay medication for both induction and maintenance therapy. Other medications such as bismuth salicylate and cholestyramine are well tolerated and suitable as adjunct or single-agent therapies. Refractory cases may require immunomodulator therapy such as azathioprine or anti-tumor necrosis factor biologic agents such as infliximab.

PREVENTION

As with many other chronic illnesses, smoking cessation is an important part of both management and prevention.

PATIENT & FAMILY EDUCATION

There is no known genetic abnormality, but presentation may trend in families.

Microscopic Polyangiitis

BASIC INFORMATION

DEFINITION

Microscopic polyangiitis (MPA) is an ANCA (antineutrophil cytoplasmic autoantibody)-associated small to medium vessel systemic vasculitis. It is characterized by necrotizing, pauciimmune, small-vessel vasculitis in the absence of granulomatous inflammation. Most patients present with both renal and pulmonary involvement that may cause severe organ dysfunction leading to renal and respiratory failure. However, MPA may affect any organ or tissue, including the skin, nervous system, and gastrointestinal (GI) tract. MPA belongs to the family of ANCA-associated vasculitides that also includes granulomatosis with polyangiitis (GPA, previously known as Wegener granulomatosis) and eosinophilic granulomatosis with polyangiitis (EGPA, previously known as Churg-Strauss syndrome) (Table E1).

TABLE E1 Classification Scheme of Vasculitides according to Size of Predominant Blood Vessels Involved

Predominantly Large-Vessel Vasculitides

Takayasu arteritis

Giant cell arteritis

Cogan syndrome

Behçet syndrome*

Predominantly Medium-Vessel Vasculitides

Classic polyarteritis nodosa

Cutaneous polyarteritis nodosa

Rheumatoid vasculitis†

Buerger disease (thromboangiitis obliterans)

Kawasaki disease

Primary angiitis of the central nervous system

Predominantly Small-Vessel Vasculitides

Immune Complex Mediated

- Cutaneous leukocytoclastic angiitis ("hypersensitivity" vasculitis)
- Henoch-Schönlein purpura
- Urticarial vasculitis
- Cryoglobulinemic vasculitis†
- Goodpasture syndrome (anti-glomerular basement membrane disease)

"ANCA-Associated" Disorders

- Granulomatosis with polyangiitis (previously, Wegener granulomatosis)†
- Microscopic polyangiitis†
- Eosinophilic granulomatosis with polyangiitis (previously known as Churg-Strauss syndrome)†

Miscellaneous Small-Vessel Vasculitides

Connective tissue disorders†

Paraneoplastic diseases

Infection

Inflammatory bowel disease

*May involve small, medium, and large blood vessels.

†Frequent overlap of involvement of small- and medium-size blood vessels.

ANCA, Antineutrophil cytoplasmic antibody.

From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.

SYNONYMS

Microscopic polyarteritis

MPA

ICD-10CM CODE

M31.7 Microscopic polyangiitis

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence is 9.5 to 95 million/yr in Europe, lower elsewhere.
- Prevalence is 20 to 50 cases per 1,000,000.
- More common in Caucasians than in African Americans.
- The male:female ratio is 1.8 to 1.
- MPA occurs at all ages, even in young children. The incidence rises with increasing age, peaking in the sixth and especially seventh decades.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- In 60% to 80% of cases, there is a protracted and indolent course over many wk to mo with nonspecific symptoms such as fatigue, fever, "flu-like" symptoms, weight loss, and anorexia
- Many have migratory arthralgias with no or only mild signs of arthritis affecting a few joints at a time
- Macroscopic hematuria, proteinuria, edema, decreased urinary output
- Pulmonary symptoms, including hemoptysis, cough, dyspnea, pulmonary hemorrhage, pleuritic pain, and lung infiltrates
- Palpable purpura (41%) is the most common cutaneous manifestation. Livedo reticularis (12%), skin ulcers, digital gangrene may also be present
- Inflammation of visceral blood and gut vessels causes pain and bloody stools, and may lead to perforation
- Peripheral nervous system involvement manifesting as mononeuritis multiplex (57%), CNS involvement manifesting as seizures (11%)
- Kidney involvement up to 90%
- Weight loss >70%
- Myalgias 50%, arthralgias (10% to 50%), arthritis
- Chest pain, heart failure symptoms
- Mild ENT symptoms including nasal congestion, sinusitis, and epistaxis can occur in up to 30% of cases
- Severe or destructive disease of the upper airways is not compatible with MPA and suggests a diagnosis of GPA
- Ophthalmic involvement: Episcleritis and ulcerative keratitis are the most common clinical manifestations, occurring in 10% to 20% of cases. Uveitis, conjunctivitis, and necrotizing scleritis have also been described

ETIOLOGY

- Autoimmune process of unknown etiology. ANCA, most specifically those directed at cytoplasmic myeloperoxidase, are felt to contribute to the inflammatory process. Once bound to their cellular epitope, antimyeloperoxidase (MPO) antibodies likely contribute to degranulation of the neutrophil, which presumably contributes to endothelial injury. Most recently, investigators have demonstrated that anti-MPO antibodies alone can cause necrotizing and crescentic glomerulonephritis.
- In addition to antibodies directed against PR3 and MPO, it has been demonstrated that patients with ANCA-associated necrotizing glomerulonephritis tend to have IgG antibodies against human lysosomal membrane protein 2 (hLAMP-2).
- Many hypotheses involve microbial agents in the development of disease activity.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Polyarteritis nodosa
- Kawasaki disease
- Infective endocarditis
- Lymphoma
- Amyloidosis
- Hypercoagulable states
- Systemic lupus erythematosus
- Paraproteinemia
- Cryoglobulinemia

MPA is distinguished from GPA by the absence of granuloma formation (Table E2) and from EGPA by the absence of asthma and eosinophilia.

WORKUP

- Thorough medical history and physical examination to detect sites of organ involvement and to exclude other illnesses that may have a similar appearance, especially infections.
- Diagnosis is confirmed with kidney biopsy revealing nongranulomatous necrotizing pauciimmune vasculitis of small vessels or pauciimmune necrotizing crescentic glomerulonephritis.

LABORATORY TESTS

- May reveal elevated sedimentation rate (ESR), C-reactive protein, leukocytosis, thrombocytosis, and normocytic anemia
- Elevated serum blood urea nitrogen and creatinine suggest renal impairment
- Urinalysis to detect proteinuria, hematuria, erythrocyte casts, abnormal urine sediment
- ANCA positive 82% to 94%
- Perinuclear ANCA directed at myeloperoxidase (50% to 70%)
- Cytoplasmic ANCA directed at proteinase 3 (25% to 30%)
- Serum complement levels
- Aspartate aminotransferase, alanine aminotransferase, and creatine phosphokinase to evaluate for liver or muscle involvement
- Blood cultures to rule out bacterial endocarditis

IMAGING AND OTHER STUDIES

- Tissue for pathology diagnosis is usually required to confirm the diagnosis; characteristic histologic lesion in MPA is pauciimmune necrotizing small-vessel vasculitis.

TABLE E2 Names and Definitions of Vasculitis Adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis

Name	Definition
Large-Vessel Vasculitis*	
Giant cell (temporal arteritis)	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 yr and often is associated with polymyalgia rheumatica.
Takayasu arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50 yr.
Medium-Sized Vessel Vasculitis*	
Polyarteritis nodosa (classic polyarteritis nodosa)	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules. Kawasaki disease arteritis involving large, medium-sized, and small arteries and associated with mucocutaneous lymph node syndrome. Coronary arteries often are involved. Aorta and veins may be involved. Usually occurs in children.
Small-Vessel Vasculitis*	
Granulomatosis with polyangiitis‡	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small- to medium-sized vessels, e.g., capillaries, venules, arterioles, and arteries. Necrotizing glomerulonephritis is common.
Churg-Strauss syndrome	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small- to medium-sized vessels and associated with asthma and blood eosinophilia.
Microscopic polyangiitis (microscopic polyarteritis)	Necrotizing vasculitis with few or no immune deposits affecting small vessels, e.g., capillaries, venules, or arterioles. Necrotizing arteritis involving small- and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs.
Henoch-Schönlein purpura‡	Vasculitis with immunoglobulin A–dominant immune deposits affecting small vessels, e.g., capillaries, venules, or arterioles. Typically involves the skin, gut, and glomeruli and is associated with arthralgias or arthritis.
Essential cryoglobulinemic vasculitis‡	Vasculitis with cryoglobulin immune deposits affecting small vessels, e.g., capillaries, venules, or arterioles, and associated with cryoglobulins in serum. Skin and glomeruli often are involved.
Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis.

*_Large artery_ refers to the aorta and the largest branches directed toward major body regions (e.g., to the extremities, head and neck); _medium-sized artery_ refers to the main visceral arteries (e.g., renal, hepatic, coronary, and mesenteric arteries); and _small artery_ refers to the distal arterial radicals that connect with arterioles (e.g., renal arcuate and interlobular arteries). Note that some small- and large-vessel vasculitides may involve medium-sized arteries, but large- and medium-sized vessel vasculitides do not involve vessels smaller than arteries.
†Strongly associated with antineutrophil cytoplasmic autoantibodies (ANCA).
‡May be accompanied by glomerulonephritis and can manifest as nephritis or pulmonary renal vasculitic syndrome.
From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.

- Biopsy of the skin reveals nonspecific leukocytoclastic vasculitis with little or no complement and immunoglobulin on immunofluorescence.
- Kidney biopsy usually reveals necrotizing crescentic glomerulonephritis that is usually pauciimmune on immunofluorescence and necrotizing vasculitis of microscopic vessels (small arteries, arterioles, capillaries, venules).
- Intestinal angina is often a result of mesenteric ischemia and can be assessed using mesenteric angiography when renal function permits.
- Chest radiograph would show diffuse parenchymal infiltrates secondary to pulmonary alveolar hemorrhages (Fig. E1).
- Computed tomographic (CT) scanning may disclose previously undetected nodules, unsuspected cavitation in nodules, alveolar opacities, large-airway inflammation or stenotic lesions, and pleural-based lesions.
- An EMG may reveal a sensorimotor peripheral neuropathy in patients with mononeuritis multiplex.
- Electrocardiography is indicated in those with cardiac symptoms.

Rx TREATMENT

ACUTE GENERAL Rx

- Induction: Depends on severity of disease and organ system involvement.
  1. Corticosteroids combined with cyclophosphamide, followed by maintenance therapy with methotrexate, azathioprine, or mycophenolate mofetil.
  2. Rituximab is an effective alternative to cyclophosphamide for initial induction therapy as well as for relapse.
  3. Plasmapheresis is an option for patients with severe bleeding in the lungs or rapidly progressive kidney failure leading to dialysis.

CHRONIC Rx

- Maintenance therapy: Mycophenolate mofetil, azathioprine, methotrexate, and rituximab can be used for maintenance therapy, although dosing intervals and duration of therapy are still being determined.
- Prophylaxis for opportunistic infections like *Pneumocystis jirovecii (carinii)* pneumonia (PCP) is with low-dose sulfamethoxazole/trimethoprim given as one double-strength tablet three times weekly or as a single-strength tablet once daily. Atovaquone is preferred in patients who are allergic to sulfonamides or who do not tolerate trimethoprim-sulfamethoxazole.
- Relapse therapy:
  1. Mild or non–life-threatening relapses while on maintenance therapy can be treated by increasing glucocorticoid dose and/or by adding azathioprine or methotrexate.
  2. In severe cases, treatment is the same as in remission induction; however, rituximab is often preferred over cyclophosphamide.

DISPOSITION

- Poor prognosis if untreated.
- Prompt diagnosis is important to permit initiation of therapy that may be life saving and organ sparing.
- Renal failure and pulmonary involvement are the major causes of morbidity and mortality.
- With treatment, 1- to 5-yr survival rates are 82% and 76%.

REFERRAL

- Nephrology consultation is needed for the diagnosis and management of renal disease.
- Multiple specialists may be consulted depending on other organ system involvement.

PEARLS & CONSIDERATIONS

- Relapse occurs in one third of the cases.
- PCP occurs in 6% of the patients as a complication of immunosuppressive therapy.

BASIC INFORMATION

DEFINITION

Microsporidiosis is an infection caused by single-celled intracellular spore-forming organisms previously classified as protozoan, but now classified as fungi. Infections occur more commonly in patients with HIV/AIDS, travelers, children, organ transplant recipients, contact lens wearers, and elderly adults.

SYNONYMS

Enterocytozoon bieneusi infection
Encephalitozoon species infection

ICD-10CM CODES

A07.8 Microsporidiosis, intestinal
B60.8 Microsporidiosis
H16.8 Keratitis, microsporidia

EPIDEMIOLOGY & DEMOGRAPHICS

Microsporidia are a phylum of ubiquitous protists that exist worldwide in the environment and can infect vertebrate and invertebrate hosts, entering via ingestion or inhalation of spores and by direct contact through broken skin or lesions in the eyes.

PREVALENCE: Prevalence in immunocompetent persons is unclear, with rates varying from 5% to 45% in recent studies of stool from healthy human subjects.

In the postantiretroviral therapy era, prevalence rates have decreased; however, in a study of asymptomatic HIV patients, 15% had evidence of microsporidia on small bowel biopsy.

RISK FACTORS: Infections such as a nonbloody watery diarrhea and keratoconjunctivitis in contact lens wearers can occur in normal hosts, but immunocompromised hosts such as AIDS patients, organ transplant recipients, and bone marrow graft recipients are at greater risk for more severe disease, other organ involvement, and disseminated infection. Patients living with AIDS who have CD4 counts <200 should be advised to avoid untreated water and undercooked meat or seafood.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Each species of microsporidia has different reported infections:

- *Enterocytozoon bieneusi* can cause diarrhea, wasting syndrome, cholangitis, rhinitis, or bronchitis.
- *Encephalitozoon intestinalis* can cause diarrhea, intestinal perforation, cholangitis, nephritis, keratoconjunctivitis, and disseminated infection.
- *Encephalitozoon cuniculi* can cause hepatitis, peritonitis, encephalitis, urethritis, prostatitis, nephritis, sinusitis, keratoconjunctivitis, cystitis, cellulitis, and disseminated infection.
- *Encephalitozoon hellem* can cause keratoconjunctivitis, sinusitis, pneumonitis, nephritis, prostatitis, urethritis, cystitis, and disseminated infection.

ETIOLOGY

- There are 1200 species of Microsporidia, but only 14 infect humans from seven different genera. The four most common species to cause human disease are:
  1. *Enterocytozoon bieneusi*
  2. *Encephalitozoon intestinalis*
  3. *Encephalitozoon cuniculi*
  4. *Encephalitozoon hellem*
- These genotypes that infect humans have been identified in domestic, farm, and wild animals and thus may be a form of zoonotic disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other causes of watery non-bloody diarrhea: *Norovirus, Giardia, Cryptosporidia, Cyclospora,* and *Isospora belli*
- Other causes of keratoconjunctivitis: Herpetic keratoconjunctivitis and acanthamoeba keratitis

WORKUP

Consists of the microscopic detection of microsporidia spores (1 to 2 μm in diameter) in stool, body fluids, or tissue samples.

LABORATORY TESTS

- Modified trichrome stain with light microscopy can be used on stool, urine, mucus, or tissues. Spores stain pink against a blue-green background
- Fluorescent techniques: Calcofluor white stain, Uvitex 2B, and Fungi-Fluor kit
- Indirect immunofluorescence
- Serology: Detects IgM and IgG antibodies
- For exact speciation: PCR

TREATMENT

ACUTE GENERAL Rx

Treatment will depend on organism and site involved.

- There is no available therapy currently for *E. bieneusi*; however, immune restoration through initiation of antiretroviral therapy (ART) has been shown to resolve symptoms in AIDS patients. ART should be offered as a part of initial management where applicable. Systemic fumagillin has shown some success.
- Intestinal or disseminated infection caused by microsporidia other than *E. bieneusi* and *V. corneae*: Albendazole 400 mg PO bid for 2 to 4 wk depending on level of immunosuppression. Children: 15 mg/kg/day PO in divided doses. For disseminated disease (especially *Trachipleistophora* or *Anncaliia* infections), consider the addition of itraconazole.
- Keratoconjunctivitis: Topical fumagillin 70 mcg/ml eye drops (2 drops every 2 hours for 4 days, then 2 drops 4 times a day). If associated with intestinal disease, add albendazole 400 mg PO bid for 2 to 4 wk depending on degree of immunosuppression.

CHRONIC Rx

- Antimotility agents are useful to control diarrhea.
- Recurrence or relapse may occur with ongoing immunosuppression; therefore, consider chronic maintenance therapy until CD4 counts remain >200 for 6 mo in those living with HIV.

REFERRAL

- Infectious diseases physician for antiretroviral therapy if positive for HIV/AIDS
- Ophthalmologist if keratoconjunctivitis is suspected

PEARLS & CONSIDERATIONS

COMMENTS

- Microsporidia infections occur particularly in HIV-positive patients with $CD4^+$ cell counts <50/ml.
- Microsporidia spores can remain active in the environment for prolonged periods of time (e.g., mos).

Middle East Respiratory Syndrome (MERS)

BASIC INFORMATION

DEFINITION

Middle East respiratory syndrome (MERS) is a viral respiratory disease caused by a novel coronavirus known as Middle East respiratory syndrome coronavirus (MERS-CoV) that was first identified in Saudi Arabia in 2012.

SYNONYMS

Human coronavirus-EMC (Erasmus Medical Center)
MERS

ICD-10CM CODE
B97.29 Other coronavirus as the cause of diseases classified elsewhere

EPIDEMIOLOGY & DEMOGRAPHICS

As of July 2018, there have been 2220 cases worldwide in 27 countries but mostly in the Middle East, with a total of 790 deaths. Outside the Middle East, cases have been travel related and traceable to the Arabian Peninsula.

INCIDENCE: In one study in Saudi Arabia of more than 10,000 people, the positive serology rate was only 0.15%, was higher in men than in women, and was higher among camel shepherds and slaughterhouse workers (3.1%) than the general population.

PREDOMINANT SEX AND AGE: More than 60% of cases are in men, and the median age is 48 yr.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The spectrum of disease for MERS ranges from a mild viral respiratory disease to a rapidly fatal viral pneumonia associated with acute respiratory distress syndrome (ARDS) and acute renal failure.
- Patients will present with an influenza-like illness with fever, chills, headache, and a dry cough.
- MERS progresses rapidly to a viral pneumonia within a wk of onset of the infection with bilateral interstitial infiltrates and development of ARDS with severe hypoxemia.
- Other possible symptoms include myalgias, sore throat, vomiting, diarrhea, abdominal pain, and hemoptysis.

ETIOLOGY

- MERS-CoV is closely related to a coronavirus found in bats, which implies that bats may be a reservoir for MERS-CoV. The virus was then transmitted to dromedary camels sometime in the distant past. Camels likely serve as hosts for MERS-CoV for animal-to-human transmission.
- Human-to-human transmission has been documented in various cluster outbreaks and in household contacts.
- While MERS has a high case fatality rate (35% to 50%), its transmissibility appears to be modest.
- The median incubation period for human-to-human transmission is 5 days.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Severe acute respiratory syndrome (SARS), also caused by a novel coronavirus (SARS-CoV), emerged in 2002 in China. The virus also likely originated in bats, and the intermediate host for the virus was the palm civet cat. SARS has a high transmissibility rate but a low case fatality rate.
- Influenza, including pandemic H1N1 influenza and avian influenza H7N9.
- MERS has a high frequency of renal failure, and influenza does not.

WORKUP

MERS should be considered when there is a direct epidemiologic link with a person with MERS or when a patient resides in or has traveled to the Middle East and presents with a febrile acute respiratory illness.

LABORATORY TESTS

- Lower respiratory tract specimens such as sputum or BAL should be tested using a real-time reverse-transcriptase polymerase chain reaction test (rRT-PCR), and these test sites appear to be more sensitive than testing of upper respiratory tract secretions via combined nasopharyngeal and oropharyngeal swab with the same rRT-PCR.
- Serology: A serum sample within first 10 to 12 days of onset should be obtained for rRT-PCR and repeated 14 days later.
- Other serologic tests include ELISA screening followed by indirect immunofluorescence.
- Nonspecific laboratory tests with MERS: Leukopenia, relative lymphopenia, and thrombocytopenia.

IMAGING STUDIES

- Radiographic abnormalities include either unilateral or bilateral airspace opacities, patchy infiltrates, interstitial changes, nodular opacities, reticular opacities, pleural effusions, and even total segmental or lobar opacification.
- ARDS pattern is typically seen with severe cases.

TREATMENT

ACUTE GENERAL Rx

Currently there are no approved treatments for MERS. Experimental therapies include:

- Combination of interferon (IFN)-alpha-2a and ribavirin
- Monoclonal antibodies
- Convalescent serum
- Nitazoxanide: A broad-spectrum antiviral agent
- Steroids are not recommended for use in patients with MERS
- Ongoing placebo controlled trial in Saudi Arabia of oral lopinavir-ritonavir and SQ interferon-beta

NONPHARMACOLOGIC THERAPY

There is ongoing research in vaccine development, including camel vaccination, which may be a novel approach to preventing human infection.

REFERRAL

If a case is suspected, the local health department should be involved as well as an infectious diseases physician.

PEARLS & CONSIDERATIONS

COMMENTS

In South Korea, a single imported case created an outbreak of 185 cases and 36 deaths in 2015.

PREVENTION

- Health care workers are at risk of exposure to the disease and thus should use both contact and airborne precautions in the hospital setting if in close contact with symptomatic individuals or patients with MERS.
- In the Middle East, infection-control practices include prohibiting consumption of unpasteurized camel milk (virus can be found in milk and feces) and use of camel urine, which is believed to have medicinal purposes.
- With 10 million Hajj pilgrims visiting Saudi Arabia each yr from more than 180 countries, a high degree of suspicion of the clinical illness is important in persons returning to their home nations.

BASIC INFORMATION

DEFINITION

Migraine headaches are recurrent severe headaches that either are preceded by a focal neurologic symptom (migraine with aura), occur independently without preceding focal neurologic symptoms (migraine without aura), or have atypical presentations (migraine variants). The migraine aura (Box 1) typically is characterized by visual or sensory symptoms that develop over 5 to 60 min. If the aura includes unilateral motor weakness, the migraine is referred to as hemiplegic. In migraine with and without aura, the headache is typically moderate to severe, unilateral, pulsatile, made worse with head movement, and associated with nausea and vomiting, photophobia, and phonophobia. Migraines that occur ≥15 days every mo for ≥3 mo are known as chronic; otherwise, they are referred to as episodic. Table 1 summarizes criteria for migraine.

ICD-10CM CODES

G43.909	Migraine, unspecified, not intractable, without status migrainosus
G43.1	Migraine with aura (classical migraine)
G43.0	Migraine without aura (common migraine)
G43.2	Status migrainosus
G43.3	Complicated migraine

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Increases from infancy, peaks during the third decade of life, then decreases
PREVALENCE (IN U.S.): Migraine is very common, affecting 1 in 6 people in the U.S. It is the fourth or fifth most common reason for an emergency room visit and the seventh leading cause of time spent disabled worldwide.
AGE: Peak prevalence between ages of 18 and 49
PREDOMINANT SEX: Female:male ratio of 3:1
GENETICS: Familial predisposition: More than 50% of migraine sufferers have an affected family member.

BOX 1 Auras of Migraine

- Sensory phenomena
  - Special senses
    - Visual, olfactory, auditory, gustatory
  - Paresthesias, especially lips and hand
- Motor deficits
  - Hemiparesis, hemiplegia
- Neuropsychologic changes
- Aphasia
- Perceptual impairment, especially for size, shape, and time
- Emotional and behavioral
  - Anxiety, depression, irritability, (rarely) hyperactivity

From Kaufman DM et al: *Kaufman's clinical neurology for psychiatrists*, ed 8, Philadelphia, 2017, Elsevier.

- Autosomal-dominant transmission for some rare migraine variants (familial hemiplegic migraine, cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy [CADASIL]); familial hemiplegic migraines have been associated with calcium channelopathy, sodium channelopathy, and Na^+/K^+-ATPase dysfunction.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Normal between episodes
- Normal for migraine without aura
- Focal motor or sensory abnormalities possible for migraine with aura or migraine variants
- Common aura types include scintillating scotoma, bright zigzags (fortifications), and other visual distortions such as macropsia or micropsia (enlargement or shrinkage of objects) that often cross visual fields. Homonymous visual disturbance, sensory phenomena such as hemibody paresthesia, speech disturbances, or hemiparesis (familial or sporadic hemiplegic migraine) also can occur independently or associated with visual symptoms

ETIOLOGY

The pathophysiology of migraines is not clearly understood, although the primary neuronal event results in a trigeminovascular reflex causing neurogenic inflammation. Calcitonin-gene related peptide (CGRP) is released by the trigeminal ganglion and binds receptors around meningeal vessels leading to inflammation. Serotonin, substance P, and nitric oxide also play a role, but the exact mechanism is unknown. Cortical spreading depressions also likely are responsible for the aura.

DIAGNOSIS

Migraine without aura:
- Five attacks fulfilling criteria
- Headache attacks lasting 4 to 72 hr
- Headache has at least two of the following characteristics:
  1. Unilateral location
  2. Pulsating quality
  3. Moderate or severe pain intensity
  4. Aggravation or causing avoidance of routine physical activity
- At least one of the following during headache:
  1. Nausea and/or vomiting
  2. Photophobia and phonophobia

Migraine with typical aura:
- At least two attacks
- Aura consisting of at least one of the following, but no motor weakness:
  1. Fully reversible visual symptoms, including positive and/or negative features
  2. Fully reversible sensory symptoms, including positive and/or negative features
  3. Fully reversible dysphasic speech disturbance
- At least two of the following:
  1. Homonymous visual symptoms and/or unilateral sensory symptoms
  2. At least one aura symptom develops gradually over >5 min and/or different aura symptoms occur in succession over >5 min
  3. Each symptom lasts between 5 and 60 min
- A migraine occurring during or within 60 min of the aura

DIFFERENTIAL DIAGNOSIS

- A diagnosis of migraine is possible only after five recurrent episodes.
- The first or the worst headache should always be investigated, and the differential includes headaches from all secondary causes.
- Headache red flags can be remembered by the mnemonic SSNOOP5:
  1. S: Systemic symptoms of fever, weight loss
  2. S: Secondary risk factors of immunosuppression from any cause, cancer
  3. N: Neurologic deficits, altered consciousness
  4. O: Onset is sudden, abrupt, split second thunderclap
  5. O: Older, age >50 for new-onset headache should be worked up for giant cell arteritis
  6. P: Pattern: change in headache pattern
  7. P: Pregnancy
  8. P: Positional or postural
  9. P: Papilledema
  10. P: Precipitation with Valsalva maneuver or exertion
- Section II describes the differential diagnosis of headaches. Table 1 compares tension-type and migraine headaches.
- Useful mnemonic for migraine is POUND: Pulsatile, One day in duration, Unilateral, Nausea/vomiting, Disabling.

WORKUP

- In general, no additional investigation is needed with recurrent, typical attacks with usual age of onset, family history, and a normal physical examination.

TABLE 1 Comparison of Tension-Type and Migraine Headaches

	Tension-Type	Migraine
Location	Bilateral	Hemicranial*
Nature	Dull ache	Throbbing*
Severity	Slight–moderate	Moderate–severe
Associated symptoms	None	Nausea, hyperacusis, photophobia
Behavior	Continues working	Seeks seclusion
Effect of alcohol	Reduces headache	Worsens headache

*In approximately half of patients, at least at onset.
From Kaufman DM et al: *Kaufman's clinical neurology for psychiatrists,* ed 8, Philadelphia, 2017, Elsevier.

- If there is an unusual presentation, headache with red flags, and/or unexpected findings on examination, investigation for other causes is required.

LABORATORY TESTS

Lumbar puncture for history of abrupt-onset headaches and uncertain diagnosis of migraine

IMAGING STUDIES

- Imaging should be done in patients with any of the red flags for secondary headache such as described by the SSNOOP5 mnemonic (see "Differential Diagnosis" above).
- MRI brain with and without contrast is the imaging modality of choice for almost all headache types, although CT head without contrast may be used in the acute setting to evaluate for subarachnoid hemorrhage or other causes of acute intracranial hemorrhage.

Rx TREATMENT

Consider the use of a headache log/diary to identify triggers of headaches, record efficacy of treatments, and track history of headaches.

NONPHARMACOLOGIC THERAPY

- Avoid any identifiable provoking factors: Caffeine, tobacco, and alcohol may trigger attacks, as may dietary or other environmental precipitants (less common).
- Avoid emotional stressors and minimize variations in daily routine with regular sleep, meals, and exercise.
- Relaxation training, behavioral therapy, and biofeedback. Trials have shown that among young persons with chronic migraine, the use of cognitive-behavioral therapy (CBT) plus amitriptyline results in greater reductions in days with headaches and migraine-related disability compared with use of headache education plus amitriptyline.
- Trials in patients with migraine without aura have shown that acupuncture may be associated with long-term reduction in migraine recurrence.[1]

ACUTE ANALGESIC Rx

- Many oral agents are ineffective because of poor absorption from migraine-induced gastric stasis. Nonoral route of administration should be selected in patients with severe nausea or vomiting.
- NSAIDs such as ketorolac, ibuprofen, and naproxen, or combination analgesics, may be used first line for mild migraine headaches.
- Barbiturate-containing compounds should be avoided because they are potentially addictive and promote medication overuse headaches.
- Opioids are not effective for treating patients with migraine headaches and should not be used.

ACUTE ABORTIVE Rx

- Triptans (SC, PO, and intranasal) are the drug class of choice for abortive therapy. Metaanalysis suggests that 10 mg rizatriptan, 40 mg eletriptan, and 12.5 mg almotriptan are most effective. Sumatriptan may also be given, especially in combination with naproxen. Early administration improves effectiveness. Triptans are relatively contraindicated in heart disease and hemiplegic migraine.
- IV antiemetics (prochlorperazine, metoclopramide, chlorpromazine) may be used in addition to triptans. Acute dystonic reactions, QT prolongation, and akathisia are rare side effects. These are generally not used as monotherapy.
- Ergotamine, ergotamine combinations (PO/PR), and dihydroergotamine (DHE 45) (SC, IV, IM, intranasal) have well-documented efficacy against migraines. DHE is usually administered in combination with an antiemetic drug (Table 2) but cannot be given within 24 hr of a triptan.
- IV dexamethasone may be used to prevent recurrence but should not be used frequently due to risk for toxicity.
- Greater and lesser occipital nerve blocks may also be performed to alleviate pain in the acute setting. These injections may be combined with auriculotemporal, supraorbital, and supratrochlear nerve block to achieve anesthesia in the area of perceived pain.
- A recent phase 3 trial with rimegepant, an oral gene-related peptide receptor showed efficacy in acute treatment.[2]

PROPHYLAXIS Rx

- Prophylactic treatment is generally indicated when headaches are disabling more than 5 days of the mo or when symptomatic treatments are contraindicated or not effective. All prophylaxes should be maintained for at least 3 mo before deeming the medication a failure.
- Well-established options for prophylactic treatment include β-blockers (propranolol, timolol, atenolol, metoprolol), tricyclic antidepressants (amitriptyline, nortriptyline), and the antiepileptic drugs topiramate and sodium divalproate (valproic acid).
- CGRP monoclonal antibodies: A new class of injectable drugs that target the CGRP molecule or its receptor have been approved recently. There are currently three FDA-approved drugs in this class, erenumab (Aimovig), fremanezumab (Ajovy), and galcanezumab (Emgality), with more under study. These drugs can be used first line for episodic and chronic migraine.
- Less-established options include calcium channel blockers, selective norepinephrine serotonin reuptake inhibitors, memantine, and other antiepileptic medications.
- Supraorbital transcutaneous electrical stimulation has been approved by the FDA for prophylaxis of episodic migraine and is widely available with a prescription in Europe and North America.
- The FDA has approved injection of onabotulinum toxin A (Botox) for prevention of headaches in adult patients with chronic migraines only (≥15 headache days/mo for ≥3 mo).
- Surgical treatment for migraine using nerve decompression remains highly controversial, with poorly established results. This should be pursued only in collaboration with a headache specialist.

DISPOSITION

With advancing age, many patients will have sustained reduction in frequency of migraine headaches.

REFERRAL

To neurologist if uncertain about diagnosis or treatment not effective

PEARLS & CONSIDERATIONS

- Migraines that change in character or headaches that are different from the patient's typical ones need to be reevaluated.
- Long-term and frequent use of analgesic medications can result in medication overuse or rebound headaches. Early initiation of prophylactic medication is key.
- Avoid use of narcotics, barbiturates, and benzodiazepines because they are habit forming. Narcotics and barbiturates also promote medication overuse headaches.
- Migraine with aura is associated with excess stroke and thromboembolism risk, and is a relative contraindication to the use of combined oral contraceptives in women.

TABLE 2 Abortive and Analgesic Therapy for Migraine*

Drug	Route	Dose
Triptans (Serotonin Agonists)		
Sumatriptan	Subcutaneous	6 mg, repeat in 2 hr (max 2 doses/day)
Sumatriptan	Oral	25 mg, 50 mg, 100 mg, repeat in 2 hr (max 200 mg/day)
Sumatriptan	Nasal spray	5 mg, 20 mg, repeat in 2 hr (max 40 mg/day)
Zolmitriptan	Oral	1.25, 2.5 mg, 5 mg, repeat in 2 hr (max 10 mg/day)
Zolmitriptan	Nasal spray	5 mg, repeat in 2 hr (max 10 mg/day)
Zolmitriptan	Orally disintegrating tab	2.5, 5 mg, repeat in 2 hr (max 10 mg/day)
Naratriptan	Oral	1 mg, 2.5 mg, repeat in 4 hr (max 5 mg/day)
Rizatriptan	Oral	5 mg, 10 mg, repeat in 2 hr (max 30 mg/day)
Almotriptan	Oral	6.25 mg, 12.5 mg, may repeat in 2 hr (max 25 mg/day)
Eletriptan	Oral	20 mg, 40 mg, may repeat in 2 hr (max 80 mg/day)
Frovatriptan	Oral	2.5 mg, may repeat in 2 hr (max 7.5 mg/day); may also be used for mini prophylaxis
Ergotamine Preparations		
Ergotamine and caffeine	Oral	2 tablets, may repeat 1 tab q30 min (max 6/day)
Ergotamine and caffeine	Rectal	1 suppository, repeat in 1 hr (max 2/day)
Ergotamine	Sublingual	1 tablet, repeat in 1 hr (max 2/day)
Dihydroergotamine	Intramuscular	0.5-1.0 mg, repeat twice at 1-hr intervals (max 3 mg/attack)
	Subcutaneous	
	Intravenous	
	Nasal spray	
Isometheptene + dichloralphenazone + acetaminophen	Oral	1 to 2 capsules, repeat in 4 hr (max 8/day)
Nonsteroidal Antiinflammatory Drugs		
Acetaminophen + (should not be used alone)	Oral	2 tablets, repeat in 6 hr (max 8/day aspirin + caffeine)
Naproxen	Oral	550-750 mg, repeat in 1 hr (max 3 times/wk)
Meclofenamate	Oral	100-200 mg, repeat in 1 hr (max 3 times/wk)
Flurbiprofen	Oral	50-100 mg, repeat in 1 hr (max 3 times/wk)
Ibuprofen	Oral	200-300 mg, repeat in 1 hr (max 3 times/wk)
Antiemetics		
Promethazine	Oral	50-125 mg
	Intramuscular	No clear benefit in migraine, may be used
Prochlorperazine	Oral	1-25 mg
	Rectal	2.5-25 mg (suppository)
	Intramuscular/IV	5-10 mg, good evidence for strong benefit
Chlorpromazine	Oral	10-25 mg
	Rectal	50-100 mg (suppository)
	Intravenous	Up to 35 mg, use with monitoring, some evidence for good benefit
Trimethobenzamide	Oral	250 mg
	Rectal	200 mg
Metoclopramide	Oral	5-10 mg
	Intramuscular	10 mg
	Intravenous	5-10 mg
Dimenhydrinate	Oral	50 mg

*For side effects and contraindications, consult the manufacturer's drug insert before prescribing any of these drugs.

BASIC INFORMATION

DEFINITION

Significant cognitive impairment in the absence of dementia with preserved activities of daily living (ADLs). Mild cognitive impairment (MCI) is an intermediate state between normal cognitive function and dementia. The main distinctions between MCI and mild dementia are that in the latter, more than one cognitive domain is invariably involved and substantial interference with daily life is evident.[1]

SYNONYMS

Mild neurocognitive disorder
MCI

ICD-10CM CODE
G31.84 Mild cognitive impairment, so stated

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:
- 12 to 15 cases per 1000 person/yr age ≥65
- 51 to 77 cases per 1000 person/yr age ≥75

PEAK INCIDENCE: In the elderly
PREVALENCE: 15% to 25% in those older than age 70
PREDOMINANT SEX AND AGE: Male, age ≥75
GENETICS: *APOE4* genotype
- Various pathways result in amyloid accumulation and deposition in pre-Alzheimer presenting as MCI.

RISK FACTORS: Male sex, age, lower socioeconomic status, lower educational level

CLINICAL PRESENTATION

- Subjective memory problems, preferably corroborated by another person.
- Preserved functional status (ADLs).
- Normal general thinking and reasoning skills.
- Subtypes of MCI include amnestic (mainly involves memory loss) vs. nonamnestic with involvement of other cognitive domains (single domain vs. multiple domains).
- Domains affected in MCI include memory, visuospatial skills, language, attention, and executive function.
- Olfactory dysfunction may be associated with amnestic MCI and progression to Alzheimer dementia.

ETIOLOGY

Neurodegenerative, vascular, traumatic, depression, or due to underlying medical condition

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Delirium
- Dementia
- Depression
- "Reversible" cognitive impairment:
  1. Medication related (anticholinergics)
  2. Hypothyroidism
  3. Vitamin B_{12} deficiency
- Reversible CNS conditions:
  1. Subdural hematoma
  2. Normal pressure hydrocephalus
  3. Metastatic disease

WORKUP

History:
- Focus on cognitive deficits and impairment.
- Review all medications that may impact cognition (i.e., anticholinergics).
- Rule out depression and delirium.
- Perform functional assessment.
- Additional history from family members or caregivers is important.

Physical exam:
- Check blood pressure
- Neurologic exam to rule out reversible CNS causes of cognitive impairment
- Gait and balance assessment

Cognitive function testing:
- Brief mental status testing using MOCA (Montreal Cognitive Assessment) or SLUMS (St. Louis University Mental Status) for office screening followed by neuropsychological testing if appropriate for specific deficits in cognitive domains. MOCA may be a better tool in identifying and following MCI with higher sensitivity to monitor cognitive decline in longitudinal monitoring.

LABORATORY TESTS

- Complete blood count
- Comprehensive metabolic profile
- TSH
- Vitamin B_{12}

IMAGING STUDIES

- CT imaging can detect most reversible CNS conditions leading to cognitive impairment.
- MRI further evaluates vascular, infectious, neoplastic, and inflammatory conditions.

TREATMENT

- There is insufficient evidence to recommend use of cholinesterase inhibitors for MCI. They are not approved for treating MCI, have shown little efficacy in altering progression to dementia, and can have significant side effects.
- Consider treatment with these medications only if memory complaints appear to be affecting day-to-day quality of life in individual patients or in amnestic subtypes of MCI after risk-versus-benefit discussion with patient and family.

NONPHARMACOLOGIC THERAPY

- Role of cognitive rehabilitation to target specific deficits
- Caregiver education and counseling
- Physical and mental exercises to maintain cognition should be recommended

COMPLEMENTARY & ALTERNATIVE MEDICINE

No clear indications for antioxidants, and studies in humans are inconclusive.

DISPOSITION

- Progression to Alzheimer at the rate of 5% to 15% per yr.
  1. Risk factors for progression to dementia include presence of vascular risk factors, significant cognitive impairment, depression, and presence of extrapyramidal signs.
- Mortality of those with MCI is twice that of those without MCI.
- Two- to threefold increase in risk of nursing home placement in those with MCI.

REFERRAL

Consider referral to a memory specialist if more than just memory is involved or for further evaluation of specific deficits.

PEARLS & CONSIDERATIONS

COMMENTS

- Patients with MCI usually report short-term memory concerns such as misplacing things, not remembering names of people, word-finding difficulties, forgetting day-to-day tasks, not being able to read a book, or not being able to follow a conversation.
- MCI becomes clinically relevant when quality of life is affected such as problems making financial decisions and problems with personal day-to-day interactions.
- Depression should be ruled out prior to making a diagnosis of MCI since it is highly prevalent in the elderly.
- Anticholinergic medication use should be evaluated carefully prior to making a diagnosis of MCI.

PREVENTION

Patients with MCI should be counseled on strategies to prevent progression to dementia. They should remain physically and mentally active, have a well-balanced diet, continue activities that are socially engaging, reduce stress in their lives, and aggressively pursue treatment of vascular risk factors.

PATIENT & FAMILY EDUCATION

- Patients with MCI typically have poor retention and rapid loss of newly learned information.
- For additional information for patients, families, and clinicians: Alzheimer's Association (http://www.alzheimers.org).

AUTHORS: **Birju B. Patel, MD,** and **N. Wilson Holland, MD**

Mitral Regurgitation PTG

BASIC INFORMATION

DEFINITION

Mitral regurgitation (MR) is retrograde blood flow into the left atrium resulting from any part of an incompetent mitral valve apparatus. This condition may cause left ventricular (LV) failure, as well as increased left atrial and pulmonary pressures leading to pulmonary hypertension and right-sided heart failure.

SYNONYMS

Mitral insufficiency
MR

ICD-10CM CODES

I34.0	Nonrheumatic mitral (valve) insufficiency
I05.1	Rheumatic mitral insufficiency
I05.9	Mitral valve disease, unspecified
I05.2	Rheumatic mitral stenosis with insufficiency
Q23.3	Congenital mitral insufficiency

EPIDEMIOLOGY & DEMOGRAPHICS

The incidence of MR has increased over the past 30 yr. However, this may be due to increasing availability of echocardiography leading to MR diagnosis rather than to an actual increase in the prevalence of this condition.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Heart sounds:
- Diminished S1 as valve leaflets fail to coapt properly
- Widely split S2 as A2 occurs earlier because of decreased LV ejection time
- Presence of an S3 as a result of increased flow into a dilated LV caused by severe MR with systolic impairment

Heart murmurs:
- Holosystolic, high-pitched, "blowing" murmur is most easily audible at apex with radiation to base, left axilla, or back. There is a poor correlation between the intensity of the systolic murmur and the degree of regurgitation. However, an early diastolic to middiastolic rumble (pseudomitral stenosis) suggests severe MR.
- The murmur of acute MR (e.g., from papillary muscle rupture) can be very soft or inaudible because of a large regurgitant volume entering a noncompliant left atrium. This causes an acute rise in left atrial pressure and a decline in LV filling pressure, and thus a lack of significant gradient for an audible murmur.
- Hyperdynamic apex, sometimes with palpable LV lift and apical thrill.
- Symptomatic patients with MR generally present with the following:
  1. Symptoms suggestive of heart failure (fatigue, dyspnea, orthopnea, paroxysmal nocturnal dyspnea, edema)
  2. Hemoptysis (caused by pulmonary hypertension)
  3. Atrial fibrillation

ETIOLOGY

Primary MR:
- Idiopathic myxomatous degeneration of the mitral valve, mitral valve prolapse (most common cause of MR in industrialized countries)
- Papillary muscle dysfunction or rupture (typically as a result of an inferior wall myocardial infarction)
- Ruptured chordae tendineae
- Infective endocarditis
- Calcified mitral valve annulus
- Rheumatic valvulitis (may be combined with mitral stenosis; common in developing countries)
- Systemic lupus erythematosus (Libman-Sacks endocarditis)
- Drugs: Fenfluramine, dexfenfluramine, pergolide, cabergoline
- Congenital cleft valve
- Ischemic MR due to papillary muscle dysfunction from multivessel coronary artery disease (CAD)

Secondary MR:
- Hypertrophic cardiomyopathy
- LV dilation (e.g., secondary to dilated cardiomyopathy)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypertrophic cardiomyopathy
- Tricuspid regurgitation
- Aortic stenosis
- Aortic sclerosis
- Ventricular septal defect
- Atrial septal defect

WORKUP

- Diagnostic workup consists of echocardiography, ECG, and chest radiograph; cardiac catheterization is sometimes needed to confirm severity of the disease.
- Tables 1 and 2 summarize stages of chronic primary and chronic secondary MR.
- Recent studies suggest that in patients with severe asymptomatic MR, normal LV function and elevations of brain natriuretic peptide (BNP) >105 pg/ml have an independent and additive prognostic value that may identify high-risk patients and aid in the selection of patients for early surgery.

IMAGING STUDIES

- Echocardiography (Fig. 1): Findings include dilated left atrium, hyperdynamic left ventricle, erratic motion of the leaflet in patients with ruptured chordae tendineae, and color flow Doppler with evidence of MR. The most important aspect of the echocardiographic examination is the quantification of the severity of MR (Table 3). A vena contracta width >0.7 cm, a regurgitant volume >60 ml, regurgitant orifice area >0.40 cm^2 by PISA (proximal isovelocity surface area), and systolic pulmonary vein flow reversal are all echocardiographic criteria of severe MR.
- Chest x-ray:
  1. Left atrial enlargement, LV enlargement
  2. Possible pulmonary congestion, although most often normal
- ECG:
  1. Left atrial enlargement
  2. LV hypertrophy
  3. Atrial fibrillation
- Cardiac catheterization: To confirm severity of MR, or to rule out presence of coronary artery disease in patients being evaluated for surgical replacement.
- Can consider cardiac MRI in cases where echocardiography is limited or LV function/dimensions are borderline, or when clinical condition and echocardiographic findings are discordant.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Salt restriction
- Surgical repair or replacement (see the following)

ACUTE GENERAL Rx

- Medical: Medical therapy is primarily directed toward treatment of the source or its complications (e.g., atrial fibrillation, ischemic heart disease, infective endocarditis, hypertension, and heart failure).
  1. The utility of afterload reduction to decrease the regurgitant fraction and increase cardiac output depends upon the etiology of MR. In acute MR, intravenous nitroprusside has shown some utility. Long-term use of oral afterload reducers (e.g., ACE inhibitors or angiotensin receptor blockers), while they do not slow the progression of MR, should be implemented when other indications such as hypertension and LV dysfunction are present.
  2. Control ventricular response in atrial fibrillation when rapid ventricular response is present. Use anticoagulants if atrial fibrillation occurs. Note that current guidelines do not consider AF in patients with MR "valvular," and non–vitamin K anticoagulation agents may be used for stroke prophylaxis.
  3. Diuresis and achieving a euvolemic state may significantly decrease the degree of functional MR caused by volume overload and heart failure.
- Surgery: Surgery is the only definitive treatment for MR. Although no randomized trial of mitral valve repair vs. replacement exists, repair is favored over replacement in degenerative mitral valve disease due to its lower perioperative risk, improved event-free survival, freedom from complications of prosthetic valves, and better postoperative LV function. It is a class I indication in patients with the following diagnoses (Fig. 2):
  1. Acute severe MR
  2. Symptomatic patients with severe primary MR despite optimal medical therapy and LVEF >30%, LV dilation, severe MR by echo criteria
  3. Asymptomatic patients with severe MR but with evidence of declining LV function (EF <60% but >30%) or progressive dilation (LV at end-systole >40 mm)

TABLE 1 Stages of Chronic Primary Mitral Regurgitation

Grade	Definition	Valve Anatomy	Valve Hemodynamics*	Hemodynamic Consequences	Symptoms
A	**At risk for MR**	Mild mitral valve prolapse with normal coaptation Mild valve thickening and leaflet restriction	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.3 cm	None	None
B	**Progressive MR**	Severe mitral valve prolapse with normal coaptation Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE	Central jet MR 20%-40% LA or late systolic eccentric jet MR Vena contracta <0.7 cm Regurgitant volume <60 ml Regurgitant fraction <50% ERO <0.40 cm^2 Angiographic grade 1-2+	Mild LA enlargement No LV enlargement Normal pulmonary pressure	None
C	**Asymptomatic severe MR**	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 ml Regurgitant fraction ≥50% ERO ≥0.40 cm^2 Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension may be present at rest or with exercise C1: LVEF >60% and LVESD <40 mm C2: LVEF ≤60% and LVESD ≥40 mm	None
D	**Symptomatic severe MR**	Severe mitral valve prolapse with loss of coaptation or flail leaflet Rheumatic valve changes with leaflet restriction and loss of central coaptation Previous IE Thickening of leaflets with radiation heart disease	Central jet MR >40% LA or holosystolic eccentric jet MR Vena contracta ≥0.7 cm Regurgitant volume ≥60 ml Regurgitant fraction ≥50% ERO ≥0.40 cm^2 Angiographic grade 3-4+	Moderate or severe LA enlargement LV enlargement Pulmonary hypertension present	Decreased exercise tolerance Exertional dyspnea

ERO, Effective regurgitant orifice; *IE,* infective endocarditis; *LA,* left atrium; *LV,* left ventricle; *LVEF,* left ventricular ejection fraction; *LVESD,* left ventricular end-systolic dimension; *MR,* mitral regurgitation.

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Classification of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

From Nishimura RA et al: 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 63:e57, 2014.

TABLE 2 Stages of Chronic Secondary Mitral Regurgitation

Grade	Definition	Valve Anatomy	Valve Hemodynamics*	Associated Cardiac Findings	Symptoms
A	At risk of MR	Normal valve leaflets, chords, and annulus in a patient with coronary disease or a cardiomyopathy	No MR jet or small central jet area <20% LA on Doppler Small vena contracta <0.30 cm	Normal or mildly dilated LV size with fixed (infarction) or inducible (ischemia) regional wall motion abnormalities Primary myocardial disease with LV dilation and systolic dysfunction	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
B	Progressive MR	Regional wall motion abnormalities with mild tethering of mitral leaflet Annular dilation with mild loss of central coaptation of the mitral leaflets	ERO <0.20 cm^2† Regurgitant volume <30 ml Regurgitant fraction <50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
C	Asymptomatic severe MR	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of the mitral leaflets	ERO ≥0.20 cm^2† Regurgitant volume ≥30 ml Regurgitant fraction ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	Symptoms due to coronary ischemia or HF may be present that respond to revascularization and appropriate medical therapy
D	Symptomatic severe MR	Regional wall motion abnormalities and/or LV dilation with severe tethering of mitral leaflet Annular dilation with severe loss of central coaptation of the mitral leaflets	ERO ≥0.20 cm^2† Regurgitant volume ≥30 ml Regurgitant fraction ≥50%	Regional wall motion abnormalities with reduced LV systolic function LV dilation and systolic dysfunction due to primary myocardial disease	HF symptoms due to MR persist even after revascularization and optimization of medical therapy Decreased exercise tolerance Exertional dyspnea

ERO, Effective regurgitant orifice; *HF,* heart failure; *LA,* left atrium; *LV,* left ventricle; *MR,* mitral regurgitation.

*Several valve hemodynamic criteria are provided for assessment of MR severity, but not all criteria for each category will be present in each patient. Categorization of MR severity as mild, moderate, or severe depends on data quality and integration of these parameters in conjunction with other clinical evidence.

†The measurement of the proximal isovelocity surface area by two-dimensional transthoracic echocardiogram (TTE) in patients with secondary MR underestimates the true ERO because of the crescentic shape of the proximal convergence.

From Nishimura RA et al: 2014 AHA/ACCF guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 63:e57, 2014.

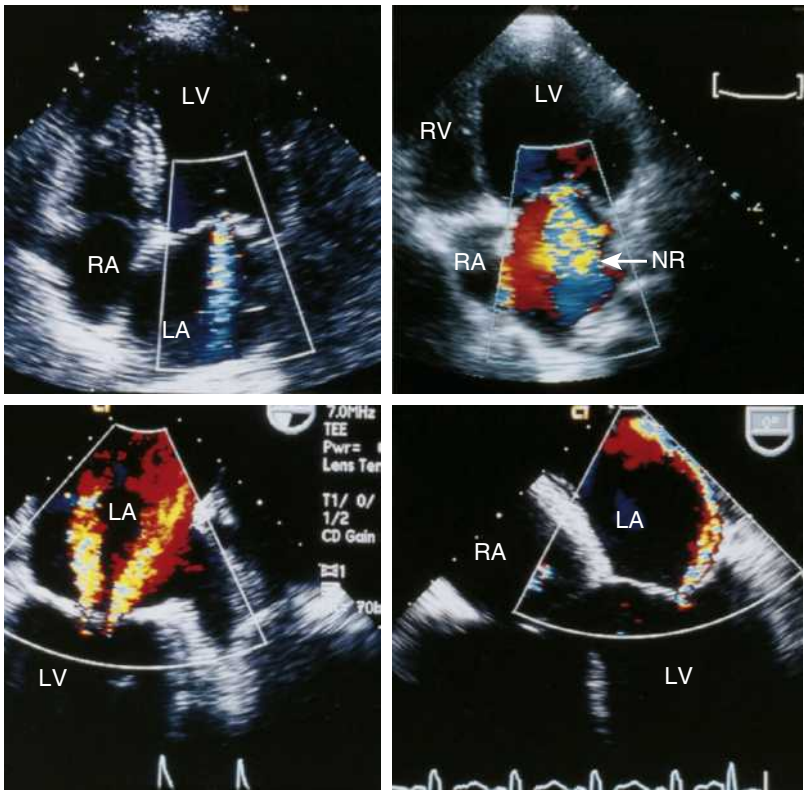

FIG. 1 Mitral regurgitation. Four panels depicting varying degrees of mitral regurgitation; the two top panels are apical four-chamber transthoracic views showing, on the left, mild mitral regurgitation and, on the right, moderate to severe mitral regurgitation. On the left, note the relatively narrow jet directed from the tips of the mitral valve toward the posterior left atrial wall. On the right, note the larger jet, filling approximately 40% of the left atrial cavity. The two bottom panels are transesophageal echocardiograms. On the left, note the mitral regurgitation occurring in two discrete jets and, on the right, the highly eccentric jet, which courses along the extreme lateral wall of the left atrium. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From Zipes DP et al [eds]: *Braunwald's heart disease,* ed 7, Philadelphia, 2005, WB Saunders.)

TABLE 3 Mitral Regurgitation Severity*

	I (Mild)	II (Moderate)	III (Moderate)	IV (Severe)
MR = jet (%LA)	<15	15-30	35-50	>50
Spectral Doppler	Faint	—	—	Dense
Vena contracta	<3 mm	—	—	≥7 mm
Pulmonary vein flow	S > D	Normal to systolic blunting	Systolic blunting	Systolic reversal
RV (ml)	<30	30-44	45-59	≥60
ERO (cm2)	<0.2	0.2-0.29	0.3-0.39	≥0.40
PISA	Small	—	—	Large

D, Antegrade flow in diastole; *ERO,* effective regurgitant orifice; %*LA,* percentage of left atrial area encompassed by the MR jet with color flow Doppler; *MR,* mitral regurgitation; *PISA,* proximal isovelocity surface area; *RV,* regurgitant volume; *S,* antegrade flow in systole.

*For some parameters, the observation is valid at the extremes of MR severity and there may be marked overlap in intermediate (grades II, III) MR. In these instances, no value is presented.

From Zipes DP et al (eds): *Braunwald's heart disease,* ed 7, Philadelphia, 2005, WB Saunders; and the 2017 American Society of Echocardiography Guidelines.

4. Concomitant mitral valve repair or MVR is indicated in patients with chronic severe primary MR undergoing cardiac surgery for other indications

- Surgery is a class IIa (reasonable) recommendation in:
  1. Severe MR with new-onset atrial fibrillation, even if asymptomatic.
  2. Asymptomatic severe MR with pulmonary hypertension (≥50 mm Hg at rest or ≥60 mm Hg during exercise).
  3. Asymptomatic severe MR secondary to flail leaflet.
  4. A recent study of early surgical intervention for severe MR secondary to a flail leaflet in patients with asymptomatic disease shows greater long-term survival and reduced rates of heart failure when compared with medical therapy alone.
     a. Asymptomatic severe MR with preserved LVEF (>60%) and size (<40 mm in end-systole) in whom the likelihood of successful repair without residual MR is >95% and operative mortality is <1%.
- Surgery is a class IIb recommendation in symptomatic patients (New York Heart Association [NYHA] class III to IV) with severe MR with severe LV dysfunction or dilatation (LVEF <30% or LV at end-systole >55 mm, respectively) in whom LV dysfunction is not the primary cause for the MR as well as functional MR where it is secondary to LV dysfunction.
- Quantitative grading of MR is a powerful predictor of the clinical outcome of asymptomatic MR. In general, patients with regurgitant orifice areas of ≥40 mm^2 should be considered for prompt surgery, whereas those with orifices between 20 and 39 mm^2 can be followed closely.
- Percutaneous mitral valve repair methods are currently being investigated. The MitraClip device is FDA approved for use in patients with significant symptomatic degenerative MR (>3+) who are too high risk for surgery. The device is a catheter-delivered clip that grasps and approximates the edges of the mitral leaflets at the origin of the regurgitant jet. Early data are limited and had not demonstrated a significant efficacy in MR reduction compared with surgical replacement; however, in a recent trial, investigators compared guideline-directed medical therapy (GDMT) alone vs. transcatheter mitral repair with MitraClip plus GDMT in patients with severe MR who were not surgical candidates. After 24 mo, heart failure hospitalizations were 36% in the MitraClip group versus 68% in the medical therapy group. Device therapy also improved symptoms and quality of life, and decreased all-cause mortality (29% in device vs. 46% in the GDMT-only group).[1]
- Ischemic MR has been a source of controversy as to whether moderate or greater MR should be fixed at the time of revascularization with coronary artery bypass graft surgery (CABG). Mitral valve repair can be considered at the time of CABG in moderate MR, and mitral valve repair is reasonable for severe MR (class IIa) in the presence of a basal aneurysm or dyskinesis, significant leaflet tethering due to wall motion abnormalities, and moderate-to-severe LV remodeling (LV end-diastolic diameter >65 mm).
- American College of Cardiology/American Heart Association (ACC/AHA) guidelines for intervention for chronic primary MR are summarized in Table 4. Interventions for chronic secondary MR are described in Table 5.

DISPOSITION

Prognosis is generally good unless there is significant impairment of LV function or significantly elevated pulmonary artery pressures. Most patients remain asymptomatic for many yr (average interval from diagnosis to onset of symptoms is 16 yr). In patients with chronic severe MR, MR is commonly progressive, with onset of other symptoms or LV dysfunction

[1] Stone GW et al: Transcatheter mitral-valve repair in patients with heart failure. *N Engl J Med* 379:2307-18, 2018.

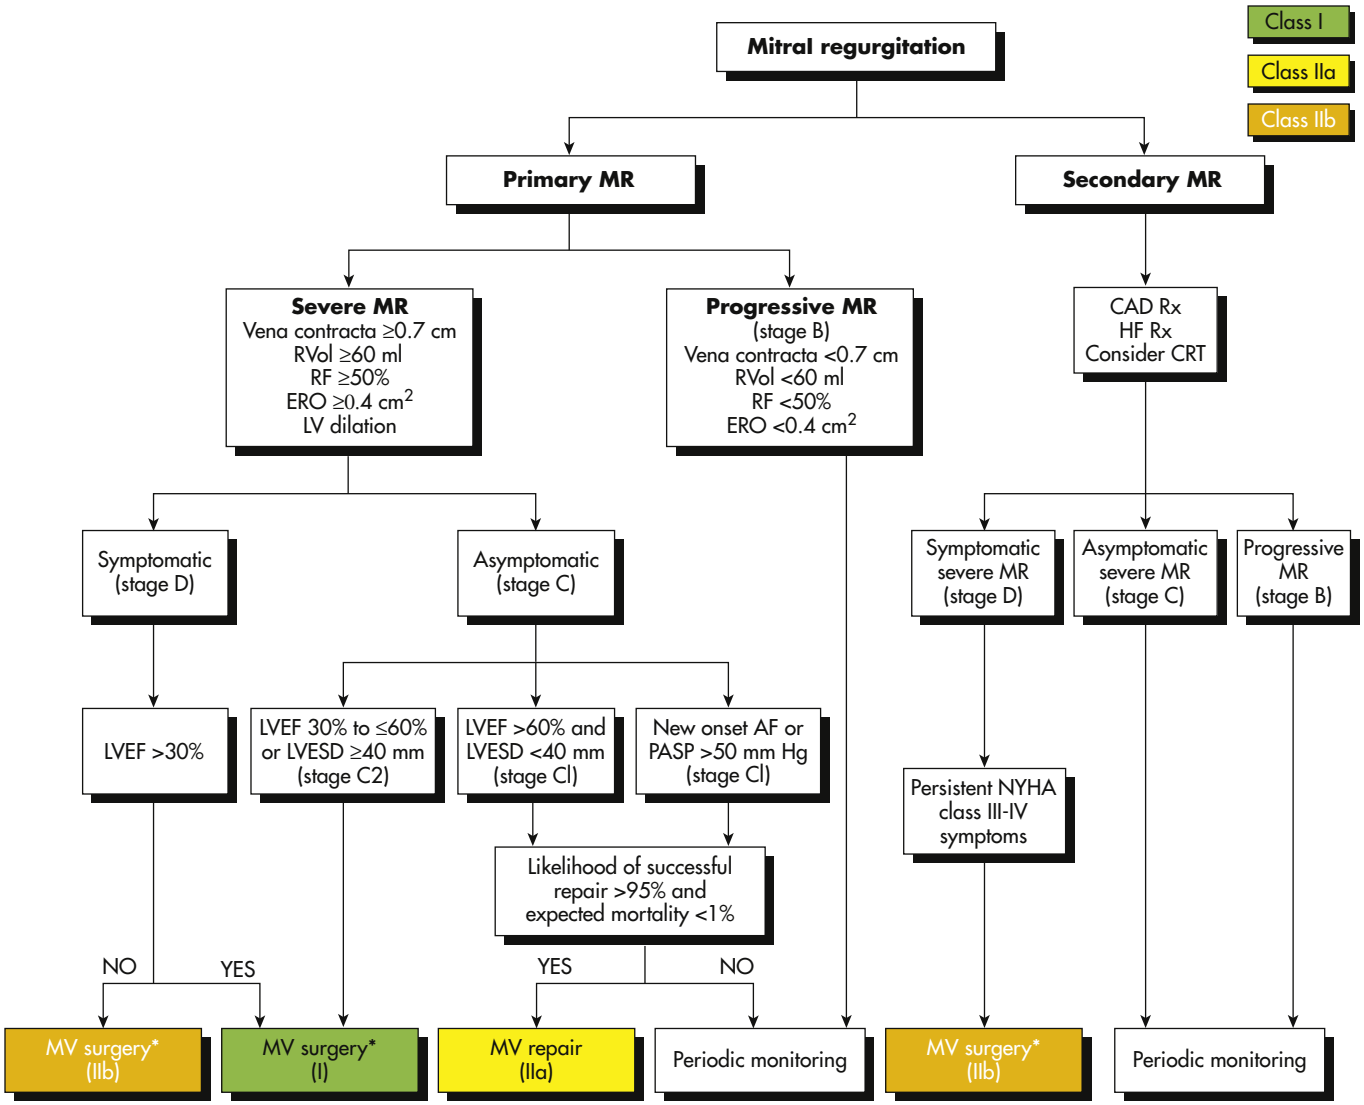

FIG. 2 Indications for surgery for MR. *Mitral valve repair is preferred over MVR when possible. *AF,* Atrial fibrillation; *CAD,* coronary artery disease; *CRT,* cardiac resynchronization therapy; *ERO,* effective regurgitant orifice; *HF,* heart failure; *LV,* left ventricle; *LVEF,* left ventricular ejection fraction; *LVESD,* left ventricle end-systolic dimension; *MR,* mitral regurgitation; *MV,* mitral valve; *MVR,* mitral valve replacement; *NYHA,* New York Heart Association; *PASP,* pulmonary artery systolic pressure; *RF,* regurgitant fraction; *RVol,* regurgitant volume; *Rx,* therapy. (From Nishimura RA et al: ACC/AHA focused update of valvular heart disease guideline, *J Am Coll Cardiol* 70:254-289, 2017.)

within 6 to 10 yr. However surgery should be advised well before the onset of symptoms in case of worsening LVEF and LV systolic dimensions and presence of pulmonary hypertension or atrial fibrillation, all of which are poor prognostic signs.

REFERRAL

- Surgical referral in selected patients (see "Acute General Rx"). Emergency surgery is usually necessary in patients with acute MR caused by ruptured papillary muscle or chordae tendineae after myocardial infarction.
- Mitral valve repair can also be accomplished with percutaneous implantation of a MitraClip device in patients who are too high risk for surgery, although exact indications for this procedure are still evolving.

PEARLS & CONSIDERATIONS

COMMENTS

- Although vasodilators and other agents should be used to treat hypertension in patients with severe MR, there is no evidence that they will delay the need for eventual valve surgery, which is the definitive treatment for severe MR.
- In 2007, the AHA guidelines for prevention of infectious endocarditis were revised and routine antibiotic prophylaxis to undergo dental or other invasive procedures is no longer recommended, unless the patient has had prior endocarditis.

Mitral Regurgitation (Patient Information)

AUTHORS: **Maad M. Alhudiary, MD, MAS,** and **Uyen T. Lam, MD**

TABLE 4 Updated ACC/AHA Guidelines for Intervention for Chronic Primary Mitral Regurgitation (MR)[1]

Class	Indication	LOE
I	MV surgery for symptomatic patients with severe primary MR (stage D) and LVEF greater than 30%.	B
	MV surgery for asymptomatic patients with severe primary MR and LV dysfunction (LVEF 30% to 60% and/or LVESD ≥40 mm, stage C2).	B
	MV repair in preference to MVR when surgical treatment for patients with severe primary MR limited to the posterior leaflet.	B
	MV repair in preference to MVR when surgical treatment for patients with severe primary MR involving the anterior leaflet or both leaflets when a successful and durable repair can be accomplished.	B
	Concomitant MV repair or replacement in patients with severe primary MR undergoing cardiac surgery for other indications.	B
IIa	MV repair is reasonable in asymptomatic patients with severe primary MR (stage C1) with preserved LV function (LVEF >60% and LVESD <40 mm) in whom the likelihood of a successful and durable repair without residual MR is greater than 95% with an expected mortality less than 1% when performed at a Heart Valve Center of Excellence.	B
	MV surgery is reasonable for asymptomatic patients with severe primary MR and preserved LV function (LVEF >60% and LVESD <40 mm) with a progressive increase in LV size or decrease in LVEF on serial imaging studies. *(New 2017)*	C
	MV repair is reasonable for asymptomatic patients with severe nonrheumatic primary MR (stage C1) and preserved LV function in whom there is a high likelihood of a successful and durable repair with (1) new onset of AF or (2) resting pulmonary hypertension (PA systolic pressure >50 mm Hg).	B
	Concomitant MV repair is reasonable in patients with moderate primary MR (stage B) undergoing cardiac surgery for other indications.	C
IIb	MV surgery may be considered in symptomatic patients with severe primary MR and LVEF of 30% or less (stage D).	C
	Transcatheter MV repair may be considered for severely symptomatic patients (NYHA class III/IV) with severe primary MR (stage D) who have a reasonable life expectancy, but a prohibitive surgical risk because of severe comorbidities.	B
III	MVR should not be performed for the treatment of isolated severe primary MR limited to less than one half of the posterior leaflet unless MV repair has been attempted and was unsuccessful.	B

BASIC INFORMATION

DEFINITION

Mitral stenosis is a narrowing of the mitral valve orifice that prevents proper opening during diastole and obstruction of blood flow from the left atrium to the left ventricle. Due to thickening of the leaflets there is restricted movement. The obstruction leads to increased pressure in the left atrium, pulmonary vasculature, and the right side of the heart. The cross section of a normal orifice measures 4 to 6 cm^2. Symptoms usually develop with exercise when the orifice measures <2.5 cm^2, and symptoms may develop at rest when the orifice is <1.5 cm^2.

SYNONYM

MS

ICD-10CM CODES

I05.0	Rheumatic mitral stenosis
I05.2	Rheumatic mitral stenosis with insufficiency
I34.2	Nonrheumatic mitral (valve) stenosis
Q23.2	Congenital mitral stenosis

EPIDEMIOLOGY & DEMOGRAPHICS

- The predominant cause of mitral stenosis is rheumatic heart disease; however, the occurrence of mitral valve stenosis has decreased worldwide over the past 30 yr (particularly in developed countries) as a result of declining incidence of rheumatic fever due to appropriate antibiotic use.
- Rheumatic heart disease has a predilection for the mitral valve, aortic valve, and to some extent the tricuspid valve.
- The incidence of MS is higher in women (2:1 female-to-male ratio).
- There is high prevalence of rheumatic heart disease in developing countries.
- Outbreaks of rheumatic fever in the U.S. are due to increased virulence of a streptococcal strain or enhanced immigration from where rheumatic heart disease is prevalent.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Dyspnea is the most common symptom, along with fatigue and decreased exercise capacity. These symptoms occur due to an inability to increase cardiac output, especially with exercise, and elevated pulmonary capillary wedge pressures, with resultant increase in pulmonary artery pressures. Stages of mitral stenosis are summarized in Table 1.
- "Mitral facies" which are pinkish-purple patches on the cheek due to low cardiac output and vasoconstriction, usually indicate severe MS.
- Paroxysmal nocturnal dyspnea (PND) and orthopnea secondary to elevated left atrial pressure may occur.
- Acute pulmonary edema may occur after an increase in flow across the mitral valve secondary to an increase in cardiac output or heart rate (exertion, tachyarrhythmias, fever, anemia, etc.).
- Pulmonary hypertension that results from chronically elevated pulmonary capillary wedge pressures can lead to right ventricular (RV) dysfunction and signs and symptoms of right heart failure (hepatomegaly, pulsatile liver, peripheral edema, ascites).
- The left ventricle is typically "protected" in mitral stenosis and exists in a low-pressure state; however, MS often coexists with mitral regurgitation and occasionally with aortic valve dysfunction, both of which can cause left ventricular dysfunction.
- Hemoptysis can be present secondary to rupture of thin-walled dilated bronchial veins due to an abrupt increase in left atrial pressure.
- Systemic embolic events are caused by left atrial thrombi. These are associated with atrial fibrillation 80% of the time, since mitral stenosis leads to left atrial enlargement, which is a predisposing factor for atrial arrhythmias.
- Atrial fibrillation is more prevalent in patients with more severe MS, increasing age, and other valvular abnormalities.
- Chest pain can be caused by RV pressure overload and/or concomitant coronary artery disease in up to 15% of patients.
- Loud first heart sound (S1) caused by delayed valve closure preceded by an opening snap and rapid rising left ventricular (LV) pressure.
- A low-pitched rumbling diastolic murmur is heard best at the apex. The intensity of the murmur is not related to the severity of the stenosis, but the duration is holodiastolic in severe MS.
- An opening snap (OS) caused by tensing of the valve leaflets after the cusps have opened completely. The OS follows S2 by 0.03 to 0.14 sec, and the shorter the S2 to OS interval, the more severe the MS, due to the increasing left atrial pressures.
- Prominent A wave on the pulmonary capillary wedge pressure tracing. This is analogous to the prominent A wave seen in systemic venous pressure tracings with tricuspid stenosis.
- A diastolic thrill may be palpable at the apex, especially with the patient in the left lateral recumbent position.
- A left parasternal heave secondary to RV hypertrophy and pulmonary hypertension.
- An accentuated P2 and/or a soft, early diastolic decrescendo murmur (Graham Steell murmur) caused by pulmonary regurgitation may be present in patients with pulmonary hypertension (not specific for mitral stenosis).
- Hoarseness due to the enlargement of the left atrium compressing the recurrent laryngeal nerve.

TABLE 1 Stages of Mitral Stenosis

Stage	Definition	Valve Anatomy	Valve Hemodynamics	Hemodynamic Consequences	Symptoms
A	**At risk for MS**	Mild valve doming during diastole	Normal transmitral flow velocity	None	None
B	**Progressive MS**	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA >1.5 cm^2	Increased transmitral flow velocities MVA >1.5 cm^2 Diastolic pressure half-time <150 msec	Mild to moderate LA enlargement Normal pulmonary pressure at rest	None
C	**Asymptomatic severe MS**	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS)	MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS) Diastolic pressure half-time ≥150 msec (Diastolic pressure half-time ≥220 msec with very severe MS)	Severe LA enlargement Elevated PASP >30 mm Hg	None
D	**Symptomatic severe MS**	Rheumatic valve changes with commissural fusion and diastolic doming of the mitral valve leaflets Planimetered MVA ≤1.5 cm^2	MVA ≤1.5 cm^2 (MVA ≤1 cm^2 with very severe MS) Diastolic pressure half-time ≥150 msec (Diastolic pressure half-time ≥220 msec with very severe MS)	Severe LA enlargement Elevated PASP >30 mm Hg	Decreased exercise tolerance Exertional dyspnea

The transmitral mean pressure gradient should be obtained to determine the full hemodynamic effect of the MS and usually is >5 to 10 mm Hg in severe MS; however, because of the variability of the mean pressure gradient with heart rate and forward flow, it has not been included in the criteria for severity.

LA, Left atrium; *MS,* mitral stenosis; *MVA,* mitral valve area; *PASP,* pulmonary artery systolic pressure.

From Mann DL et al: *Braunwald's heart disease,* ed 10, Philadelphia, 2015, Elsevier.

- Straightening of the left heart border seen on chest radiography indicative of left atrial enlargement.
- Fig. 1 shows schematic representations of LV, aortic, and left atrial (LA) pressures, showing normal relationships and alterations with mild and severe MS.

ETIOLOGY

- Rheumatic fever (RF) is the predominant cause of MS. RF causes thickening of the leaflet tips, commissure fusion, and chordal shortening and fusion. This leads to the classic doming of the leaflets in diastole due to fusion of the leaflet tips at the commissures. Rheumatic fever involves the leaflet tips first with progression toward the annulus. This is opposite of mitral annular calcification, which typically starts in the annulus and proceeds out to the leaflet tips, leading to mitral stenosis in severe cases.
- Congenital defect (parachute valve) has the usual two mitral leaflets, but the chordae, instead of diverging to insert into two papillary muscles, converge into one major papillary muscle, which allows little mobility of the leaflets, as in cor triatriatum (heart with three atria), in which there is a thin membrane that obstructs the pulmonary vein flow and simulates mitral stenosis.
- Rare causes are severe mitral annular calcification usually seen in end-stage renal disease patients, endomyocardial fibroelastosis, malignant carcinoid syndrome, systemic lupus erythematosus, Whipple disease, Fabry disease, rheumatoid arthritis, and 3,4-methylenedioxy-methamphetamine (MDMA) use.
- Atrial septal defect in association with rheumatic mitral stenosis is termed Lutembacher syndrome.
- Medications: Ergot alkaloids (methysergide and ergotamine).

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Left atrial myxoma
- Ball valve thrombus
- Other valvular abnormalities (e.g., tricuspid stenosis, mitral regurgitation)
- Atrial septal defect

IMAGING STUDIES

- Echocardiography (Fig. 2):
  1. Two-dimensional echocardiogram can measure valve area by direct planimetry or calculate it by the Doppler pressure half-time method (this may be inaccurate in patients with concomitant diastolic dysfunction, atrial septal defects, or aortic insufficiency, and those who recently have undergone mitral valvuloplasty), or the continuity equation can be used to calculate the valve area. It also can be measured using the proximal isovelocity surface area method. A valve area ≤1.5 cm^2 is consistent with severe MS (and ≤1.0 cm^2 with very severe MS). The transmitral gradient can also be calculated. A mean gradient of >10 mm Hg indicates severe MS, a gradient of 5 to 10 mm Hg is consistent with moderate MS, and 0 to 5 mm Hg is consistent with mild MS or no MS.
  2. M-Mode echocardiography will also show a markedly diminished E-to-F slope of the anterior mitral valve leaflet during diastole. There can be loss of the "A-wave" due to increased left atrial pressure or the

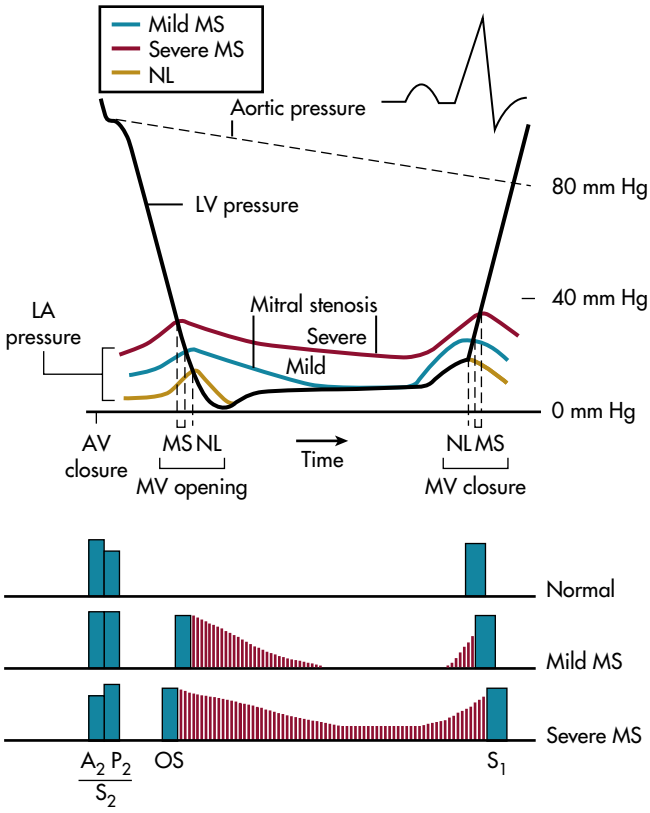

FIG. 1 Schematic representation of left ventricular *(LV)*, aortic, and left atrial *(LA)* pressures, showing normal relationships and alterations with mild and severe mitral stenosis *(MS)*. Corresponding classic auscultatory signs of MS are shown at the bottom. The higher left atrial V wave of severe MS causes earlier pressure crossover and earlier mitral valve *(MV)* opening, leading to a shorter time interval between aortic valve *(AV)* closure and the opening snap *(OS)*. The higher left atrial end-diastolic pressure with severe MS also results in later closure of the mitral valve. With severe MS, the diastolic rumble becomes longer and there is accentuation of the pulmonic component *(P_2)* of the second heart sound *(S_2)* in relation to the aortic component *(A_2)*. *NL*, Normal limits. (From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

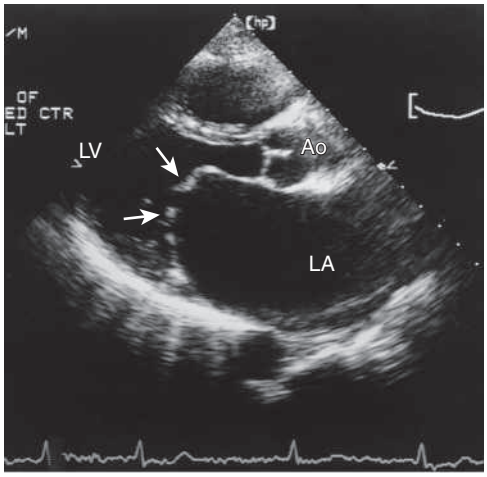

FIG. 2 Mitral stenosis. Parasternal long-axis view of a patient with mitral stenosis and a pliable noncalcified mitral valve leaflet. Note the "doming" motion of the mitral valve leaflets *(arrows)*. Valves with these morphologic features are excellent candidates for percutaneous balloon valvotomy. *Ao,* Aorta; *LA,* left atrium; *LV,* left ventricle. (From Zipes DP et al [eds]: *Braunwald's heart disease,* ed 7, Philadelphia, 2005, WB Saunders.)

presence of associated atrial fibrillation. There is also fusion of the commissures, resulting in "doming" of the leaflets during diastole.

3. Grading of leaflet thickness, mobility, calcification, and subvalvular thickening (Wilkins score) with a score of 0 to 4 for each characteristic can predict hemodynamic results and outcome of balloon mitral valvuloplasty (a low score of less than 8 is favorable for balloon valvuloplasty and a high score is unfavorable). A score above 8 would favor a surgical approach. In addition, mitral regurgitation that is greater than mild would preclude a balloon mitral valvuloplasty procedure.
4. Doppler echocardiography can be used to assess for pulmonary hypertension and to give an estimate of the pulmonary artery systolic pressure at rest and with exercise.
5. Patients with known mitral stenosis: A follow-up echocardiography is recommended to assess for pulmonary artery pressures and valve gradient, and to determine the optimal timing of surgical or percutaneous intervention. According to the 2014 American Heart Association/American College of Cardiology (AHA/ACC) valve guideline, echocardiogram is recommended every yr for very severe MS with mitral valve area <1.0 cm^2, every 1 to 2 yr with severe MS with mitral valve area ≤1.5 cm^2, and every 3 to 5 yr with progressive MS with mitral valve area >1.5 cm^2.

- Chest radiograph:
  1. Straightening of the left cardiac border caused by enlarged left atrium
  2. Left atrial enlargement on lateral chest radiograph
  3. Prominence of pulmonary arteries that indicates pulmonary hypertension
  4. Possible pulmonary congestion and edema (Kerley B lines)
- ECG:
  1. RV hypertrophy; right axis deviation caused by pulmonary hypertension
  2. Left atrial enlargement (broad, biphasic P waves in lead V1 and duration of P-waves >0.11 sec in lead II); this is termed "P-mitrale"
  3. Atrial fibrillation
- Cardiac catheterization:
  1. Allows the measurement of pulmonary artery pressure and transmitral pressure gradients at rest or with exercise (supine biking or raising weights with arms while lying supine).
  2. Allows the measurement of transmitral flow and calculation of the valve area.
  3. Is not routinely recommended for the evaluation of MS but is useful when the echocardiographic findings are nondiagnostic or discrepant with the clinical scenario.
  4. Cardiac catheterization in addition to echocardiography can be used to monitor the hemodynamics during a balloon mitral valvuloplasty procedure.

TABLE 2 Approaches to Mechanical Relief of Mitral Stenosis

Approach	Advantages	Disadvantages
Closed surgical valvotomy	Inexpensive Relatively simple Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible, noncalcified valves Contraindicated with MR grade higher than 2+ Surgical procedure with general anesthesia
Open surgical valvotomy	Visualization of valve allows directed valvotomy. Concurrent annuloplasty for MR is feasible.	Best results with flexible, noncalcified valves Surgical procedure with general anesthesia
Valve replacement	Feasible in all patients regardless of extent of valve calcification or severity of MR	Surgical procedure with general anesthesia Effect of loss of annular-papillary muscle continuity on LV function Prosthetic valve Chronic anticoagulation
Balloon mitral valvotomy	Percutaneous approach Local anesthesia Good hemodynamic results in selected patients Good long-term outcome	No direct visualization of valve Only feasible with flexible noncalcified valves Contraindicated with MR grade higher than 2+

LV, Left ventricular; *MR,* mitral regurgitation.
From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

Decrease level of activity in symptomatic patients, and salt restriction if pulmonary congestion is present.

ACUTE GENERAL Rx

- Medical:
  1. Anticoagulation for the prevention of systemic embolic events in patients with MS and:
     a. Atrial fibrillation: In patients with atrial fibrillation and rheumatic mitral stenosis, anticoagulation with a vitamin K antagonist with a goal international normalized ratio (INR) of 2.5 is indicated. Further study is needed to establish the efficacy of direct oral anticoagulants (DOACs) in this setting
     b. Prior embolic event
     c. Documented left atrial thrombus or left atrial appendage thrombus
  2. Ventricular rate control (to increase diastolic filling period) with beta-blockers, non dihydropyridine calcium channel blockers, or digitalis and aggressive treatment of tachyarrhythmias.
  3. Treat congestive heart failure with loop diuretics and sodium restriction.
  4. Antibiotic prophylaxis to prevent recurrent rheumatic fever is usually not indicated unless presence of high-risk features such as prior endocarditis, prosthetic heart valves, valvulopathy of the transplanted heart, and certain cases of cyanotic congenital heart disease.
  5. Physical activity and exercise. Patients with mild MS in sinus rhythm with a peak pulmonary artery pressure <50 mm Hg can participate in all competitive sports. Patients with moderate MS and in sinus rhythm or atrial fibrillation with a peak pulmonary artery pressure of <50 mm Hg can participate in low to moderate static and dynamic sports. Patients in sinus rhythm with severe MS should not participate in any competitive sports. Patients in atrial fibrillation with any degree of MS and on anticoagulation should avoid all competitive sports.
  6. Pregnancy in females with advanced MS may be poorly tolerated due to the hemodynamic changes such as increased cardiac output occurring in pregnancy. Mild to moderate MS may be tolerated in pregnancy with medical therapy alone.
- Table 2 summarizes approaches to mechanical relief of mitral stenosis.
- Percutaneous mitral balloon commissurotomy (PMBC) is the therapy of choice for symptomatic patients with severe MS (valve area ≤1.5 cm^2) with a favorable valvuloplasty score, minimal or no mitral regurgitation, and no left atrial thrombus. PMBC is reasonable for asymptomatic patients with very severe MS (mitral valve area ≤1.0 cm^2) and favorable valve morphology in the absence of left atrial thrombus or moderate to severe MR (class IIa indication). PMBC is also considered the procedure of choice in pregnant women with rheumatic MS and in New York Heart Association (NYHA) class III to IV heart failure and/or unresponsive to adequate medical treatment. In addition, it may be considered for severely symptomatic (NYHA class III/IV) patients with very severe MS (mitral valve area ≤1.5 cm^2) who are not candidates for surgery or are at high risk for surgery, even if they have suboptimal valve anatomy (class IIb indication). Regular follow-up is needed

TABLE 3 ACC/AHA Guidelines for Intervention for Mitral Stenosis (MS)[1]

Class	Indication	LOE
I	PMBC for symptomatic patients with severe MS (MVA ≤1.5 cm^2, stage D) and favorable valve morphology in the absence of contraindications.	A
	Mitral valve surgery in severely symptomatic patients (NYHA Class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) who are not high risk for surgery and who are not candidates for or failed previous PMBC.	B
	Concomitant mitral valve surgery for patients with severe MS (MVA ≤1.5 cm^2, stages C or D) undergoing other cardiac surgery.	C
IIa	PMBC is reasonable for asymptomatic patients with very severe MS (MVA ≤1 cm^2, stage C) and favorable valve morphology in the absence of contraindications.	C
	Mitral valve surgery is reasonable for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) provided there are other operative indications.	C
IIb	PMBC may be considered for asymptomatic patients with severe MS (MVA ≤1.5 cm^2, stage C) and favorable valve morphology who have new onset of AF in the absence of contraindications.	C
	PMBC may be considered for symptomatic patients with MVA greater than 1.5 cm^2 if there is evidence of hemodynamically significant MS during exercise.	C
	PMBC may be considered for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA ≤1.5 cm^2, stage D) who have suboptimal valve anatomy and are not candidates for surgery or at high risk for surgery.	C
	Concomitant mitral valve surgery may be considered for patients with moderate MS (MVA, 1.6 to 2.0 cm^2) undergoing other cardiac surgery.	C
	Mitral valve surgery and excision of the left atrial appendage may be considered for patients with severe MS (MVA ≤1.5 cm^2, stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation.	C

[1]Nishimura R et al: 2013 AHA/ACCF guideline for valvular heart disease: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 63:e57-e185, 2014.

New York Heart Association (NYHA) *LOE,* level of evidence; *MVA,* mitral valve area; *NYHA,* New York Heart Association; *PMBC,* percutaneous mitral balloon commissurotomy.

From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

after PMBC because restenosis may reoccur. Repeat intervention can be performed as long as valve anatomy remains favorable; however, there is usually more fibrosis and deformation of the valve with subsequent procedures. The approximate frequency of repeat intervention is 10% at 7 yr.

- Mitral valve surgery is indicated for patients with moderate to severe symptomatic MS when PMBC is not available or is contraindicated (valvuloplasty score greater than or equal to 8) or the valve is calcified, when MR is more than mild, when left atrial thrombus is present, and when the surgical risk is acceptable. The surgical approaches include closed mitral valvotomy, open valvotomy and repair (preferred), and mitral valve replacement when repair is not possible.
- Table 3 summarizes guidelines for intervention for mitral stenosis.

DISPOSITION

- Prognosis is generally good except in patients with chronic pulmonary hypertension.
- Operative mortality rates for mitral valve replacement are 1% to 5% at most institutions.

BASIC INFORMATION

DEFINITION

Mitral valve prolapse (MVP) is the bulging of one or both of the mitral valve leaflets ≥2 mm above the annular plane into the left atrium during systole. MVP syndrome refers to a constellation of MVP and associated symptoms (e.g., autonomic dysfunction, palpitations) or other physical abnormalities (e.g., pectus excavatum). Table 1 describes a classification of mitral valve prolapse.

SYNONYMS

MVP
Mitral click murmur syndrome
Barlow syndrome

ICD-10CM CODES
I34.1 Nonrheumatic mitral (valve) prolapse
I34.0 Nonrheumatic mitral (valve) insufficiency

EPIDEMIOLOGY & DEMOGRAPHICS

- MVP can be found by echocardiogram in 1% to 2.4% of the general population, with some studies suggesting that it is more common in women than in men.
- Increased incidence is seen with autoimmune thyroid disorders, Ehlers-Danlos syndrome, Marfan syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, pectus excavatum, anorexia nervosa, and bulimia.
- Compared to men, women with MVP have less posterior prolapse (22% vs. 31%), less flail (2% vs. 8%), more leaflet thickening (32% vs. 28%), and less frequent severe mitral regurgitation (MR) (10% vs. 23%).

TABLE 1 Classification of Mitral Valve Prolapse

Mitral Valve Prolapse Syndrome
Younger age (20-50 yr)
Predominantly female
Click or click-murmur on physical examination
Thin leaflets with systolic displacement on echocardiography
Associated with low blood pressure, orthostatic hypotension, palpitations
Benign long-term course
Myxomatous Mitral Valve Disease
Older age (40-70 yr)
Predominantly male
Thickened, redundant valve leaflets
Mitral regurgitation on physical exam and echocardiography
High likelihood of progressive disease requiring mitral valve surgery
Secondary Mitral Valve Prolapse
Marfan syndrome
Hypertrophic cardiomyopathy
Ehlers-Danlos syndrome
Other connective tissue diseases

Modified from Otto CM: *Valvular heart disease,* ed 2, Philadelphia, 2004, WB Saunders, p. 369.

- Although MVP is more common in women than men, men more often develop severe regurgitation requiring surgical intervention.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The most common auscultatory finding in cardiac examination is a nonejection mid to late systolic click, heard best at the apex. It is caused by degeneration of the valve resulting in an abnormal ratio between the length of the mitral apparatus and left ventricle (LV) during contraction. When the valve prolapses, it gets caught by the subvalvular structures, causing an abrupt halt that creates the click.
- If regurgitation is present, a crescendo mid to late systolic murmur may be heard that worsens with standing and Valsalva maneuver.
- Timing of click within the cardiac cycle varies with loading conditions within the left ventricle (i.e., may occur earlier with standing or Valsalva and later with squatting or expiration).
- May be associated with small anteroposterior chest diameter, scoliosis, pectus excavatum, or low BMI.
- Most patients with MVP are asymptomatic; symptoms if present consist primarily of chest pain, palpitations, fatigue, dyspnea, and anxiety.
- Neurologic abnormalities (e.g., transient ischemic attack [TIA] or stroke) are rare.
- A spectrum of arrhythmias, mainly paroxysmal supraventricular tachycardia and atrial and ventricular premature beats, etc. is also observed with mitral valve prolapse. There is also an increased association with Wolff-Parkinson-White syndrome and QT prolongation.

ETIOLOGY

- Myxomatous degeneration of connective tissue within mitral valve, usually involving multiple leaflet segments (e.g., Barlow disease). In contrast, fibroelastic deficiency of single leaflet segment develops in elderly patients.
- Congenital deformity of mitral valve and supportive structures.
- Secondary to other disorders of connective tissue such as Ehlers-Danlos, Marfan, or pseudoxanthoma elasticum; association with other connective tissue disorders suggests MVP result of defective embryogenesis in cells of mesenchymal origin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other valvular abnormalities (especially mitral regurgitation [MR])
- Anxiety or panic disorders
- Pulmonary embolism
- Atypical chest pain

WORKUP

- Medical history and physical examination, with increased suspicion in patients with other findings of connective tissue disorder.
- Two- or three-dimensional echocardiography in patients with a systolic click or murmur on careful auscultation.
- Cardiac MRI is an emerging tool for the evaluation and diagnosis of MVP but has not yet been independently validated. However, MRI should be considered because it may be helpful in accurately quantifying the amount of mitral regurgitation when present. ECG is most often normal but may show nonspecific ST-T wave changes, prolonged QT interval, prominent Q waves, or early repolarization with J-point elevation in young patients.

IMAGING STUDIES

Echocardiography (Fig. 1) shows one or more leaflets prolapsing >2 mm into the left atrium during systole in a long axis view. Mitral leaflets may be thickened (>5 mm) with myxomatous degeneration. MR is typically present but may only occur during late systole or with exertion. If moderate or severe MR is present findings of dilated left atrium, LV dilation and/or dysfunction, and elevated estimated RV systolic pressures may also be present. There is an increased incidence of secundum-type atrial septal defects (ASDs) in patients with MVP, which may also be identified with echocardiography.

TREATMENT

NONPHARMACOLOGIC THERAPY

Avoidance of stimulants (e.g., caffeine, nicotine) in patients with palpitations. Sometimes

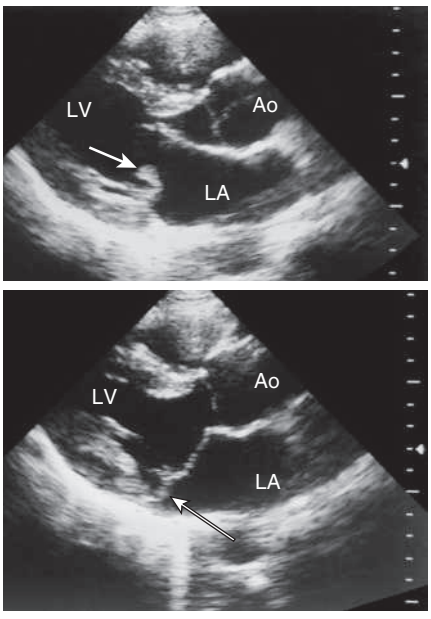

FIG. 1 Mitral valve prolapse. Parasternal long-axis view in diastole *(top)* and systole *(bottom)* in a patient with mitral valve prolapse and myxomatous changes. In the *upper panel,* note the open mitral valve and the diffuse thickening of the posterior mitral valve leaflet *(arrow).* The *lower panel* was recorded in systole. Note that both leaflets prolapse behind the plane of the mitral valve annulus. The prolapse of the posterior leaflet is somewhat more prominent *(arrow). TABLE 2 Predictors of Clinical Outcome in Mitral Valve Prolapse

Predictor	Survival	Valve Surgery	Arrhythmias or Sudden Death	Endocarditis
Age	+++	+++	–	–
Gender	++	++	–	–
Leaflet thickness or redundancy	+++	+++	++++	++++
Severity of mitral regurgitation	++++	++++	++++	++++
Systolic click	+	–	–	–
Left ventricular dilation	+	++++	++	–
Left atrial dilation	–	++	+	–

Symbols indicate the relative predictive value of each variable for the listed clinical outcomes on a scale of no predictive value (–) to strongly predictive (++++).
From Bonow RO et al: *Braunwald's heart disease: a textbook of cardiovascular medicine,* Philadelphia, 2012, WB Saunders.

reassurance is sufficient to reduce the severity of symptoms in many patients.

ACUTE GENERAL Rx

β-blockers may be used in symptomatic patients (e.g., palpitations, chest pain) to decrease the heart rate and contractility, thus potentially decreasing the stretch on the prolapsing valve leaflets.

CHRONIC Rx

Monitoring for complications:

- Mitral regurgitation (most common complication); on rare occasion may occur acutely due to rupture of chordae tendineae.
- Routine echocardiographic monitoring is indicated at the following intervals with patients with evidence of mitral regurgitation:
  1. Stage B with mild regurgitation: Every 3 to 5 yr.
  2. Stage B with moderate regurgitation: Every 1 to 2 yr.
  3. Stage C1 (asymptomatic severe MR without LV dysfunction): Every 6 to 12 mo.
- Bacterial endocarditis (risk is three to eight times that of the general population); higher risk in patients with concomitant regurgitation. However, routine antibiotic prophylaxis is not recommended.
- TIA or stroke caused by embolic phenomena (from fibrin and platelet thrombi) in patients with thickened leaflets; risk in young patients is <0.05% per yr. If present, aspirin (75 to 325 mg) is indicated for secondary prevention.
- Cardiac arrhythmias with the vast majority being supraventricular and benign.
- Sudden death (rare); most often associated with acute flail leaflets or caused by ventricular arrhythmias associated with other structural heart disease.
- The incidence of complications of MVP is very low (<1% per yr). Mitral leaflet thickness is ≤0.5 mm, young patients <45 yr, and in the absence of mitral systolic murmur or MR on Doppler echocardiography. Table 2 lists variables that are predictors of favorable clinical outcome in mitral valve prolapse.
- Risk factors that predict higher risk of complications are presence of moderate to severe MR, LV ejection fraction <50%, LA dimension >40 mm, age >50 yr.

SURGICAL REFERRAL

Surgical referral may be necessary in patients who develop progressive MR with surgical indications as per guidelines for valvular heart disease (see topic on mitral regurgitation).

PEARLS & CONSIDERATIONS

COMMENTS

- Recent studies suggest that the prevalence of MVP and its propensity to cause symptoms and serious complications have been overestimated in the past.
- The relationship between MVP syndrome and sudden cardiac death is unclear. The best evidence suggests that there is only a slight risk in subsets of patients with MVP who have severe MR, severe valvular deformity, complex ventricular arrhythmias, QT prolongation, and a history of syncope.
- Asymptomatic patients with MVP and mild or no MR can be evaluated clinically every 3 to 5 yr. High-risk patients (those with symptoms, arrhythmias, or significant regurgitation) should undergo a follow-up examination once a year.
- In 2007, the AHA guidelines for prevention of infectious endocarditis were revised and prophylactic antibiotics are no longer recommended for patients with MVP without previous endocarditis.

Mixed Connective Tissue Disease

BASIC INFORMATION

DEFINITION

An overlap syndrome with clinical features of systemic lupus erythematosus (SLE), inflammatory myositis, and systemic sclerosis (SSc), requiring a high titer of anti U1-ribonucleoprotein (RNP) antibodies, especially to the 68- to 70-kDa epitope. Raynaud phenomenon is present in almost all mixed connective tissue disorder (MCTD) patients.

SYNONYMS

MCTD
Overlap syndrome
Sharp syndrome

ICD-10CM CODES

M35.1 Other overlap syndrome
M35.9 Systemic involvement of connective tissue, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Rare, with little data. From a 2011 Norwegian study, 3.8 per 100,000 adults.
PREDOMINANT SEX: Female predominant, ranging from 3:1 to 15:1
PREDOMINANT AGE: Average age at onset is 37 yr, with range between 40 and 80 yr

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- **General:** Malaise, fatigue, low-grade fever.
- **Joints:** Arthralgias are an early symptom, often more severe than with classic lupus. 60% develop arthritis, including Jaccoud arthropathy. Erosions are less common.
- **Skin and mucosa:** Often the presenting feature. Raynaud phenomenon is present in 90%. Swollen hands and puffy fingers are characteristic (Fig. E1). May also see malar rash, discoid plaques, orogenital or buccal ulcerations, nasal septal perforation, sicca complex, sclerodermatous change, and abnormal nail fold capillaries.
- **Muscle:** Myalgias are common. Most patients have no demonstrable weakness, although persistent inflammatory myopathy can occur (similar to polymyositis).
- **Lung:** 75% have lung involvement, although most are asymptomatic. Manifestations may include pleural effusions, pleuritic pain, pulmonary artery hypertension (PAH), interstitial lung disease, thromboembolic disease, alveolar hemorrhage, diaphragmatic dysfunction, aspiration pneumonitis, obstructive airway disease, pulmonary infections, and pulmonary vasculitis. Need screening echocardiograph to evaluate for PAH.
- **Heart:** All three layers of the heart may be involved. Up to 20% of patients have an abnormal ECG with hemiblock, bundle branch block, and atrioventricular block. Echocardiogram findings include pericardial effusions and mitral valve prolapse. The most common cardiac clinic manifestation is pericarditis. Patients are at risk of accelerated atherosclerosis.
- **Hematopoietic:** Anemia of chronic disease, leukopenia (usually lymphopenia), hypergammaglobulinemia, Coombs positivity, thrombocytopenia.
- **Gastrointestinal tract:** Similar to those of SSc, with disordered motility, mostly esophageal dysfunction. Less commonly seen: Intestinal vasculitis, pancreatitis, autoimmune hepatitis, primary biliary cirrhosis, portal hypertension, and ascites.
- **Kidney:** Absence of renal involvement is characteristic but may have membranous nephropathy or nephrotic range proteinuria.
- **Nervous system:** Trigeminal neuropathy, headache, aseptic meningitis, sensorineural hearing loss. Rare to have severe central nervous system disease.

ETIOLOGY

Autoimmune disorder

FIG. E1 Sausage-shaped fingers in a patient with mixed connective tissue disease. An identical appearance may be found in patients with early scleroderma and eosinophilic fasciitis. (From Hochberg MC et al: *Rheumatology,* ed 5, St Louis, 2011, Mosby.)

TABLE E1 Diagnostic Criteria by Alarcon-Segovia and Kahn

Alarcon-Segovia Criteria	Kahn Criteria
Serologic Criteria	
Anti-RNP at hemagglutination titer of ≥1:1600	High-titer anti-RNP corresponding to a speckled ANA of ≥1:1200 titer
Clinical Criteria	
1. Swollen hands	1. Swollen fingers
2. Synovitis	2. Synovitis
3. Myositis	3. Myositis
4. Raynaud phenomenon	4. Raynaud phenomenon
5. Acrosclerosis	
MCTD is present if:	
Serologic criteria + ≥3 clinical criteria (must include synovitis or myositis)	Serologic criteria + Raynaud + ≥2 of other 3 clinical criteria

ANA, Antinuclear antigen; *MCTD,* mixed connective tissue disease; *RNP,* ribonucleoprotein.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other connective tissue disorders (SLE, SSc, rheumatoid arthritis [RA], myositis), infection, malignancy

WORKUP

- Table E1 summarizes diagnostic criteria.
- Alarcon-Segovia: Serologic criterion accompanied by ≥3 clinical criteria, one of which must be synovitis or myositis (sensitivity 63%, specificity 86%).
- Kahn: Serologic criterion accompanied by Raynaud phenomenon and at least two out of three remaining clinical criteria.
- Once diagnosis is made, must screen for PAH.

LABORATORY TESTS

- Positive antinuclear antibody (ANA), speckled, often high titer (>1:1280).
- High titer of U1-RNP antibodies, especially to the 68- to 70-kDa antigen.
- SLE-specific and SSc-specific autoantibodies are generally absent (possible overlap).
- Rheumatoid factor and anti-CCP are positive in 50% to 70% of patients.
- Antiphospholipid antibodies may be associated with pulmonary hypertension.

TREATMENT

- Generally therapy is targeted to the specific features present.
- Arthralgias, arthritis, fatigue, myalgias, pleurisy may respond to NSAIDs, antimalarials, and low-dose corticosteroids (<20 mg/day).

- Inflammatory myositis is treated with high doses of prednisone (60 mg/day).
- Methotrexate, cyclophosphamide, azathioprine, mycophenolate may be considered.
- Intravenous immunoglobulin (IVIG) can be used for steroid-resistant myositis or severe skin disease.
- Rituximab can be considered for steroid-resistant thrombocytopenia or autoimmune hemolytic anemia.
- For Raynaud phenomenon, keeping warm, avoiding beta-blockers, and smoking cessation are important. Can use dihydropyridine calcium channel blocker, if necessary.
- Most require acid-lowering therapies (proton pump inhibitors, antacids).
- For PAH and/or lung disease, therapy may include steroids, cyclophosphamide, low-dose aspirin. May also require anticoagulation, angiotensin-converting-enzyme inhibitors, endothelin receptor antagonist, IV prostacyclin, cyclic GMP phosphodiesterase type 5 inhibitors (sildenafil and tadalafil). Lung transplant may be necessary when severe.

DISPOSITION

- Patients with high titers of U1-RNP antibodies have low prevalence of serious renal disease and life-threatening neurologic disorders.
- Disease-related mortality is usually related to PAH and cardiac sequelae.

REFERRAL

Rheumatology consultation

PEARLS & CONSIDERATIONS

COMMENTS

Pulmonary arterial hypertension is definitively diagnosed by cardiac catheterization and is the main disease-related cause of death. Early detection of PAH and aggressive treatment may improve prognosis.

Molar Pregnancy ALG

BASIC INFORMATION

DEFINITION

Molar pregnancy (hydatidiform mole) is a premalignant gestational disorder and is included in the spectrum of disorders characterized as gestational trophoblastic disease. Molar pregnancies are classified as complete or partial based on morphologic and pathologic examination. Both complete and partial molar pregnancies have an abnormal placenta with enlargement and swelling of the chorionic villi and hyperplasia of the villous trophoblastic cells. Most molar pregnancies are complete and are characterized by generalized hydropic villous changes with no fetal tissue. Partial moles are characterized by a mixture of large hydropic villi and normal placental tissue and often have fetal tissue present. Gestational trophoblastic disease (GTD) is composed of a spectrum of neoplastic conditions derived from the placenta. Whereas hydatidiform moles, gestational choriocarcinoma, and placental site trophoblastic tumor (PSTT) are histologic diagnoses, postmolar gestational trophoblastic neoplasia (GTN) is defined by clinical and laboratory criteria. The disease entities included in GTD have a wide variation in behavior, but GTN specifically refers to those with the potential for tissue invasion and metastases.

The risk of malignant sequelae (gestational trophoblastic neoplasia) for a complete mole is 6% to 32% and for a partial mole is less than 5%.

SYNONYM

Hydatidiform mole

ICD-10CM CODES	
O01.0	Classical hydatidiform mole
O01.1	Incomplete and partial hydatidiform mole
O01.9	Hydatidiform mole, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 1/1500 pregnancies in the U.S.
PREDOMINANT SEX & AGE: Females of reproductive age, highest rates at extremes of reproductive ages
RISK FACTORS:

- Extremes of reproductive age (<21 and >40 yr)
- Previous molar pregnancy
- History of spontaneous abortion
- Use of combined oral contraceptives

PHYSICAL FINDINGS & CLINICAL PRESENTATION (TABLE E1)

Complete molar pregnancy:

- 80% to 90% present with vaginal bleeding at 6 to 16 wk gestational age
- 28% with uterine enlargement greater than expected for gestational age
- 8% with hyperemesis gravidarum
- 1% with pregnancy-induced hypertension in the first or second trimester
- 15% to 25% with bilateral theca lutein cysts
- 15% will have a beta hCG >100,000 mIU/ml
- <10% with anemia

Partial molar pregnancy:

- 90% present with an incomplete or missed abortion
- 75% present with vaginal bleeding
- <10% will have a beta hCG of >100,000 mIU/ml

ETIOLOGY

Complete molar pregnancy:

- Fertilization of an oocyte with absent or inactive maternal chromosomes (Fig. E1) and duplication of paternal chromosomes (85% to 90% are 46, XX) or fertilization of an empty oocyte with 2 sperm (46, XY or XX).
- Diffuse villous enlargement and trophoblastic proliferation (Fig. E2) with no development of a fetus.

Partial molar pregnancy:

- Fertilization of a normal oocyte with two sperm (usually 69, XXY or 69, XXX)
- Focal villous edema and trophoblastic proliferation with identifiable fetus

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Complete mole, partial mole (Table E2), ectopic pregnancy, abortion (incomplete or spontaneous), normal intrauterine pregnancy

WORKUP

- Pelvic exam to evaluate for uterine size and bleeding
- Blood pressure to assess for gestational hypertension or preeclampsia (systolic blood pressure >140 or diastolic blood pressure >90)
- Fig. E3 describes an algorithm for the diagnosis and management of molar pregnancy

LABORATORY TESTS

- Quantitative beta human chorionic growth hormone (beta hCG); significantly elevated levels >100,000 will raise suspicion for molar pregnancy
- Complete blood count (CBC) to assess for acute anemia from vaginal bleeding
- Comprehensive metabolic panel to evaluate for renal or liver disease
- Thyroid stimulating hormone to evaluate for hyperthyroidism
- Urinalysis for proteinuria to evaluate for preeclampsia
- Type and screen to evaluate Rh status and to prepare for surgery

IMAGING STUDIES

- Pelvic ultrasound (Figs. E4 and E5):
  1. Complete moles in the first trimester will demonstrate a complex, echogenic, intrauterine mass containing many small cystic spaces that are secondary to swollen chorionic villi and no identifiable fetus. This is the classic "snowstorm" appearance (Fig. E6).
  2. Partial mole will show a thickened, hydropic placenta with fetal parts.
  3. Baseline chest x-ray to use for comparison if malignant trophoblastic disease develops.
- Magnetic resonance image (Fig. E7)

TREATMENT

NONPHARMACOLOGIC THERAPY

Surgical uterine evacuation with dilatation and curettage (D&C) is the mainstay of management of a molar pregnancy, either partial or complete. Tables E3 and E4 summarize the management of hydatidiform moles.

ACUTE GENERAL Rx

D&C, Rh immune globulin if Rh negative

CHRONIC Rx & DISPOSITION

If pathology results are consistent with complete or partial mole, patients must be followed to evaluate for trophoblastic neoplasia. 15% to 20% of complete moles and 1% to 5% of partial moles can develop into trophoblastic neoplasia. Quantitative beta hCG should be followed weekly until three consecutive results show normal levels. After that, check quantitative beta hCG every month for a total of 6 mo. Patients should remain on reliable contraception during this time to prevent confusion from a rising beta hCG in the case of a new pregnancy.

TABLE E1 Classic Presenting Signs and Symptoms of Complete and Partial Hydatidiform Moles

Sign or Symptom	Complete Mole (%) (*n* = 306)	Partial Mole (%) (*n* = 81)
Vaginal bleeding	97	73
Excessive uterine size	51	4
Theca lutein cysts >6 cm	50	0
Preeclampsia	27	3
Hyperemesis	26	0
Hyperthyroidism	7	0
Trophoblastic emboli	2	0

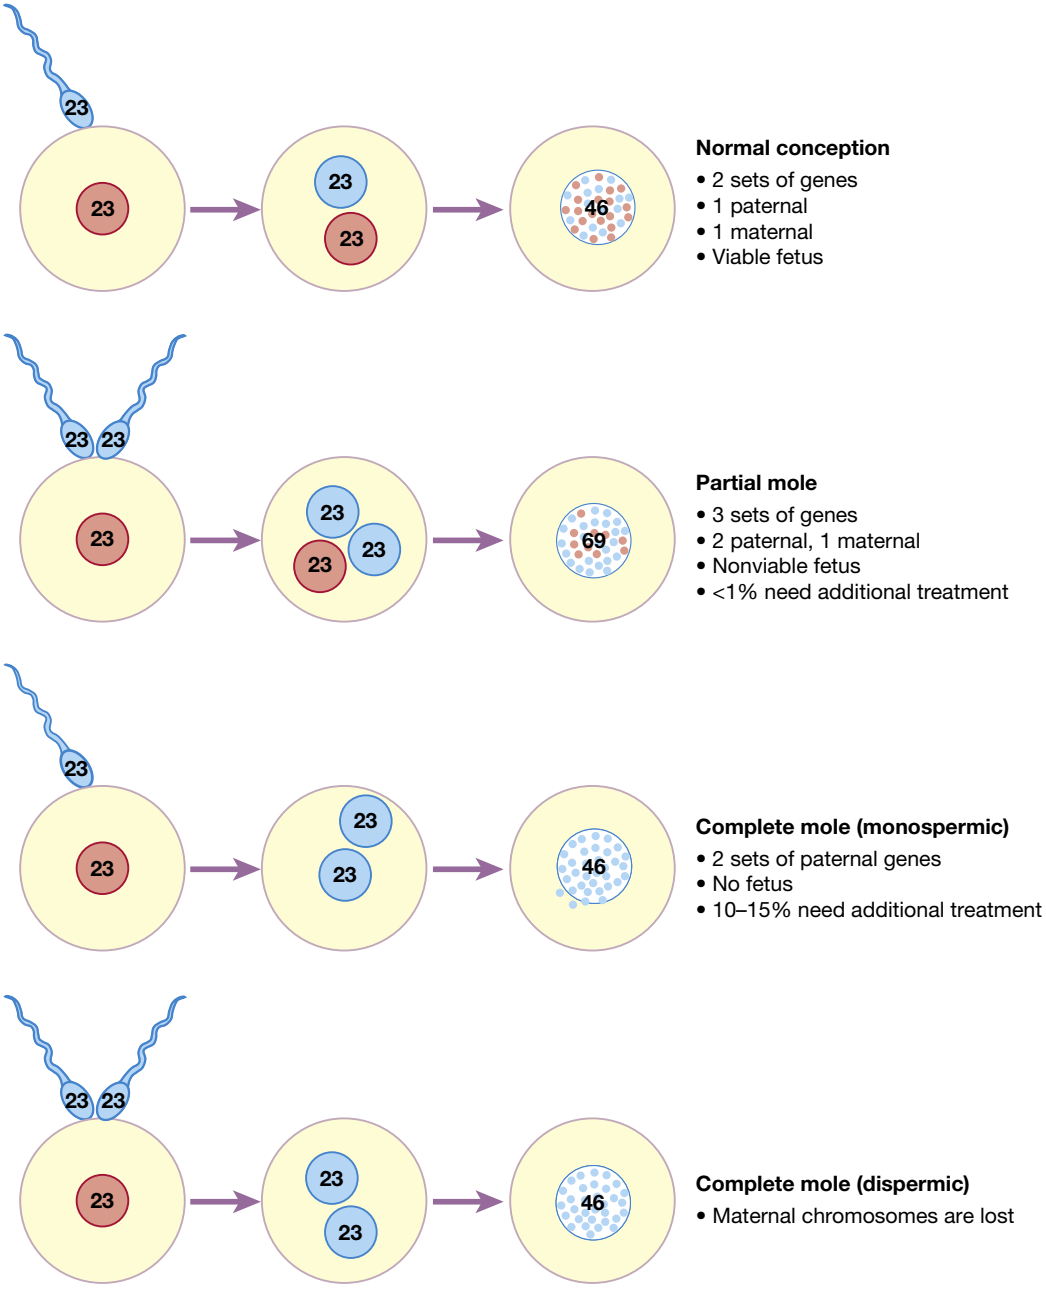

FIG. E1 Genetic makeup of normal pregnancy and partial and complete molar pregnancies. (From Magowan BA: *Clinical obstetrics & gynecology,* ed 4, 2019, Elsevier.)

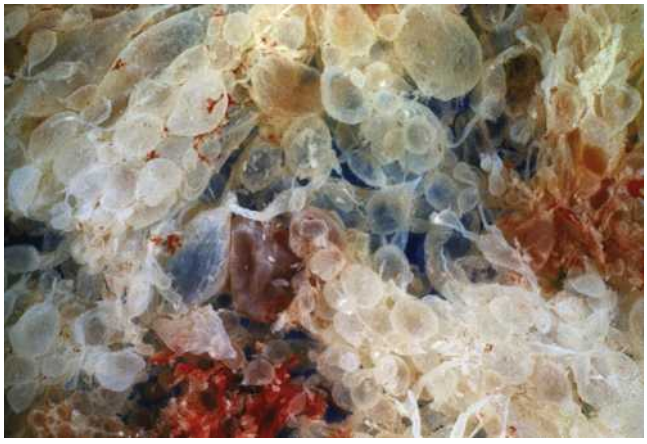

FIG. E2 Complete hydatidiform mole, gross specimen. Note the diffuse hydropic placental villi that make up almost the entire specimen. (Courtesy David Mutch, MD. From Disaia PJ et al: *Clinical gynecologic oncology,* ed 9, Philadelphia, 2017, Elsevier.)

TABLE E2 Features of Partial and Complete Hydatidiform Moles

Feature	Partial Mole	Complete Mole
Karyotype	69, XXX or –, XXY	46, XX or –, XY
Pathology		
Fetus	Often present	Absent
Amnion, fetal RBC	Usually present	Absent
Villous edema	Variable, focal	Diffuse
Clinical Presentation		
Diagnosis	Missed abortion	Molar gestation
Uterine size	Small for dates	50% large for dates
Theca-lutein cysts	Rare	25%-30%
Postmolar GTN	2.5%-7.5%	6.8%-20%

GTN, Gestational trophoblastic neoplasia; *RBC,* red blood cell.
From Disaia PJ et al: *Clinical gynecologic oncology,* ed 9, Philadelphia, 2017, Elsevier.

Specific criteria by beta hCG have been established by International Federation of Gynecology and Obstetrics (FIGO) for diagnosis of postmolar gestational trophoblastic disease (see Tables E5, E6, and E7).

REFERRAL

- If there is concern for a molar pregnancy, the patient should be managed by a gynecologist for uterine evacuation and follow-up.
- If there is a plateau or rise of the beta hCG during follow-up, the patient should be referred to a gynecologic oncologist for treatment with either further surgery or prophylactic chemotherapy.

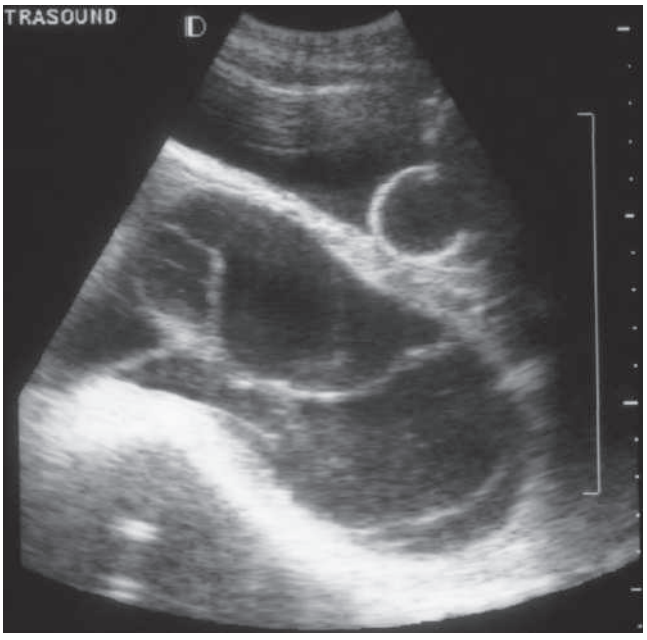

FIG. E5 Ultrasound image demonstrating a large theca-lutein ovarian cyst associated with a complete hydatidiform mole. These usually contain multiple thin septations and have an appearance similar to iatrogenic ovarian hyperstimulation during ovulation induction. Theca-lutein cysts regress spontaneously after evacuation of the molar pregnancy, but regression often lags behind human chorionic gonadotropin level decline. (Courtesy John Soper, MD. From Disaia PJ et al: *Clinical gynecologic oncology,* ed 9, Philadelphia, 2017, Elsevier.)

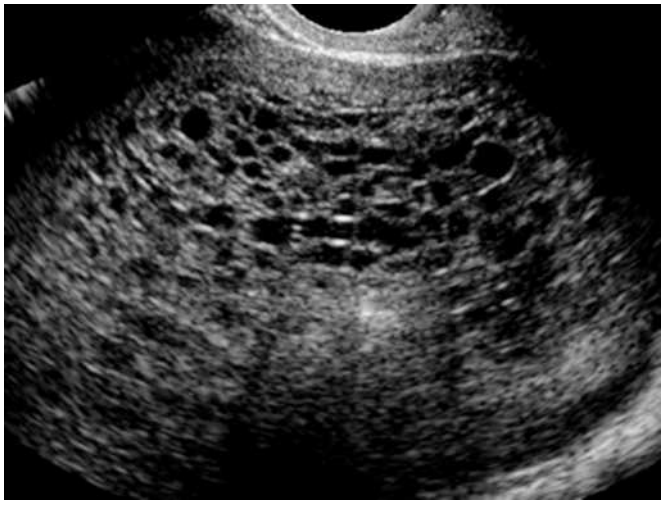

FIG. E6 Complete molar pregnancy: Classic appearance. Transabdominal scan shows a vesicular echogenic mass distending the endometrium. The mass is filled with innumerable uniformly distributed cystic spaces that corresponded to hydropic chorionic villi at pathology. (From Rumack CM et al: *Diagnostic ultrasound,* ed 4, Philadelphia, 2011, Mosby.)

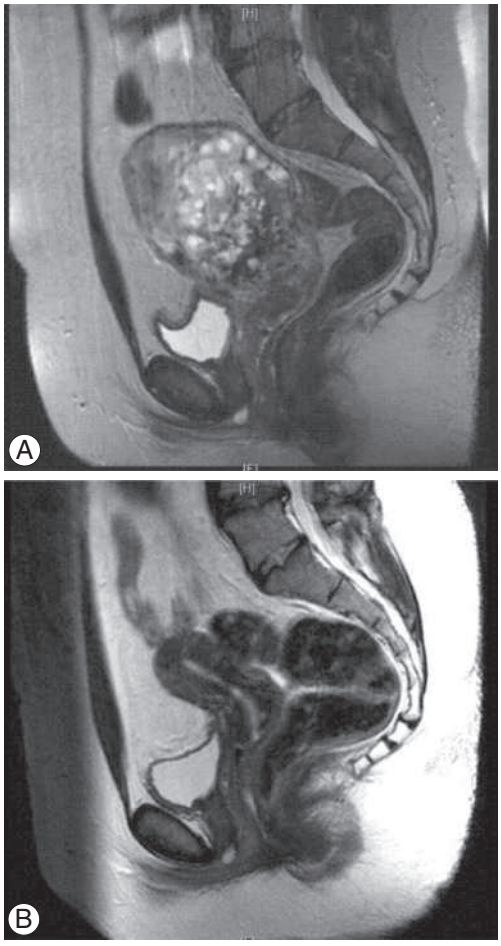

FIG. E7 Invasive complete molar pregnancy. A, Magnetic resonance imaging appearance prior to chemotherapy treatment. **B,** Follow-up scan performed 3 months after chemotherapy completion. (From Magowan BA: *Clinical obstetrics & gynecology,* ed 4, 2019, Elsevier.)

TABLE E3 Management of Hydatidiform Mole

Evacuation: Suction D&E (or hysterectomy in selected patients)

Postevacuation quantitative hCG level and chest radiography

Monitor quantitative hCG levels every 1-2 wk until three normal values or criteria for GTN

After hCG level is normal for three values, then monitor hCG levels every 1-3 mo for 6 mo

Initiate chemotherapy for GTN using indications listed in Table E4:
1. Plateaued or rising hCG values
2. Histologic diagnosis of choriocarcinoma, invasive mole, or placental site trophoblastic tumor
3. Persistent hCG >6 mo after evacuation
4. Metastatic disease

D&E, Suction dilation and evacuation; *GTN,* gestational trophoblastic neoplasia; *hCG,* human chorionic gonadotropin.
From Disaia PJ et al: *Clinical gynecologic oncology,* ed 9, Philadelphia, 2017, Elsevier.

TABLE E4 Diagnosis and Evaluation of Gestational Trophoblastic Neoplasia

Diagnosis of GTN

After molar evacuation: Four values or more of plateaued hCG (±10%) over at least 3 wk: Days 1, 7, 14, and 21

After molar evacuation: A rise of hCG of 10% or greater for three values or more over at least 2 wk: Days 1, 7, and 14

After molar evacuation: Persistence of hCG beyond 6 mo

The histologic diagnosis of choriocarcinoma, invasive mole, or PSTT

Metastatic disease without established primary site with elevated hCG (pregnancy has been excluded)

Evaluation of GTN

Complete physical and pelvic examination; baseline hematologic, renal, and hepatic functions

Baseline quantitative hCG level

Chest radiograph or CT scan of chest

Brain MRI

CT or MRI scan of abdomen and pelvis

CT, Computed tomography; *GTN,* gestational trophoblastic neoplasia; *hCG,* human chorionic gonadotropin; *MRI,* magnetic resonance imaging; *PSTT,* placental site trophoblastic tumor.
From Disaia PJ et al: *Clinical gynecologic oncology,* ed 9, Philadelphia, 2017, Elsevier.

TABLE E5 The 2002 Criteria for the Diagnosis of Post Hydatidiform Mole Trophoblastic Neoplasia

hCG-level plateau of 4 values ±10% recorded over a 3-wk duration (days 1, 7, 14, and 21)

An hCG-level increase of more than 10% of 3 values recorded over a 2-wk duration (days 1, 7, and 14)

Persistence of detectable hCG for more than 6 mo after molar evacuation

hCG, Human chorionic gonadotropin.

TABLE E6 International Federation of Gynecology and Obstetrics Staging of Gestational Trophoblastic Neoplasia

Stage I	Disease confined to the uterus
Stage II	GTN extends outside the uterus but is limited to the genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extends to the lungs with or without genital tract involvement
Stage IV	All other metastatic sites

GTN, Gestational trophoblastic neoplasia.
From Kohorn EI: The new FIGO 2000 staging and risk factor scoring system for gestational trophoblastic disease: description and critical assessment, *Int J Gynecol Cancer* 11:73-77, 2001.

TABLE E7 The World Health Organization (WHO) Prognostic Scoring System Is Used for the Medical Management of Patients with Partial, Complete Moles, and Choriocarcinomas

FIGO Scoring	0	1	2	4
Age	<40	≥40	—	—
Antecedent pregnancy	Mole	Abortion	Term	—
Interval months from index pregnancy	<4	4-<7	7-<13	≥13
Pretreatment serum hCG (IU/L)	<103	103-<104	104-<105	≥105
Large tumor size (including uterus) cm	<3	3-<5	≥5	—
Site of metastases	Lung	Spleen, kidney	Gastrointestinal	Liver, brain
Previous failed chemotherapy	—	—	Single drug	2 or more drugs

BASIC INFORMATION

DEFINITION

Molluscum contagiosum is a poxvirus infection characterized by discrete skin lesions with central umbilication.

SYNONYM

MC

ICD-10CM CODE
B08.1 Molluscum contagiosum

EPIDEMIOLOGY & DEMOGRAPHICS

- Molluscum contagiosum spreads by autoinoculation, scratching, or touching a lesion.
- It usually occurs in young children. It is also common in sexually active adults and patients with HIV infection.
- Incubation period varies between 4 and 8 wk.
- Spontaneous resolution in immunocompetent patients can occur after several mo.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The individual lesion appears initially as a small (2 to 3 mm), flesh-colored, firm, smooth-surfaced papule with subsequent central umbilication. Lesions are frequently grouped (Fig. 1). The size of each lesion generally varies from 2 to 6 mm in diameter.
- Typical distribution in children involves the face, extremities, and trunk. Mucous membranes are spared.
- Distribution in adults generally involves pubic and genital areas (Fig. E2).
- Erythema and scaling at the periphery of the lesions may be present as a result of scratching or hypersensitivity reaction.
- Lesions are not present on the palms and soles.

ETIOLOGY

Viral infection of epithelial cells caused by a poxvirus, molluscum contagiosum

DIAGNOSIS

Diagnosis is usually established by the clinical appearance of the lesions (distribution and central umbilication). A magnifying lens can be used to observe the central umbilication. If necessary, the diagnosis can be confirmed by removing a typical lesion with a curette and examining the content on a slide after adding potassium hydroxide and gentle heating. Staining with toluidine blue will identify viral inclusions.

DIFFERENTIAL DIAGNOSIS

- Verruca plana (flat warts): No central umbilication, not dome shaped, irregular surface, can involve palms and soles
- Herpes simplex: Lesions become rapidly umbilicated
- Varicella: Blisters and vesicles are present
- Folliculitis: No central umbilication, presence of hair piercing the pustule or papule
- Cutaneous cryptococcosis in AIDS patients: Budding yeasts will be present on cytologic examination of the lesions
- Basal cell carcinoma: Multiple lesions are absent
- Cellulitis

WORKUP

Careful examination of the papules

LABORATORY TESTS

Generally not indicated in children. Screening for other sexually transmitted diseases is recommended in all cases of genital molluscum contagiosum.

TREATMENT

GENERAL Rx

- Therapy is individualized depending on number of lesions, immune status, and patient's age and preference.
- Observation for spontaneous resolution is reasonable in patients with few, small, nonirritated, and nonspreading lesions. Genital lesions should be treated in all sexually active patients.
- Liquid nitrogen cryotherapy.
- Carbon dioxide laser.
- Curettage after pretreatment of the area with combination prilocaine 2.5% with lidocaine 2.5% cream (EMLA) for anesthesia is useful for treatment of a few lesions. Curettage should be avoided in cosmetically sensitive areas because scarring may develop.
- Treatments with liquid nitrogen therapy in combination with curettage are effective in older patients who do not object to some discomfort.
- Application of cantharidin 0.7% to individual lesions covered with clear tape will result in blistering over 24 hr and possible clearing without scarring. This medication should be avoided on facial lesions.
- Other treatment measures include use of imiquimod cream or tretinoin 0.025% gel or 0.1% cream at bedtime, daily use of salicylic acid (Occlusal) at bedtime, and use of laser therapy.
- Trichloroacetic acid peel generally repeated every 2 wk for several wk is useful in immunocompromised patients with extensive lesions.

DISPOSITION

Most patients respond well to the therapeutic modalities listed previously. Spontaneous resolution can occur after 6 to 9 mo in some immunocompetent patients.

REFERRAL

To dermatology when diagnosis is in doubt or in patients with extensive lesions

PEARLS & CONSIDERATIONS

COMMENTS

Genital molluscum contagiosum in children may be indicative of sexual abuse.

RELATED CONTENT

Molluscum Contagiosum (Patient Information)

AUTHOR: **Fred F. Ferri, MD**

FIG. 1 Grouped molluscum. (From Kliegman RM et al: *Nelson textbook of pediatrics*, ed 19, Philadelphia, 2011, WB Saunders.)

FIG. E2 A, Clinical presentation of molluscum contagiosum, with discrete, dome-shaped, pink papules. **B,** A depressed center (umbilicated papule), characteristic of the disease, allows for clinical diagnosis in most cases. (From Crum CP et al: *Diagnostic gynecologic and obstetric pathology*, ed 3, Philadelphia, 2018, Elsevier.)

BASIC INFORMATION

DEFINITION

Monoclonal gammopathy of renal significance (MGRS) describes a group of hemato-nephrologic disorders characterized by production of a serum nephrotoxic M protein, but they do not meet criteria for symptomatic multiple myeloma (MM) or lymphoma. The term *MGRS* was introduced to distinguish monoclonal gammopathies that result in the development of kidney disease from benign disorders. All forms of MGRS arise from B-cell clones. The monoclonal proteins may be of light chain, heavy chain, or intact immunoglobulin origin. The hematologic disorder is generally consistent with monoclonal gammopathy of undetermined significance (MGUS) in which the M protein is <3 g/dl, clonal plasma cells in the bone marrow are <10%, and there is no evidence of end-organ dysfunction.

SYNONYMS

Monoclonal immunoglobulin deposition disease (MIDD) with MGUS
Glomerulopathies with MGUS

ICD-10CM CODE
None currently exists for MGRS.

EPIDEMIOLOGY & DEMOGRAPHICS

MM and other malignant conditions with monoclonal gammopathy commonly lead to kidney disease, and the majority are associated dysproteinemia. Renal impairment is a defining criterion in MM. Although a growing number of kidney diseases associated with monoclonal gammopathies are being recognized, these gammopathies are typically characterized as MGUS and treatments are withheld. MGRS has been estimated to accompany 10% of MGUS cases, with prevalence rates of 0.32% and 0.53% in persons older than 50 and 70 yr, respectively. Although MGRS is considered a benign or premalignant condition, its effects on the kidney are not benign. Afflicted individuals may develop progressive kidney disease and/or end-stage renal disease (ESRD). The high rate of recurrence (60% to 90%) of MGRS-related kidney disease is associated with significant morbidity.

INCIDENCE: The exact frequency of MGRS is unclear. Many patients with MGRS are miscategorized as MGUS.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Kidney disease in patients with MGRS can present as a complication of a previously diagnosed, nonmalignant or premalignant hematologic disorder; MGUS; smoldering MM; or the initial clinical manifestation of a monoclonal gammopathy.
- Affected individuals may present with acute or subacute kidney injury, chronic kidney disease, proteinuria, and/or nephrotic syndrome.
- The most common presentation is renal impairment with proteinuria, with or without hematuria.
- Electrolyte abnormalities may be prominent when renal tubular lesions are present.

DIAGNOSIS

- MGRS should be suspected in the presence of nonmalignant or premalignant monoclonal gammopathy, i.e., MGUS, smoldering MM, Waldenström macroglobulinemia, or monoclonal B-cell lymphocytosis that presents with unexplained renal impairment and/or proteinuria.
- Individuals who manifest unexplained renal impairment and/or proteinuria with a monoclonal gammopathy (i.e., by serum or urine protein electrophoresis, serum or urine immunofixation electrophoresis, or serum free light chain assay) should be evaluated for MGRS.
- Percentage of proteinuria ratios to delineate the proportion of proteinuria that is albuminuria may be helpful. This urine ratio equals the albumin:creatinine ratio (mg/g) divided by the total protein:creatinine ratio (mg/g).
  1. In myeloma cast nephropathy, the bulk of protein is constituted by a Bence Jones protein (monoclonal light chain). In these cases, the albumin percentage is frequently <10% and typically <20%.
  2. For patients with MGRS, the albumin proportion may exceed 50% when there is principally glomerular pathology. In light chain proximal tubulopathy and crystal-storing histiocytosis, the glomeruli are relatively spared, and the albumin percentage can be low.
- A kidney biopsy is required for diagnosis, unless contraindicated. The presence of monoclonal immunoglobulin deposits in the kidney establishes the diagnosis of MGRS.
- Immunofluorescence reveals monoclonal proteins restricted to a single class of light and/or heavy chain.

CLASSIFICATION ACCORDING TO RENAL PATHOLOGY

The renal lesions on MGRS are classified based on the ultrastructure of deposits in the kidney (Table 1). Although glomerular and tubulointerstitial regions are most affected by MGRS, the renal vasculature may also be involved. Immunofluorescence and electron microscopy are essential to identification of MGRS lesions specifically. Identification of specific MGRS lesions is critical for assessing prognosis and to initiate proper therapy, MGRS renal lesions are broadly divided into those that are organized (with substructure) and those that are nonorganized (granular without substructure). Fig. 1 demonstrates the MGRS-associated lesions.

LABORATORY TESTS

- Kidney biopsy: It is the definitive means of demonstrating the nephrotoxicity of the monoclonal protein. The existence of a serum or urine monoclonal protein alone does not prove that a monoclonal protein is responsible for the kidney disease.

TABLE 1 Classification of Monoclonal Gammopathy of Renal Significance Lesions in the Kidney

Glomerulopathies (GN)	Tubular Disorders	Intrarenal Lesions
Renal amyloidosis (light chain, heavy chain, light and heavy chain)	Light chain Fanconi syndrome (LCFS)	Atypical hemolytic uremic syndrome (aHUS)
Fibrillary GN	Light chain proximal tubulopathy without crystals	
Immunotactoid GN	Crystal-storing histiocytosis	
Cryoglobulinemic glomerulonephritis (CG)		
Randall-type monoclonal immunoglobulin (Ig) deposition disease (MIDD) (light chain, heavy chain, light and heavy chain)		
Proliferative glomerulonephritis with monoclonal Ig deposits (PGNMID)		
Membranoproliferative glomerulonephritis (MPGN) associated with monoclonal Ig		
Membranous nephropathy (MN) secondary to monoclonal Ig		
C3 glomerulopathy (C3G) associated with monoclonal Ig		
C4 dense deposit disease (C4 DDD) associated with monoclonal Ig		

Adapted from Ciocchini M et al: Monoclonal gammopathy of renal significance (MGRS): the characteristics and significance of a new meta-entity, *Int Urol* Nephrol 49:2171-2175, 2017.

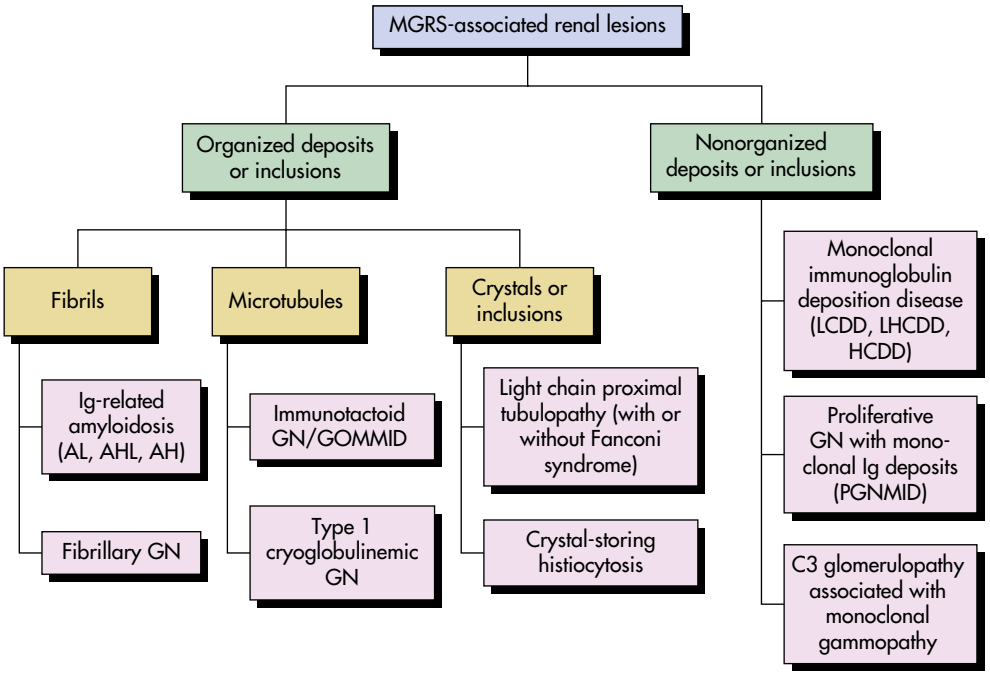

FIG. 1 Diagram of MGRS-associated renal lesions. *AH,* Immunoglobulin heavy chain amyloidosis; *AHL,* immunoglobulin heavy and light chain amyloidosis; *AL,* immunoglobulin light chain amyloidosis; *GN,* glomerulonephritis; *GOMMID,* glomerulonephritis with organized microtubular monoclonal immunoglobulin deposits; *HCDD,* heavy chain deposition disease; *Ig,* immunoglobulin; *LCDD,* light chain deposition disease; *LHCDD,* light and heavy chain deposition disease; *MGRS,* monoclonal gammopathy of renal significance; *PGNMID,* proliferative glomerulonephritis with monoclonal immunoglobulin G deposits. (From Bridoux F et al: Diagnosis of monoclonal gammopathy of renal significance, Kidney Int 87:698-711, 2015.)

- Monoclonal protein testing: The circulating monoclonal protein, if detected, must match the monoclonal protein within kidney deposits.
- Serum protein electrophoresis and immunofixation
- 24-hour urine protein electrophoresis and immunofixation
- Serum free light chain assay
- The value of urine free light chain evaluation is unknown and not required
- Bone marrow aspirate and biopsy: Analysis of the bone marrow should include immunohistochemistry and flow cytometry for surface and intracellular markers of plasma cells and B cells.
- Staining for kappa and lambda light chains should be performed to demonstrate that an identified clone exhibits the same light chain restriction as the monoclonal deposits in the kidney.

IMAGING STUDIES

Imaging studies (such as computed tomography of the chest, abdomen, and pelvis, combined with positive emission tomography, if available) may be required in patients who do not have a B-cell clone or have an IgM monoclonal protein.

Rx TREATMENT

- MGRS requires treatment to prevent progression of renal failure and not from a "tumoral" (proliferative rate and bulk) standpoint.
- Historically, reluctance in treatment was due to concerns of toxicity associated with chemotherapeutic agents.
- The treatment of MGRS-related kidney diseases should be tailored to the underlying clone responsible. Identification of a serum or urine monoclonal protein, if present, is also important in monitoring the response to therapy. No therapies are available to remove existing deposits.
- Hematologic response to chemotherapy is associated with improvement in kidney function and prevention of recurrence after kidney transplantation.
- Evidence suggests that once the specific renal lesion has been identified by kidney biopsy, chemotherapeutic agents directed against the pathologic clone are required.
- Agents such as monoclonal antibodies, cytotoxic agents, proteasome inhibitors, and immunomodulatory drugs have been proposed.
- Autologous hematopoietic cell transplantation may be considered in some patients with amyloidosis or MIDD. This disorder is defined by Congo red–negative deposits of monoclonal light or heavy chains, or both.

REFERRAL

The treatment of MGRS should be selected and administered in consultation with a hematologist or oncologist experienced in the use of antimyeloma and antilymphoma agents.

Monoclonal Gammopathy of Undetermined Significance (MGUS)

BASIC INFORMATION

DEFINITION

MGUS is a premalignant disorder characterized by the clonal expansion of plasma cells or lymphoplasmacytic cells. It is typically detected incidentally when patients undergo testing with serum or urine protein electrophoresis. The term "monoclonal gammopathy of undetermined significance" (MGUS) is defined by the presence of a serum monoclonal (M) protein less than 3 g/dl and clonal plasma cells less than 10% in the bone marrow. In addition, there must be no evidence of end organ dysfunction such as renal insufficiency, anemia, hypercalcemia, or bony lesions on skeletal surveys (Table 1).

SYNONYMS

MGUS
Non-IgM MGUS
IgM MGUS
Light chain MGUS

ICD-10CM CODE

D47.2 Monoclonal gammopathy of undetermined significance (MGUS)

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: In the U.S., the estimated age-adjusted incidence of MGUS is higher in men than in women. The annual incidence of MGUS in men is 120 per 100,000 at age 50 yr and increases to 530 per 100,000 at age 80 yr, whereas the incidence for women is 60 per 100,000 at age 50 yr and 370 per 100,000 at age 80 yr.

PREVALENCE: MGUS is associated with increasing age; approximately 1.5% of persons older than 50 yr and 3.0% of persons older than 70 yr have an elevated M protein level without end organ dysfunction. Studies have shown that at clinical diagnosis, MGUS is most likely to have been present undetected for a median duration of more than 10 yr. The prevalence of MGUS is also higher in African Americans. In one study, there was an almost threefold increase in prevalence among the African American population compared with the Caucasian population (8.6% vs. 3.6%).

PREDOMINANT SEX & AGE: The median age at diagnosis is about 70 yr. Prevalence is higher in men than in women at any given age.

RISK FACTORS: Race (African American), older age, male sex, or exposure to pesticides. Environmental and/or genetic defects play an important role, since the risk of MGUS in relatives of multiple myeloma or MGUS patients is increased twofold to threefold when compared to the general population. The cumulative risk of progression into multiple myeloma or related disorders is approximately 1% per yr. A variety of disorders (Table 2) are also associated with monoclonal gammopathy.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- MGUS typically is detected after a routine blood test reveals an elevated total protein concentration and is a common finding in medical practice.
- Patients are asymptomatic.
- Physical exam is normal.

ETIOLOGY

- The mechanism is unknown, and most cases are sporadic. The causes of malignant transformation of MGUS into multiple myeloma is still not well understood. Genetic predisposition, cytokine release, and bone marrow angiogenesis may play a role in the progression of MGUS into multiple myeloma.
- Characterized by a rearrangement of immunoglobulin genes resulting in the production of a monoclonal protein.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Smoldering myeloma (Table E3)
- Multiple myeloma
- Waldenström agammaglobulinemia
- Secondary monoclonal gammopathies
  1. Chronic liver disease
  2. Rheumatologic diseases
  3. Chronic myelomonocytic leukemia
  4. Chronic neutrophilic leukemia
  5. Lichen myxedematosus
- Pyoderma gangrenosum
- AL amyloidosis
- Idiopathic Bence Jones proteinuria

LABORATORY TESTS

- Protein studies with serum free light chain assay
- Serum protein electrophoresis (Fig. E1): IgG most common, followed by IgM and IgA
- 24-hour urine protein excretion and urine electrophoresis
- Serum and urine immunofixation
- Determination of serum free light chain ratio (kappa and lambda free light chains)
- Hemoglobin
- Serum calcium and creatinine
- Examination of the bone marrow aspirate only when clinically indicated. It is not necessary in MGUS patients with low risk fractures (no end organ damage. Ig gammopathy less than 1.5 g/dl, normal serum free light chain ratio)

IMAGING STUDIES

- Skeletal survey
- Bone mineral density resting at baseline (MGUS is associated with increased risk of osteoporosis)

TREATMENT

- Risk stratification:
  1. Low risk: Serum M protein <1.5 g/dl, IgG subtype, normal genetics, free light chain ratio between 0.26 and 1.65. Absolute risk of progression (ARP) at 20 yr is 5%
  2. Low-intermediate risk: Any 1 factor abnormal. ARP at 20 yr is 21%
  3. High-intermediate risk: Any 2 factors abnormal. ARP at 20 yr is 37%
  4. High risk: More than 3 factors abnormal. ARP at 20 yr is 58%
- Follow-up by risk category: Patients with MGUS should be tested again within 4 to 6 mo from the time of first diagnosis to exclude evolving multiple myeloma. Those with low-risk MGUS can be followed up every 1 to 2 yr, whereas those with intermediate- or high-risk MGUS need to be followed up at least annually for life or until they develop a life-expectancy-threatening condition.
- Reevaluation consists of:
  1. Serum protein electrophoresis with immunofixation
  2. 24-hour urine protein excretion
  3. Serum free light chain assessment:
     a. Complete blood count
     b. Serum creatinine and calcium
     c. Careful history and physical examination to look for signs and symptoms known to evolve from MGUS

DISPOSITION

- Risk of myeloma at 25 yr is 30%
- Annual risk of transformation to myeloma depends on type of M protein:
  1. Immunoglobulin MGUS: 1% per yr
  2. Light-chain MGUS: 0.3% per yr
- IgM MGUS are more likely to progress to Waldenström macroglobulinemia, at a rate of 1.5% per yr
- Risk of infection (bacterial and viral) is twofold compared with healthy controls
- Increased risk of mortality from bacterial infections

REFERRAL

To hematologist/oncologist for evaluation

PEARLS & CONSIDERATIONS

- Approximately 55% of 70-yr-old patients diagnosed as having MGUS have had the condition for more than 10 yr.
- Most patients with MGUS should be monitored every 6 to 12 mo for signs and symptoms of progression.
- There is no indicated treatment, but some patients with MGUS can develop MGUS-related renal disease or neuropathy, and treatment sometimes is indicated in these cases.

TABLE 1 Disease Definitions for the Monoclonal Gammopathies: MGUS and Related Disorders

Type of Monoclonal Gammopathy	Premalignancy with a Low Risk of Progression (1%-2% per yr)	Premalignancy with a High Risk of Progression (10% per yr)	Malignancy
IgG and IgA (non-IgM) monoclonal gammopathies*	**Non-IgM MGUS** All 3 criteria must be met: Serum monoclonal protein <3 g/dl Clonal bone marrow plasma cells <10%, and Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder	**Smoldering multiple myeloma** Both criteria must be met: Serum monoclonal protein (IgG or IgA) ≥3 g/dl and/or clonal bone marrow plasma cells ≥10%, and Absence of end-organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder	**Multiple myeloma** All 3 criteria must be met except as noted: Clonal bone marrow plasma cells ≥10% Presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma), and Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically Hypercalcemia: Serum calcium >11.5 mg/dl or renal insufficiency: Serum creatinine >2 mg/dl or estimated creatinine clearance <40 ml/min Anemia: Normochromic, normocytic with a hemoglobin value of >2 g/dl below the lower limit of normal or a hemoglobin value <10 g/dl Bone lesions: Lytic lesions or severe osteopenia attributed to a plasma cell proliferative disorder or pathologic fractures
IgM monoclonal gammopathies	**IgM MGUS†** All 3 criteria must be met: Serum IgM monoclonal protein of any level Normal bone marrow and absence of end-organ damage such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder	**Smoldering Waldenström macroglobulinemia** Both criteria must be met: Serum IgM monoclonal protein of any level and/or bone marrow lymphoplasmacytic infiltration of any level, and No evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder	**Waldenström macroglobulinemia** All criteria must be met: IgM monoclonal gammopathy of any level, and any level of bone marrow lymphoplasmacytic infiltration (usually intratrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (e.g., surface IgM^{+}, CD5$^{+/-}$, CD10^{-}, CD19^{+}, CD20^{+}, CD23^{-}) that satisfactorily excludes other lymphoproliferative disorders including chronic lymphocytic leukemia and mantle cell lymphoma Evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to the underlying lymphoproliferative disorder. Presence of the *MYD88* L265P mutation **IgM myeloma** All criteria must be met: Symptomatic monoclonal plasma cell proliferative disorder characterized by a serum IgM monoclonal protein regardless of size Presence of 10% plasma cells on bone marrow biopsy Presence of lytic bone lesions related to the underlying plasma cell disorder and/or translocation t(11;14) on fluorescence in situ hybridization
Light-chain monoclonal gammopathies	**Light-chain MGUS** All criteria must be met: Abnormal FLC ratio (<0.26 or >1.65) Increased level of the appropriate involved light-chain (increased kappa FLC in patients with ratio >1.65 and increased lambda FLC in patients with ratio <0.26) No immunoglobulin heavy-chain expression on immunofixation Clonal bone marrow plasma cells <10%, and Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder	**Idiopathic Bence Jones proteinuria** All criteria must be met: Urinary monoclonal protein on urine protein electrophoresis ≥500 mg/24 h and/or clonal bone marrow plasma cells ≥10% No immunoglobulin heavy-chain expression on immunofixation Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions (CRAB) that can be attributed to the plasma cell proliferative disorder	**Light-chain multiple myeloma†** Same as multiple myeloma except no evidence of immunoglobulin heavy-chain expression

CRAB, hypercalcemia, renal failure, anemia, and bone disease; *FLC,* free light chain; *Ig,* immunoglobulin; *MGUS,* monoclonal gammopathy of undetermined significance.

*Occasionally patients with IgD and IgE monoclonal gammopathies have been described and will be considered to be part of this category as well.

†Note that conventionally IgM MGUS is considered a subtype of MGUS, and similarly light-chain multiple myeloma is considered as a subtype of multiple myeloma. Unless specifically distinguished, when the terms MGUS and multiple myeloma are used in general, they include IgM MGUS and light-chain multiple myeloma, respectively.

Modified from Rajkumar SV et al: Advances in the diagnosis, classification, risk stratification, and management of monoclonal gammopathy of undetermined significance: implications for recategorizing disease entities in the presence of evolving scientific evidence, *Mayo Clin Proc* 85:945-948, 2010.

TABLE 2 Diseases Associated with Monoclonal Gammopathy

Plasma cell and related disorders	MGUS Solitary plasmacytoma: Bone Soft tissue Multiple myeloma Waldenström macroglobulinemia Primary amyloidosis	
Lymphoid disorders	Non-Hodgkin lymphoma	Monoclonal protein observed in CLL (>20% of cases with IgM, ≈50% with IgG, light chains also observed), extranodal marginal zone lymphomas (>30% of cases and correlated with BM involvement), follicular, mantle cell, and diffuse large B-cell lymphomas also reported with serum M proteins as has AITL
	Hodgkin lymphoma	Rare but reported
	Castleman disease	<2% with monoclonal gammopathy
Other hematologic disorders	Acquired von Willebrand disease	IVIG more effective than factor concentrate in increasing factor VIII coagulant and VWF levels
	Gaucher disease	Observed in 25% in one study; M protein declined after splenectomy
	Pernicious anemia, pure RBC aplasia, hereditary spherocytosis, MPD, MDS	
Connective tissue disorders	SLE	IgG, IgM, and IgA have been observed, no difference in disease activity or outcome
	Inclusion body myositis	80% with IgG M protein
	Polymyositis, RA, scleroderma	
Neurologic disorders	POEMS syndrome	Most have M-protein of λ light chain
	Peripheral neuropathy	Most common is IgM followed by IgG and IgA In half, IgM protein binds to myelin-associated glycoprotein Size of M protein not correlated with severity of neuropathy Some benefit from plasma exchange for those with IgG and IgA Fludarabine and rituximab with some benefit for IgM
	Myasthenia gravis, ALS, Alzheimer disease	
Dermatologic disorders	Schnitzler syndrome	Neutrophilic urticarial dermatitis, monoclonal IgM protein, and two of: Lymphadenopathy, fever, hepatosplenomegaly, joint pain, increased ESR, increased neutrophils, or abnormal bone imaging
	Scleredema	
	Pyoderma gangrenosum	Frequently an IgA protein
Infections	HIV	Both IgG and IgM M proteins observed
	HCV	M protein present in up to 10% of patients
Immunosuppression	Renal transplant	In children CMV infection associated with M protein
	Liver and heart transplant	Most patients with posttransplant lymphoproliferative disorders have M proteins
	BM transplant	Observed in both autologous and allogeneic transplants Appearance of M protein correlated with GVHD

AITL, Angioimmunoblastic T-cell lymphoma; *ALS,* amyotrophic lateral sclerosis; *BM,* bone marrow; *CLL,* chronic lymphocytic leukemia; *CMV,* cytomegalovirus; *ESR,* erythrocyte sedimentation rate; *GVHD,* graft-versus-host disease; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *Ig,* immunoglobulin; *IVIG,* intravenous immunoglobulin; *MDS,* myelodysplastic syndrome; *MGUS,* monoclonal gammopathy of uncertain significance; *MPD,* myeloproliferative disorder; *POEMS,* polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; *RA,* rheumatoid arthritis; *RBC,* red blood cell; *SLE,* systemic lupus erythematosus; *VWF,* von Willebrand factor.

BASIC INFORMATION

DEFINITION

Infectious mononucleosis (IM) is a symptomatic infection most commonly caused by Epstein-Barr virus (EBV) and characterized by a classic triad of fever, tonsillar pharyngitis, and lymphadenopathy (predominantly cervical). Fatigue is also a very common finding. IM was first coined in 1920 to describe a syndrome characterized as an acute infectious process accompanied by atypical large peripheral blood lymphocytes.

SYNONYMS

Mononucleosis
EBV
Kissing disease

ICD-10CM CODES

B27 Infectious mononucleosis
B27.0 Gamma herpesviral mononucleosis
B27.1 Cytomegaloviral mononucleosis
B27.8 Other infectious mononucleosis
B27.9 Infectious mononucleosis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 500 cases/100,000 persons/yr; worldwide, approximately 90% lifetime prevalence by age 30 yr

PREDOMINANT SEX: Incidence is the same, but occurs earlier in females.

PREDOMINANT AGE: Symptomatic infection most common between the ages of 15 and 24 yr. The age at which primary EBV infection is acquired is potentially increasing in developed countries.

Young children rarely develop clinical signs of IM. Infection during childhood is more common in lower socioeconomic groups and may vary by geographic location or social factors, such as crowding, sharing a bedroom, maternal education, daycare attendance, and school catchment area.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Following an incubation period of 4 to 7 wk, there are two common presentations. The first presentation represents the prodromal period with gradual onset of fever, chills, malaise, and anorexia for several days. This is followed by the second presentation of the classic triad of pharyngitis, fever, and lymphadenopathy. These patients often report the worst sore throat of their life. Pharyngitis (Fig. E1) is typically the most severe symptom and is characterized by white tonsillar exudates that may spread to the tongue. Up to half of patients may have palatal petechiae.
- Lymphadenopathy (nonnecrotic) can be diffuse, but most commonly occurs in both the anterior and posterior triangles of the neck.
- Splenomegaly may be palpable, most commonly during the second wk of illness. Most patients have some degree of splenomegaly on ultrasound assessment. Hepatomegaly with some degree of hepatitis is also common. In 75% of cases there is some increase in alanine aminotransferase (ALT).
- Rash (Fig. E2) is uncommon but will occur in nearly all patients who receive ampicillin or amoxicillin due to a transient penicillin hypersensitivity.
- IM is usually a self-limited illness (2 to 4 wk), but symptoms of malaise and fatigue may last mos before resolving.
- At times, IM can present as fever and adenopathy without pharyngitis.
- Although acute complications may be severe, they are uncommon and tend to resolve completely. Reported complications include cholestatic liver disease, chronic hepatitis, or even liver failure; hemolytic anemia; splenic rupture; or airway compromise.
- Splenic rupture is rare, with an incidence rate <1%, but it is the most feared. It should be suspected in anyone with confirmed or suspected IM who presents with acute abdominal or chest pain. Most cases occur in the first 3 wk of symptoms.
- Airway compromise, as evidenced by stridor, cyanosis, and/or tachypnea, is reported in 1% to 3% of cases and is an indication for hospitalization.
- Systemic corticosteroids are indicated for treating those at risk or with impending airway obstruction, and usually leads to improvement in 12 to 36 hr. Acute tonsillectomy may be pursued if steroids are not sufficient to mitigate the risk for obstruction.
- Late complications may include lymphoproliferative cancers (Burkitt lymphoma and Hodgkin lymphoma), multiple sclerosis, rheumatoid arthritis, and chronic active EBV infection (CAEBV).
- EBV may also cause hemophagocytic disease, alternatively referred to as EBV-associated hemophagocytic lymphohistiocytosis (EBV-HLH), characterized by fever, splenomegaly, and cytopenias with high ferritin and soluble CD25.
- Box 1 and Table 1 summarize the features of IM in immunocompetent patients.

ETIOLOGY

The most common cause of IM (90%) is primary infection with EBV. Cytomegalovirus (CMV) is the most common cause of the other 10% of IM, but CMV infection often occurs in infancy or early childhood and is minimally symptomatic. Other causes include human herpes virus-6, herpes simplex virus-1, and HIV. Primary EBV infection during childhood also often causes few or no symptoms; persistent fatigue and recurrent/persistent fevers are the most common reasons parents bring symptomatic children to medical care.

BOX 1 Summary of Features of Infectious Mononucleosis (IM) in Immunocompetent Patients

Epstein-Barr Virus (Human Herpesvirus-4)

Pathophysiology
- Virus enters through oropharyngeal epithelial and lymphoid cells.
- Virus attaches to CD21 on B cells.
- Viral antigens—viral capsid antigen (VCA), early antigen (EA), Epstein-Barr nuclear antigen (EBNA)—are produced and elicit antibody production.

Humoral Immune Response
- Immunoglobulin (Ig)M against VCA rises during incubation and prodrome, falls over few wks to mos.
- IgG against VCA rises during incubation, decreases during convalescence, remains detectable for life.
- Antibodies to EA rise 2-3 wk after onset of illness, then fall.
- Antibodies to EBNA rise during convalescence, detectable for life.

Cellular Immune Response
- T cells activated during second wk of illness.
- CD8-positive cytotoxic T cells kill infected B cells.
- Natural killer cells kill infected B cells.
- Some resting memory B cells remain latently infected.

Clinical Features
- 4- to 7-wk incubation period
- Vague onset of symptoms
- Fever, sore throat, lymphadenopathy
- Adolescents, young adults more often symptomatic than younger children

Laboratory Features
- Leukocytosis with absolute lymphocytosis and atypical lymphocytes
- Transient monocytosis
- Relative and absolute neutropenia early on
- Mild thrombocytopenia in half of cases
- Hemolytic anemia in 1% to 3% of cases, often with anti-I specificity
- Elevated transaminases in 85% to 100% of cases, but clinical jaundice rare
- Spot test is simple, rapid, specific, based on agglutination of horse red blood cells (RBCs)
- Heterophil antibody (HA) test is based on differential absorption of IM-specific HA by beef RBC stroma and guinea pig kidney

From McPherson RA, Pincus MR: *Henry's clinical diagnosis and management by laboratory methods,* ed 23, Philadelphia, 2017, Elsevier.

EBV infects epithelial cells and resting B cells of the oropharynx. It is then found in saliva, making it transmittable through coughing, sharing drink/food, and kissing; thus the pseudonym "kissing disease." IM is more prevalent during adolescence when these types of close contact increase. How it is transmitted in younger children is less clear.

EBV levels peak during the active phase of infection but can persist in the oropharynx for up to 18 mo. Transmission may also occur sexually because EBV can be isolated in cervical epithelial cells and male seminal fluid. It has also been shown to be transmitted by blood transfusion, solid organ transplantation, or hematopoietic cell transplantation.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Heterophile-negative IM caused by CMV
- Bacterial and viral causes of pharyngitis
- Toxoplasmosis
- Acute retroviral syndrome of HIV, lymphoma

WORKUP

Initial testing consists of heterophile antibody (monospot) and CBC with differential. Fig. 3 illustrates the serologic evaluation of patients with clinical symptoms of acute IM and atypical lymphocytosis.

LABORATORY TESTS

- About 85% of patients with EBV-related IM will have a positive heterophile antibody test, making it the best initial test for diagnosis of EBV infection (sensitivity of 71% to 90% for diagnosing IM). However, the test has a 25% false-negative rate in the first wk of illness because the amount of heterophile antibody may not be above the limit for detection early in the disease. A negative test should be repeated if clinical suspicion is high; negative results are common in patients symptomatic for <2 wk and children <4 yr. False-positive heterophile antibody tests have been reported in other acute infections, autoimmune diseases, and cancer.
- About 10% of patients will have a persistently negative heterophile antibody test. In this event, further testing may be pursued with EBV viral capsid antigen (VCA) IgG and IgM antibody testing, as well as EBV nuclear antigen (EBNA) antibodies for staging of infection. Early diagnosis in monospot-negative cases may be made by isolating IgM to the VCA, which is usually positive during the acute illness and disappears after 4 to 6 wk. If the monospot test remains negative (without evidence of acute infection with antibody testing) for 8 wk, alternative diagnoses should be considered. The monospot usually remains positive for 3 to 6 mo but can last >1 yr.
- Increased white blood count (WBC) is common, with a relative lymphocytosis and neutropenia. Atypical lymphocytes (Fig. E4) are the hallmark of IM but are not pathognomonic. Mild thrombocytopenia is common. A falling hematocrit may signal splenic rupture or severe immune-mediated hemolytic anemia. Elevated hepatocellular enzymes and cryoglobulins occur in many cases.

IMAGING STUDIES

Chest x-ray may rarely show infiltrates. An elevated left hemidiaphragm may occur in cases of splenic rupture.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- No specific treatment exists; focus is on supportive care and symptomatic relief with analgesics, antipyretics, and hydration. Supportive rest is advocated by some, but the effect on outcome is not clear. Prolonged rest may result in deconditioning, which may contribute to further fatigue.
- Splenectomy if rupture occurs; transfusions for severe anemia or thrombocytopenia.

GENERAL Rx

- Pharmacologic therapy, including corticosteroids, is not indicated in mild illness or for symptomatic relief. Use of corticosteroids is controversial because they may impair clearance of the viral load.
- The use of steroids, however (Fig. E5), should be considered in patients who have severe acute complications, such as thrombocytopenia, hemolytic anemia, or impending airway obstruction.
- There is no role for antiviral agents such as acyclovir in the management of IM.

CHRONIC Rx

CAEBV is treated with hematopoietic cell transplantation.

DISPOSITION

Eventual resolution of all symptoms is the rule.

PEARLS & CONSIDERATIONS

COMMENTS

- Contact sports should be avoided during the first mo of illness because splenic rupture can occur during this time, even in the absence of clinically detectable splenomegaly.
- Between 30% and 75% of college freshmen are seronegative for EBV. Each yr nearly 20% of susceptible persons become infected and up to 50% of these persons develop IM.

BASIC INFORMATION

DEFINITION

Morton neuroma is a compressive neuropathy of the interdigital nerve that results in forefoot pain. Morton neuroma manifests as pain or burning in the forefoot, often localized between the metatarsal heads.

SYNONYMS

Morton metatarsalgia
Interdigital neuroma
Interdigital neuritis
Plantar neuroma
Metatarsal neuralgia

ICD-10CM CODES

G57.6 Lesion of plantar nerve
G57.8 Other mononeuropathies of lower limb
G57.9 Mononeuropathy of lower limb, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- Morton neuroma affects one of the common plantar digital nerves located at any of the four interspaces of the foot.
  1. The term "Morton neuroma" refers to a neuroma specifically in the second or third intermetatarsal space, whereas the term "neuroma" may be used to describe a nerve lesion in any interspace.
- Morton neuroma is usually unilateral.
- The condition occurs more frequently in women and usually presents between the fourth and sixth decade of life.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients with Morton neuroma will present complaining of pain and burning in the forefoot, typically localized between the metatarsal heads of the affected interspace.
- The pain may be described as stabbing, burning, or tingling and may radiate to the digits.
- The pain is exacerbated by the use of tight-fitting shoes. Patients often feel as though they are walking on a marble.
- The pain can often be recreated by applying pressure at the plantar aspect of the interspace, starting just proximal to the metatarsal heads and proceeding distally.
- Mulder sign: Compression of the forefoot at the level of the metatarsophalangeal joints combined with plantar pressure at the affected interspace elicits a palpable "click."

ETIOLOGY

- While the exact etiology of Morton neuroma is uncertain, most histologic studies show evidence of hyperplasia within the nerve.
- The neuroma is further considered to be an entrapment neuropathy of the affected common digital plantar nerve (Fig. E1) between adjacent metatarsal heads or by the transverse metatarsal ligament.
- The common plantar digital nerves are branches of the medial and lateral plantar nerve that course distally to supply the digits of the foot, passing just beneath the deep transverse intermetatarsal ligament. Within the third intermetatarsal space, a communicating branch of the medial plantar nerve often joins with a communicating branch of the lateral plantar nerve to supply the third and fourth digits. This anatomic variation results in a thicker nerve that is more prone to trauma between the constrictive metatarsal heads, a reason often cited to explain the prevalence of Morton neuroma specifically within the third interspace.
- The deep transverse intermetatarsal ligament may also be implicated in the cause of a neuroma. If it is thickened or has aberrant bands, it may cause compression of the affected nerve.
- Soft tissue masses such as a plantar lipoma may also cause compression of the nerve against the ligament, leading to the formation of a neuroma.
- Histologic examination of resected Morton neuroma exhibits increased neural width, demyelination, intraneural fibrosis, and thickened endoneural capillaries.

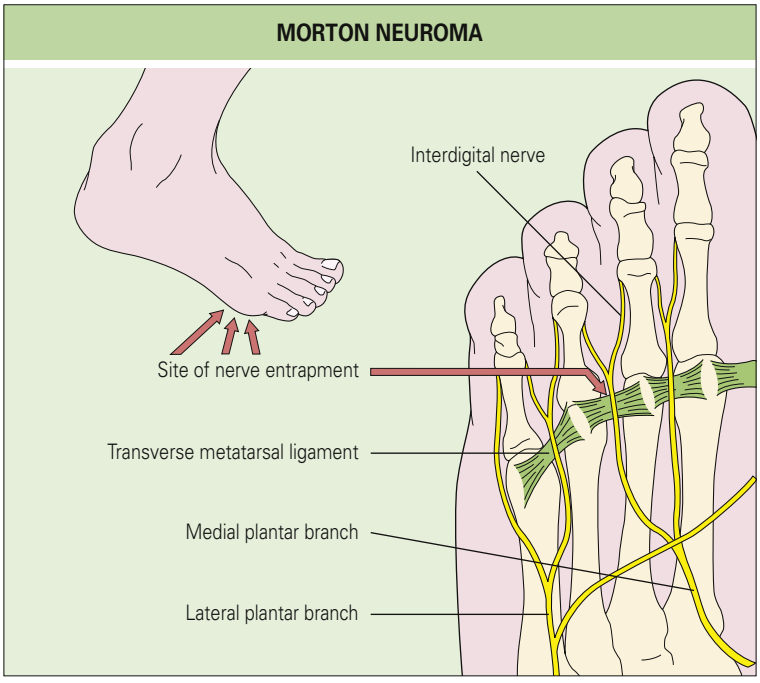

FIG. E1 On the plantar surface of the foot, the interdigital nerve is compressed below the transverse metatarsal ligament and not between the metatarsal heads (plantar view). (From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.)

DIAGNOSIS

The diagnosis of Morton neuroma is primarily clinical. Laboratory tests and imaging modalities are generally not necessary.

DIFFERENTIAL DIAGNOSIS

- Peripheral neuropathy
- Tarsal tunnel syndrome
- Metatarsal stress fracture
- Freiberg infraction
- Metatarsophalangeal joint capsulitis or bursal swelling
- Osteoarthritis
- Rheumatoid nodule
- Plantar lipoma

WORKUP

- Exclude other causes mentioned in "Differential Diagnosis."
- A common digital nerve block with a small amount of local anesthetic into the interspace has significant diagnostic value if temporary pain relief is achieved.

IMAGING STUDIES

As Morton neuroma is a clinical diagnosis, imaging is not an absolute requirement; however, it can be useful when clinical assessment is unclear or when more than one interspace is affected.

- Weight-bearing radiographs may be performed to exclude other pathology.
- MRI may be indicated when evaluating patients with recurrent neuromas or atypical symptoms.
- Ultrasound imaging (Fig. E2) can be used to visualize a larger neuroma, which will typically present as a hypoechoic mass. Smaller lesions may be missed by imaging but are still able to cause symptoms.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Altering footwear is the first line of treatment.
- Wide shoes with a low heel are recommended.

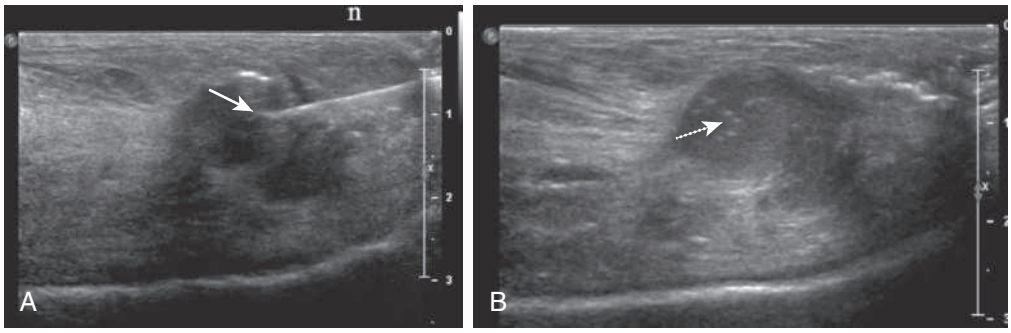

FIG. E2 Ultrasound-guided injection of a Morton neuroma in the third intermetatarsal space with steroid and anesthetic. Ultrasound image **(A)** shows the needle tip inside the Morton neuroma *(solid arrow).* Ultrasound image **(B),** immediately following the injection, shows multiple punctate echogenic foci within the Morton neuroma *(dashed arrow),* indicating successful injection of the steroid and anesthetic into the lesion. (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2014, WB Saunders.)

FIG. E3 Injection for interdigital (Morton) neuroma. The area is injected most easily from the dorsal aspect, usually between the metatarsal heads of the third and fourth toes. The area of tenderness is marked, the needle is inserted to 1 inch, and steroid with anesthetic is injected. (From Firestein GS et al: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2013, WB Saunders.)

- A metatarsal pad may also provide relief as it splays the metatarsal heads thereby decreasing the pressure on the neuroma.
- If adequate relief is noted with the previous steps, then orthotics may also be considered.
- Physical therapy treatment and evaluation may be beneficial and includes cryotherapy, ultrasonography, deep-tissue massage, and stretching exercises.

ACUTE GENERAL Rx

- If conservative measures are unsuccessful, other treatment options include serial injections (Fig. E3) with corticosteroids or a sclerosing agent. A recent level one randomized controlled trial with 41 patients demonstrated good short-term outcomes for patients with corticosteroid injections. Despite this, 48% opted for surgical excision of the neuroma at the conclusion of the trial.
- Nonsteroidal antiinflammatory agents may also provide relief.

CHRONIC RX

- Recent small-scale studies support use of new conservative modalities, including radio frequency ablation, extracorporeal shockwave therapy, and laser therapy.
- If conservative treatment fails to provide a resolution to symptoms, then surgical intervention (neurectomy) should be considered.
- Possible complications of surgery include hematoma formation, numbness, infection, and recurrent "stump" neuroma.

DISPOSITION

- Following surgery, patients are often placed on a partial weight-bearing status. Sutures are removed 2 to 3 wk following the initial surgery. Patients generally return to their previous activity level in 4 to 6 wk.
- Should a neuroma recur, a second surgical procedure may be performed.

REFERRAL

If surgery is being considered, a consultation with either a podiatrist or a foot and ankle specialized orthopedic surgeon is indicated.

PEARLS & CONSIDERATIONS

COMMENTS

- Dr. Thomas G. Morton is given credit for describing this disorder in 1876.
- Morton neuroma may occur in any of the four interspaces of the foot but most commonly affects the third interspace.
- If conservative treatment and serial injections fail, surgery should be considered for the excision of the neuroma.

Motion Sickness (PTG)

BASIC INFORMATION

DEFINITION

Motion sickness is a clinical syndrome associated with motion or perception of motion. Patients with motion sickness suffer perspiration, nausea, vomiting, increased salivation, and generalized malaise in response to movement.

SYNONYM

Physiologic vertigo

ICD-10CM CODE
T75.3 Motion sickness

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Common
PREVALENCE (IN U.S.): Common
PREDOMINANT SEX: Male = female
PREDOMINANT AGE: Any age
PEAK INCIDENCE: Any age
GENETICS: Not known to be genetic

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Vomiting
- Sweating
- Pallor

ETIOLOGY

- Motion (e.g., amusement rides, rides in automobiles or planes)
- Exacerbated by anxiety, fumes (e.g., industrial pollutants), visual stimuli
- Fig. E1 describes a proposed neural pathway resulting in motion sickness

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute labyrinthitis
- Gastroenteritis
- Metabolic disorders
- Viral syndrome

WORKUP

None necessary in routine case

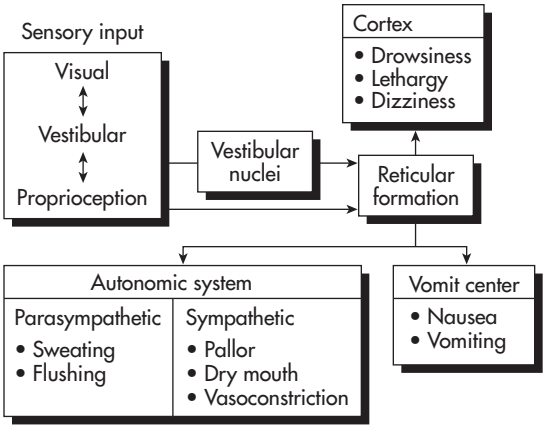

FIG. E1 Proposed neural pathway resulting in motion sickness. (From Kuhn SM: Motion sickness. In Keystone JS et al: *Travel medicine,* ed 2, Philadelphia, 2008, Elsevier, pp. 435-440.)

TREATMENT

NONPHARMACOLOGIC THERAPY

- Fixate on far object
- Cease motion
- Avoid reading
- Avoid alcohol

ACUTE GENERAL Rx

- Scopolamine patch is most effective. It should be applied to a hairless area behind the ear every 3 days prn. It should be applied >4 hr before antiemetic effect is required.
- Oral promethazine is effective but highly sedating.
- Over-the-counter oral preparations (e.g., Dramamine) are less effective.
- Meclizine 12.5 to 25 mg q6h may be effective but is very sedating.

CHRONIC Rx

- Rarely chronic
- Symptoms generally resolve completely with cessation of motion exposure

DISPOSITION

Follow-up is not needed.

REFERRAL

If another diagnosis is suspected (e.g., purulent ear, fever, cranial nerve abnormalities)

PEARLS & CONSIDERATIONS

COMMENTS

- Many patients with migraine report having had severe motion sickness as a child.
- Improved ventilation, avoidance of large meals before travel, semirecumbent sitting, and avoidance of reading while in motion will minimize the risk of motion sickness.

Motion Sickness (Patient Information)

AUTHOR: **Fred F. Ferri, MD**

BASIC INFORMATION

DEFINITION

Mucormycosis is a fungal infection by Zygomycetes fungi and includes species in the order Mucorales (*Rhizopus* sp., *Rhizomucor, Cunninghamella, Apophysomyces, Saksenaea, Absidia, Syncephalastrum, Cokeromyces, Mortierella*) and in the order Entomophthorales (*Conidiobolus* and *Basidiobolus*).

SYNONYM

Zygomycosis

ICD-10CM CODES

B46.0 Pulmonary mucormycosis
B46.1 Rhinocerebral mucormycosis
B46.3 Cutaneous mucormycosis
B46.4 Disseminated mucormycosis
B46.5 Mucormycosis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- Mucormycosis is the third most frequent cause of invasive fungal infections in immunocompromised hosts. These fungi are ubiquitous in nature and can be found in soil and decaying vegetation. Infection is seen in association with underlying conditions, including diabetes mellitus especially with ketoacidosis, hematologic malignancies, stem cell or solid organ transplants, severe burns or trauma, treatment with deferoxamine or iron overload states, steroid treatment, immunodeficiency states (e.g., AIDS), injection drug use, and malnutrition. Immunocompetent hosts may become infected in tropical climates.
- The fungus gains entry to the body most commonly through the respiratory tract. The spores are deposited in the nasal turbinates and may be inhaled into the pulmonary alveoli. In cases of cutaneous mucormycosis, the spores are introduced directly into the skin lesion.
- After a tornado with winds >200 mph struck Joplin, Missouri, in May 2011, there were 13 confirmed cases of mucormycosis *(Apophysomyces trapeziformis),* including five deaths. While two patients had diabetes, none were immunocompromised. It was felt that the fungus entered through wounds sustained during the tornado. Wooden splinters were found in four patients.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Rhinocerebral-rhinoorbital-paranasal syndrome (Fig. E1) is the most common presentation, which presents with fever, facial and orbital pain, headache, diplopia, loss of vision, facial or orbital cellulitis, facial anesthesia, cranial nerve dysfunction, black nasal discharge, epistaxis, and seizure. Physical findings in this situation include proptosis; chemosis; nasal, palatal, or pharyngeal necrotic ulcerations; and retinal infarction. Thrombosis of the cavernous sinus or internal carotid artery may occur. This form of mucormycosis is found most commonly in diabetics, primarily in the presence of acidosis, and in patients with leukemia and neutropenia. Isolated CNS mucormycosis may result from hematogenous spread (can occur with injection drug users).
- Pulmonary mucormycosis can present with pneumonia, lung abscess, pulmonary infarction, pleurisy, pleural effusion, hemoptysis, chills, and fever. This form of mucormycosis is found most commonly in immunocompromised neutropenic hosts after chemotherapy for hematologic malignancies.
- Gastrointestinal zygomycosis presents with abdominal pain, diarrhea, gastrointestinal hemorrhage, ulcers, peritonitis, and bowel infarction. This form of mucormycosis is found most commonly in patients with extreme malnutrition and is believed to arise from ingestion of spores of the fungi.
- Cutaneous zygomycosis presents as nodular lesions (hematogenous seeding) or a wound infection. It primarily involves the epidermis and dermis after use of occlusive dressings that have not been properly sterilized.
- Cardiac mucormycosis is a form of endocarditis.
- Septic arthritis and osteomyelitis.
- Brain abscess occurs most often from extension of the fungus from the nose or paranasal sinuses through adjacent bones in severely debilitated patients.
- Disseminated zygomycosis (rare but uniformly fatal).
- Physical findings depend on the location of the infection.

ETIOLOGY & PATHOGENESIS

The cause of mucormycosis is infection by a fungus of the Zygomycetes class (see "Definition"). Rhizopus and mucor species are the most common causes. Normal host defenses include leukocytes and pulmonary macrophages. Quantitative (e.g., neutropenia) or qualitative (e.g., diabetes mellitus or steroid treatment) disruption in the host defenses predisposes the patient to infection. Patients treated with deferoxamine for iron-overload states are also at risk.

DIAGNOSIS

A high index of suspicion is critical since mucormycosis infection is acute and rapidly faster if untreated. The hallmark of mucormycosis is infarction and necrosis of host tissues that result from invasion of the vasculature by the fungal elements. Black eschars and discharges should be closely evaluated. Diagnosis depends on the demonstration of the organism in the tissue of a biopsy specimen.

DIFFERENTIAL DIAGNOSIS

- Infection of the sites described previously by other organisms (bacterial [including tuberculosis and leprosy], viral, fungal, or protozoan)
- Noninfectious tissue necrosis (e.g., neoplasia, vasculitis, degenerative) of the sites described previously

WORKUP

- Biopsy of infected tissue with direct-light microscopy examination establishes the diagnosis within minutes of the biopsy in the case of nasopharyngeal infection. Fungal hyphae are broad (5- to 15-micron diameter) and irregularly branched and have rare septations, in contrast to molds such as *Aspergillus,* which are narrower, have regular branching, and have many septations.
- Bronchoalveolar lavage or bronchoscopy with biopsy for smear, culture, and histologic examination.
- Radiographs and other imaging studies such as CT of symptomatic sites may be required before infection is suspected and tissue specimens are obtained.
- It should be noted that serum tests that measure fungal cell wall components, such as the 1, 3-beta D glucan assay and the Aspergillus galactomannan assay used to diagnosis other invasive fungal diseases, will be negative in mucormycosis, as mucormycosis agents lack these cell wall components.

TREATMENT

- Aggressive correction of underlying disease (e.g., hyperglycemia, high steroid doses, use of immunosuppressive drugs) should be undertaken.
- Standard therapy consists of aggressive surgical debridement of involved tissues and antifungal therapy. For invasive mucormycosis recommended treatment is with a lipid formulation of amphotericin B that allows higher doses with less nephrotoxicity. The start dose is 5 mg/kg of liposomal amphotericin B or amphotericin B lipid complex. Doses as high as 10 mg/kg have also been used. Weeks of therapy are usually required.
- Traditional amphotericin B given IV at a daily dose of 1.0 to 1.5 mg/kg infused over 2 to 4 hr daily for a total of 1 to 4 g can also still be used, but is associated with significant nephrotoxicity and adverse reactions such as fever, chills, myalgias, vomiting, and electrolyte disturbances.
  1. Other antifungals do not appear to be effective except posaconazole, which may serve as an oral step-down therapy after amphotericin B at a dose of 400 mg bid with a fatty meal. Isavuconazole is another agent with efficacy in mucormycosis that, like posaconazole, comes in IV and oral formulation and can serve to transition patient from IV to PO.
  2. Some studies suggest that caspofungin with amphotericin B may be synergistic for *Rhizopus oryzae* infections only.
  3. The role of colony-stimulating factors remains unclear, beyond that of increas-

ing the neutrophil count in patients with neutropenia.
4. Hyperbaric oxygen has been used in some patients but its utility in therapy is still not clear.

PROGNOSIS

- Sinus infection with no underlying disease: 75% survival
- Sinus infection with diabetes: 60% survival
- Sinus infection with renal disease: 25% survival

BASIC INFORMATION

DEFINITION

These are gram-negative bacteria that are resistant to at least one antimicrobial in three or more antimicrobial classes (antipseudomonal penicillins, third-generation cephalosporins, fluoroquinolones, carbapenems, and aminoglycosides).

SYNONYMS

Carbapenem-resistant Enterobacteriaceae (CRE)
Extended-spectrum beta-lactamases (ESBL)
Multidrug-resistant gram-negative bacilli (MDR-GNB)
Multidrug-resistant organisms (MDRO)
New Delhi metallo-beta-lactamase-1 (NDM-1)

ICD-10CM CODES

Z16.10	Resistance to unspecified beta lactam antibiotics
Z16.30	Resistance to unspecified antimicrobial drugs

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: There is an increasing incidence of these bacteria in hospitals and long-term care facilities in the U.S. and around the world. ESBL bacteria were first discovered in Europe in 1984 and in the U.S. in 1988. CRE bacteria were first described in the late 1990s in the U.S. The NDM-1 bacteria were first noted in 2009 in Sweden in a patient from India.

PREDOMINANT SEX & AGE: These bacteria can be seen in any age group. They may be more frequent in women due to increased risk of urinary tract sepsis.

RISK FACTORS: In general, these bacteria are more common in hospitals and long-term care facilities, but they are spread nosocomially through patient care and thus are now entering the community, where the incidence is also increasing. Specific risk factors include:

- Length of stay in the hospital
- Length of ICU stay
- Use of central line catheters
- Abdominal surgery
- Presence of gastrostomy or jejunostomy tube
- Prior administration of any antibiotic
- Prior residence in a long-term care facility
- Presence of indwelling urinary catheter

PHYSICAL FINDINGS & CLINICAL PRESENTATION

All these resistant bacteria have the capability of causing diverse infections, including:

- Pneumonia
- Bacteremia
- Urinary tract sepsis
- Central line–associated infections
- Ventilator-associated pneumonia (VAP)
- Surgical site infections
- VAP from *A. baumannii* now accounts for 8.4% of GNR pneumonias in the ICU

ETIOLOGY

- Several different classes of MDR-GNRs exist based on their resistance mechanism.
  1. ESBL: These bacteria contain enzymes that break open the beta-lactam ring of penicillins, cephalosporins, and aztreonam and thus inactivate antibiotics from those classes. Enzymes conferring resistance include:
     a. TEM beta-lactamases
     b. SHV beta-lactamases
     c. CTX-M beta lactamases
     d. OXA beta-lactamases
     e. These enzymes are plasmid-mediated and thus can spread from one gram-negative bacteria to another, causing outbreaks in a single institution
  2. CRE: Enzymes conferring resistance include:
     a. Class A beta-lactamases: Encoded on chromosomes or plasmids (e.g., *Klebsiella pneumoniae* carbapenemase [KPC], which has caused outbreaks in hospitals around the world)
     b. Class B: Metallo-beta-lactamases (e.g., NDM-1). Encoded on a mobile plasmid that can spread to other gram-negative bacteria
     c. Class C and class D beta-lactamases
  3. *MCR-1* gene: In May 2016, the *MCR-1* gene was reported for the first time in *E. coli* from a patient (urine culture) in the U.S. This gene makes bacteria resistant to the antibiotic colistin, which is used to treat other MDR-GNR organisms. This raises the concern that this plasma-encoded gene could be spread to CRE bacteria.
- *Stenotrophomonas maltophilia:* MDR-GNR that acts as an opportunistic pathogen among mostly hospitalized patients with high morbidity and mortality. It has intrinsic or acquired resistance mechanisms to multiple antibiotic classes and has the ability to adhere to foreign materials and form a biofilm, which escapes host defenses.
- *Acinetobacter* sp. (e.g., *Acinetobacter baumannii*): Strains have emerged that are resistant to all commercially available antibiotics. These bacteria have the capability to acquire diverse mechanisms of resistance including:
  1. AmpC beta-lactamases
  2. Beta-lactamases: Serine and metallo-beta-lactamases

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other gram-negative rods such as:

- *Pseudomonas aeruginosa*
- *Klebsiella pneumoniae* that are not ESBL or CRE by resistance pattern
- *Morganella morganii*
- *Providencia, Proteus* sp., *Serratia*

WORKUP

- Detection of ESBL and CRE bacteria can pose problems for the clinical microbiology laboratory:
  1. To detect ESBL bacteria: Automated systems such as Vitek use disk diffusion or broth dilution techniques, or double disk test or E-test strip with clavulanate.
  2. To detect CRE: Modified Hodge test to detect carbapenemase-producing bacteria. Polymerase chain reaction testing, pulsed-field gel electrophoresis, and whole genome sequencing are useful for detecting CRE.
  3. In 2010, testing guidelines with respect to susceptibility involving several beta-lactam antibiotics were changed to better identify these bacteria via automated systems.

LABORATORY TESTS

Clinical testing is the same in infections from these resistant organisms as with nonresistant organisms:

- Cultures of any wounds, blood, sputum, urine, catheter tips
- CBC, liver function tests, urinalysis

TREATMENT

- Because of multidrug resistance, only a few reliable antibiotics are available to treat these infections.
  1. ESBL bacteria: Carbapenem antibiotics such as imipenem, meropenem, ertapenem, or the cephalosporin cefoxitin or tigecycline.
  2. CRE bacteria: Selection of antibiotic will depend on testing but tigecycline may be used clinically. Other alternatives include:
     a. IV colistin.
     b. *Stenotrophomonas maltophilia*: Only available agents are Bactrim (drug of choice), Levaquin, and minocycline.
     c. *A. baumannii*: Will depend on susceptibility testing, but ampicillin-sulbactam, imipenem or meropenem, or tigecycline can be used for MDR strains. For pan-resistant strains, IV colistin ± rifampin can be used. Inhaled colistin can be used for pneumonia patients.
     d. Newer antibiotics such as ceftolozane/tazobactam and ceftazidime/avibactam offer coverage for some of the resistant enzymes, but not all, and thus they require susceptibility testing to confirm.
     e. A next generation aminoglycoside plazomicin (Zemdri) was approved in 2018 for complicated urinary tract infections and has efficacy against CRE.

DISPOSITION

- Morbidity and mortality can be quite high with infections from these MDR bacteria.
  1. Nosocomial *Acinetobacter* pneumonia carries a mortality rate of 35% to 70%.
  2. *Stenotrophomonas* infections carry a mortality rate of 21% to 69%.
  3. ESBL infections carry a mortality rate of 3.7% despite therapy with carbapenem antibiotics.

Multifocal Atrial Tachycardia

BASIC INFORMATION

DEFINITION

Multifocal atrial tachycardia (MAT) is a supraventricular tachyarrhythmia (rate greater than 100 beats/min) with P waves having at least three or more different morphologies and irregular P-P, P-R, and R-R intervals. MAT is differentiated from atrial fibrillation by discrete P wave depolarizations and an isoelectric baseline between P waves.

SYNONYMS

MAT
Chaotic atrial rhythm
Chronic atrial tachycardia
Repetitive multifocal paroxysmal atrial tachycardia
Multifocal ectopic atrial tachycardia
The term *wandering pacemaker* is used for a similar arrhythmia associated with a normal or slow heart rate (<100 beats/min)

ICD-10CM CODE

I47.1 Supraventricular tachycardia

EPIDEMIOLOGY & DEMOGRAPHICS

Estimated prevalence in hospitalized patients of 0.05% to 0.32%. Average age is 70s. Usually associated with underlying pulmonary disease with right atrial electromechanical delay. Chronic obstructive pulmonary disease (COPD) is present in approximately 55% of patients with MAT. It may also be seen in patients with valvular heart disease, pulmonary hypertension, and hypomagnesemia.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Symptoms:
- Palpitation
- Lightheadedness
- Syncope
- Symptoms of the underlying pulmonary disease
- Physical findings associated with the underlying pulmonary disease

ETIOLOGY

- Exact mechanism unknown
- Potentially caused by right atrial distention such as in pulmonary hypertension due to underlying lung disease
- Exacerbated by underlying pulmonary disease (COPD, hypoxia, pulmonary embolism, pneumonia), cardiac disease, hypercarbia, acidosis, electrolyte disturbances

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Atrial fibrillation (up to 55% of patients with MAT will develop atrial fibrillation)
- Atrial flutter with variable AV conduction
- Sinus tachycardia
- Paroxysmal atrial tachycardia
- Sinus tachycardia with premature atrial or ventricular contractions

WORKUP

- ECG (Fig. 1)
- Chest x-ray
- Pulmonary function tests
- Electrolytes
- Arterial blood gases

TREATMENT

- Correction and/or improvement in the underlying pulmonary or metabolic dysfunction if possible.
- Avoid drugs such as theophylline, isoproterenol, etc.
- Electrolyte repletion, especially magnesium and potassium, to normal levels.
- Intravenous magnesium infusion may occasionally be helpful in patients with normal magnesium levels.
- Calcium channel blockers: Verapamil may be effective acutely and chronically and is often used as first line in patients with preserved LV function.
- β-blockers are typically contraindicated by obstructive lung disease or acute heart failure.
- If the arrhythmia is asymptomatic, it can be left untreated.
- Direct current cardioversion is ineffective.
- No significant role for antiarrhythmics or catheter ablation.
- Anticoagulation is not indicated, although some recent studies have linked frequent atrial ectopy on ambulatory monitoring with stroke risk.
- In extreme cases of refractory MAT in symptomatic patients who cannot tolerate medical therapy or in MAT resistant to medical therapy, AV nodal ablation with pacemaker implantation has been performed.
- Table E1 summarizes the treatment of multifocal atrial tachycardia.

SUGGESTED READINGS

Available at ExpertConsult.com

AUTHOR: **John Wylie, MD, FACC**

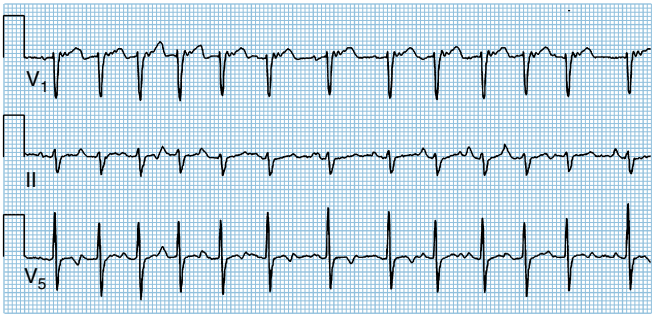

FIG. 1 Multifocal atrial tachycardia. This three-lead rhythm strip (leads V_1, II, and V_5) shows an irregularly irregular narrow QRS complex rhythm. However, unlike atrial fibrilation (AF), each QRS complex is preceded by discrete P waves. There are at least three different P wave morphologies and PR intervals, consistent with MAT. (From Olshansky B et al: *Arrhythmia essentials,* ed 2, Philadelphia, 2017, Elsevier.)

SUGGESTED READINGS

Link MS: Evaluation and initial treatment of supraventricular tachycardia, *N Engl J Med* 367:1438-1448, 2012.

Page RL et al: ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia, *J Am Coll Cardiol*, 2015.

TABLE E1 Multifocal Atrial Tachycardia Therapy

Acute therapy, stable and unstable	• Treat underlying condition. Aggressive treatment of COPD exacerbation usually treats arrhythmia, but MAT may persist for hours to days after management of the underlying condition is effective. Treatment of the MAT itself does not affect the course or prognosis of the medical illness. Avoid digoxin, as AV block and slowing of ventricular rate is unlikely to occur. DCC is ineffective in terminating the rhythm. • Cardioversion is of no benefit for MAT. However, AF may be confused with MAT; if the diagnosis is uncertain and the patient is hemodynamically unstable, cardioversion can be considered in selected cases. Hemodynamic instability generally results from the underlying medical condition and not from the rhythm or rapid rate per se. • Lower the dose of sympathomimetics and methylxanthines, as tolerated, if applicable. • Maintain K^+ and Mg^{2+} within normal limits. • Drugs to control ventricular rate (data on effectiveness are inconclusive): Preferred: Calcium blocker (IV or oral diltiazem). Verapamil can cause substantial hypotension in patients with COPD but may be effective. Ventricular rate control is difficult due to excess catecholamines for most of these patients. β-adrenergic blockers rarely can be given due to concurrent bronchospastic pulmonary disease. • IV magnesium 2- to 4-g bolus of magnesium sulfate may terminate the episodes and help control the ventricular rate, but success is limited and unpredictable. • Digoxin may worsen MAT and is unlikely to control the ventricular response. • Amiodarone can be considered to control ventricular rate and suppress the arrhythmia, but there are no data to support its use.
Chronic prevention	• Options include calcium channel blockers (e.g., oral diltiazem) for ventricular rate control or possibly amiodarone to prevent recurrences; drug therapy without aggressive treatment of the underlying condition is often futile. • Treat pulmonary disease; maintain K^+ >4.0 and Mg^{2+} >2.0, if possible.
MI	• Rapid rate and ineffective atrial kick (PR interval <0.14 s) can worsen ischemia and CHF. Rate control is often required. A calcium channel blocker such as diltiazem is the first-line therapy, unless β-adrenergic blockers can be tolerated.

AF, Atrial fibrillation; *AV,* atrioventricular; *CHF,* congestive heart failure; *COPD,* chronic obstructive pulmonary disease; *DCC,* direct current cardioversion; *IV,* intravenous; *MAT,* multifocal atrial tachycardia; *MI,* myocardial infarction.

BASIC INFORMATION

DEFINITION

Multiple endocrine neoplasia (MEN) refers to a group of heritable genetic syndromes characterized by the development of specific groups of tumors of the endocrine glands.

SYNONYMS

MEN I: Wermer syndrome
MEN IIA: Sipple syndrome

ICD-10CM CODES

E31.2	Multiple endocrine neoplasia [MEN] syndromes
E31.20	Multiple endocrine neoplasia [MEN] syndrome, unspecified
E31.21	Multiple endocrine neoplasia [MEN] syndrome type I
E31.22	Multiple endocrine neoplasia [MEN] syndrome type IIA
E31.23	Multiple endocrine neoplasia [MEN] syndrome type IIB

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- MEN I: 25 in 10,000
- MEN II: 1 in 30,000

PREVALENCE:

- MEN I: 1/30,000
- MEN II: 1/35,000 (predominantly MEN IIA)

GENETICS:

- MEN I: Autosomal-dominant mutation in MEN1 tumor-suppressor gene
- MEN IIA and MEN IIB: Autosomal-dominant mutations in RET proto-oncogene

RISK FACTORS: Family history of MEN syndrome, although it can also occur sporadically

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients may present due to screening or may present with a MEN-associated tumor. Tumors are found incidentally due to biochemical abnormalities or to symptoms.
- MEN I (PPP [pituitary, pancreas, parathyroid])
  1. Diagnostic criteria generally include two MEN-associated tumors, one tumor in a patient with a family history, or positive genetic testing.
  2. Primary hyperparathyroidism (parathyroid adenoma or hyperplasia) is the most common manifestation and can cause hypercalcemia (urolithiasis, GI disturbance, bone pain, neuropsychiatric disturbances).
  3. Pancreatic neuroendocrine tumors cause symptoms related to their secretory properties or metastases.
     a. Gastrinoma: Peptic ulcers, diarrhea, esophageal symptoms (see "Gastrinoma")
     b. Insulinoma: Hypoglycemic symptoms upon fasting and after exercise (see "Insulinoma")
     c. Glucagonoma: Necrolytic migratory erythema (a blistering skin lesion), diabetes/glucose intolerance, weight loss
     d. VIPoma: Diarrhea, hypokalemia, decreased gastric acid
     e. Nonfunctioning tumors can metastasize (frequently to the liver), a frequent cause of death in MEN I
  4. Pituitary tumors may cause compressive symptoms, such as visual field defects or hypopituitarism (see "Pituitary Adenoma"). Hormonal secretion may also cause symptoms.
     a. Prolactinoma (most common pituitary tumor in MEN I): Menstrual irregularities, sexual dysfunction, gynecomastia, and/or galactorrhea (see "Prolactinoma").
     b. Somatotroph adenomas (producing growth hormone): Gigantism or acromegaly (frontal bossing, increased shoe/hat size, hyperglycemia, hyperhidrosis) depending on patient age (see "Acromegaly").
     c. Corticotroph adenomas (producing adrenocorticotropic hormone): Cushingoid features such as weight gain, moon facies, hyperglycemia, bone loss, proximal muscle weakness, hypertension, hypokalemia (see "Cushing Disease and Syndrome").
     d. Nonfunctioning (nonsecretory) tumors.
  5. Other manifestations: Carcinoid tumors, collagenomas, angiofibromas, meningiomas, lipomas.
- MEN IIA:
  1. Medullary thyroid carcinoma (MTC) is a tumor of the thyroid's calcitonin-secreting C cells. It can present with a neck mass, as well as flushing and diarrhea due to elevated calcitonin levels.
  2. Primary hyperparathyroidism: See MEN I. Less aggressive in MEN IIA.
  3. Pheochromocytoma is an adrenal tumor producing catecholamines, which can lead to life-threatening hypertensive crises.
- MEN IIB:
  1. Medullary thyroid carcinoma (MTC)
  2. Pheochromocytoma
  3. Oral mucosal neuromas

ETIOLOGY

Tumor development facilitated by the previously described genetic mutations (Table E1).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Tumors associated with MEN may occur sporadically.

WORKUP

- MEN I: Note that opinions vary regarding the aggressiveness and frequency of screening for MEN-associated tumors.
  1. Genetic testing: Offered to patients meeting MEN I clinical criteria or to patients in whom there is high suspicion, as well as to first-degree relatives of MEN I patients.
  2. Hyperparathyroidism screening: Parathyroid hormone (PTH) and calcium annually.
  3. Pancreatic tumor screening: Annual pancreas imaging (endoscopic ultrasonography, CT, or MRI) and annual biochemical testing (glucose, gastrin, vasoactive intestinal peptide [VIP], glucagon, insulin, pancreatic polypeptide, chromogranin A). Notably, Gallium-68 DOTATATE PET-CT is an exciting new tool for neuroendocrine tumor localization, though it is not typically utilized in screening at this time.
  4. Pituitary tumor screening: Insulin-like growth factor 1 (IGF-1) and prolactin annually and pituitary MRI every 3 to 5 yr.
  5. Carcinoid tumor screening: Chest CT or MRI every 2 yr.
- MEN IIA:
  1. Genetic testing: At-risk members of families with known RET mutations should undergo screening for the specific mutation. Patients with MTC should have genetic testing of the tumor and genetic testing based on results. Cutaneous lichen amyloidosis (a skin finding) should prompt testing; Hirschsprung disease may also prompt testing.
  2. Hyperparathyroidism screening: PTH and calcium annually.
  3. Pheochromocytoma: Plasma catecholamines and metanephrines annually for screening, age to begin depending on specific mutation; CT and MRI may localize; I-123 and PET (possibly including Gallium-68 DOTATATE PET-CT) also helpful for localization.
  4. MTC screening: Depends on risk category; physical exam, neck ultrasound, and calcitonin level yearly; carcinoembryonic antigen may also be indicated.
- MEN IIB:
  1. Genetic testing: See MEN IIA
  2. Pheochromocytoma: See MEN IIA
  3. MTC screening: Although there may be a role for monitoring, prophylactic thyroidectomy is typically performed early

LABORATORY TESTS

See "Workup."

IMAGING STUDIES

See "Workup."

TREATMENT

No therapy to reverse the underlying cause. Treatment (both medical and surgical) focuses on tumor prevention and management.

NONPHARMACOLOGIC THERAPY

- MEN I:
  1. For hyperparathyroidism, surgical parathyroidectomy is indicated in patients with significant hypercalcemia, osteoporosis, renal disease, or nephrolithiasis or found to be at high risk for nephrolithiasis. Hyperparathyroidism may be treated surgically with subtotal or total

parathyroidectomy, which may include gland reimplantation at an alternate site.
2. Pituitary tumors may be surgically excised via transsphenoidal approach; notably, medical therapy is first line for prolactinoma.
3. Pancreatic tumor treatment is extremely variable. Gastrinoma is frequently complicated by duodenal metastases, which are difficult to treat surgically. Ulcers caused by gastrinoma may require endoscopic or surgical management. Surgery is preferred for insulinoma, VIPoma, and glucagonoma. Nonfunctioning tumors may be treated surgically depending on tumor size and location. Conservative management for insulinoma may involve frequent carbohydrate intake.

- MEN IIA:
  1. MTC is generally treated surgically. Prophylactic thyroidectomy is considered based on genetic mutation. Almost all children with MEN IIA will require thyroidectomy (screening as previously described). Patients should undergo ultrasound and total thyroidectomy with cervical lymph node dissection. Extent of further neck dissection depends on metastases and may be guided by calcitonin levels. A more palliative surgical approach is considered in the setting of advanced disease.
  2. Hyperparathyroidism: Resection of only enlarged glands with intraoperative PTH monitoring is preferred.
  3. Pheochromocytoma is treated surgically. Unilateral adrenalectomy is preferred, although many patients will develop a contralateral pheochromocytoma. Preoperative blood pressure control with alpha blockade is key. If present, pheochromocytoma must be removed before thyroidectomy.
- MEN IIB:
  1. MTC: Prophylactic thyroidectomy offered in childhood.
  2. Pheochromocytoma: See MEN IIA.

ACUTE GENERAL Rx

- MEN I:
  1. Hyperparathyroidism causes hypercalcemia that may be treated with IV hydration, diuretics, and bisphosphonates. Early vitamin D repletion prevents bone destruction postoperatively.
  2. Gastrinoma may lead to peptic ulcers requiring IV proton-pump inhibitor (PPI).
  3. Supportive care (glucose for hypoglycemia caused by insulinoma; fluids and electrolytes for hypovolemia caused by diarrhea from VIPoma or gastrinoma) is required.
- MEN IIA:
  1. Hyperparathyroidism: See "MEN I."
  2. Pheochromocytoma: Preoperative blood pressure control is key; alpha blockers are first line. Phenoxybenzamine irreversibly blocks alpha adrenergic receptors; doxazosin is also first line. Calcium channel blockers and then beta-blockers can be added if needed.
- MEN IIB:
  1. Pheochromocytoma: See "MEN IIA."

CHRONIC Rx

- MEN I:
  1. Hyperparathyroidism may be amenable to agonists of the calcium-sensing receptor (cinacalcet), although surgery is preferred in patients who meet surgical criteria and are operative candidates.
  2. Pancreatic tumors may benefit from medical therapy.
     a. Gastrinoma: PPI or H2 antagonists
     b. Insulinoma: Diazoxide or somatostatin agonists (such as octreotide)
     c. Glucagonoma and VIPoma: Somatostatin agonists
  3. Pituitary tumors may be treated medically although surgical treatment is first-line with the exception of prolactinoma (for which medical therapy is first line). Radiation therapy and/or medical therapy are considered in cases of incomplete resection or regrowth.
     a. Prolactinoma: Dopamine agonists (bromocriptine or cabergoline)
     b. Somatotroph adenoma: Somatostatin or dopamine agonists, growth hormone receptor antagonists
     c. Corticotroph adenoma: Antiadrenal agents, adrenal enzyme blocker (such as ketoconazole), somatostatin or dopamine agonists, glucocorticoid receptor blockers
  4. MEN II A:
     a. Hyperparathyroidism: See "MEN I."
     b. MTC: Tyrosine kinase inhibitors and chemotherapy may help treat metastatic disease. After thyroidectomy, levothyroxine is indicated (TSH suppression not required).

COMPLEMENTARY & ALTERNATIVE MEDICINE

MEN is unlikely to be amenable to this.

DISPOSITION

Most workup can be done as an outpatient (multidisciplinary team); inpatient stays may be required due to acute complications or for surgical procedures.

REFERRAL

Patients with MEN should be followed by a multispecialty team, including endocrinologists, endocrine surgeons, and genetic counselors.

PEARLS & CONSIDERATIONS

COMMENTS

MEN is a group of genetic syndromes that requires close monitoring and intervention to prevent and treat tumor development, as well as genetic counseling of patients and family members.

PREVENTION

Prevention focuses on screening for MEN in persons at risk and early identification of MEN-associated tumors.

BASIC INFORMATION

DEFINITION

Multiple myeloma (MM) is a plasma cell neoplasm characterized by clonal proliferation of malignant plasma cells in the bone marrow, monoclonal protein in the blood or urine, and associated end-organ dysfunction. The transition from normal cells to genomic instability is not well understood, but current evidence suggests that antigenic stimulation may be a key factor (Fig. E1). Diagnostic criteria for the diagnosis of MM was revised by the International Myeloma Working Group (IMWG) in 2014 and now requires the following:

- Presence of ≥10% plasma cells on examination of the bone marrow (or biopsy of a tissue with monoclonal plasma cells) and any one or more of the following myeloma-defining events:
  1. Evidence of end-organ damage (calcium elevation, renal insufficiency, anemia, or bone lesions [CRAB criteria])
  2. Clonal bone marrow plasma cell percentage ≥60%
  3. Involved: Uninvolved serum free light ratio ≥100
  4. >1 focal lesion on MRI studies

SYNONYM

MM

ICD-10CM CODES

C90.00	Multiple myeloma not having achieved remission
C90.01	Multiple myeloma in remission
C90.02	Multiple myeloma in relapse

EPIDEMIOLOGY & DEMOGRAPHICS

ANNUAL INCIDENCE:

- Five cases/100,000 persons (African Americans affected twice as frequently as whites, males more than females).
- MM accounts for 10% of all hematologic cancers and is the most common primary bone malignancy.
- More than 30,770 new cases and 12,770 deaths occurred in 2018 in the U.S.

PREDOMINANT AGE: The peak incidence is in the seventh decade at a median age of 70 yr.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The patient usually comes to medical attention because of one or more of the following:

- Bone pain (58%) commonly in the back and thorax or pathologic fractures (30%) caused by osteolytic lesions
- Anemia from bone marrow infiltration by plasma cells
- Recurrent infections as a result of impaired neutrophil function and deficiency of normal immunoglobulins (humoral deficiency)
- Nausea and vomiting caused by constipation and uremia
- Delirium resulting from hypercalcemia
- Neurologic complications, such as spinal cord or nerve root compression, blurred vision from hyperviscosity
- Purpura, epistaxis from thrombocytopenia
- Paresthesias, weight loss, generalized weakness

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Metastatic carcinoma to bone marrow
- Lymphoma, non-Hodgkin
- Bone neoplasms (e.g., sarcoma)
- Monoclonal gammopathy of undetermined significance
- Primary amyloidosis
- Waldenström macroglobulinemia
- Table 1 compares diagnostic criteria for multiple myeloma, myeloma variants, and monoclonal gammopathy of unknown significance (MGUS)

LABORATORY TESTS

- The evaluation of patients with multiple myeloma is summarized in Table 2.
- Normochromic, normocytic anemia; rouleaux formation on peripheral smear (Fig. 2).

TABLE 1 Diagnostic Criteria for Multiple Myeloma, Myeloma Variants, and Monoclonal Gammopathy of Unknown Significance

Monoclonal Gammopathy of Undetermined Significance (MGUS) or Monoclonal Gammopathy, Unattributed/Unassociated (MG[u])

M protein in serum <30 g/L
Bone marrow clonal plasma cells <10%
No evidence of other B-cell proliferative disorders
No myeloma-related organ or tissue impairment (no end-organ damage, including bone lesions)

Asymptomatic Myeloma (Smoldering Myeloma)

M protein in serum >30 g/L and/or
Bone marrow clonal plasma cell ≥10%-60%
No related organ or tissue impairment (no end-organ damage, including bone lesions) or symptoms

Symptomatic Multiple Myeloma (MM)

M protein in serum and/or urine[a]
Bone marrow (clonal) plasma cells[a] or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)
Clonal bone marrow plasma cell percentage ≥60%
Involved: Uninvolved serum free light ratio ≥100
>1 focal lesion on MRI studies

Solitary Plasmacytoma of Bone

No M protein in serum and/or urine[b]
Single area of bone destruction caused by clonal plasma cells
Bone marrow not consistent with MM
Normal skeletal survey (and MRI of spine and pelvis if done)
No related organ or tissue impairment (no end-organ damage other than solitary bone lesion)[b]

Nonsecretory Myeloma

No M protein in serum and/or urine with immunofixation
Bone marrow clonal plasmacytosis ≥10% or plasmacytoma
Related organ or tissue impairment (end-organ damage, including bone lesions)

Extramedullary Plasmacytoma

No M protein in serum and/or urine[c]
Extramedullary tumor of clonal plasma cells
Normal bone marrow
Normal skeletal survey
No related organ or tissue impairment (end-organ damage including bone lesions)

Multiple Solitary Plasmacytomas (Recurrent or Not)

No M protein in serum and/or urine[d]
More than one localized area of bone destruction or extramedullary tumor of clonal plasma cells that may be recurrent
Normal bone marrow
Normal skeletal survey and MRI of spine and pelvis if done
No related organ or tissue impairment (no end-organ damage other than the localized bone lesions)

Myeloma-Related Organ or Tissue Impairment (End-Organ Damage)

Calcium levels increased: Serum calcium >0-25 mmol/L above the upper limit of normal or >2-75 mmol/L
Renal insufficiency: Creatinine >173 mmol/L
Anemia: Hemoglobin 2 g/dl below the lower limit of normal or hemoglobin <10 g/dl
Bone lesions: Lytic lesions or osteoporosis with compression fractures (MRI or CT may clarify)
Other: Symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (more than two episodes in 12 mo)

[a]If flow cytometry is performed, most plasma cells (>90%) will show a neoplastic phenotype.
[b]A small M component may sometimes be present.
[c]A small M component may sometimes be present.
[d]A small M component may sometimes be present.
CT, Computed tomography; *MRI,* magnetic resonance image.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE 2 Evaluation of Patients with Multiple Myeloma

Evaluation for Diagnosis

Evaluation for Monoclonal Protein

Serum protein electrophoresis, immunofixation
Quantitative immunoglobulin by nephelometric method
24-hour urine collection for electrophoresis and Bence Jones protein assessment and immunofixation
Serum free light chain and ratio

Evaluation for Clonal Plasma Cells

Bone marrow aspirate and biopsy for
Histology
Clonality by immunostaining or flow cytometry by κ/λ staining
Fine-needle aspiration of plasmacytoma if indicated

Evaluation for End-Organ Damage

Hemogram to detect anemia
Chemistry panel for renal function and calcium
Radiologic evaluation: Skeletal survey
PET-CT or MRI as indicated for bone lesions or extramedullary disease

Evaluation for Risk Stratification

β_2-Microglobulin and serum albumin for ISS stage
Cytogenetics and fluorescence in situ hybridization on bone marrow sample
LDH
C-reactive protein

Other Investigations for Selected Patients

Abdominal fat pad or rectal biopsy for amyloid
Solitary lytic lesion biopsy
Serum viscosity if IgM component or high IgA levels or serum M component >7 g/dl
Immunofixation for IgD or IgE in select cases

CT, Computed tomography; *Ig,* immunoglobulin; *ISS,* International Staging System; *LDH,* lactate dehydrogenase; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

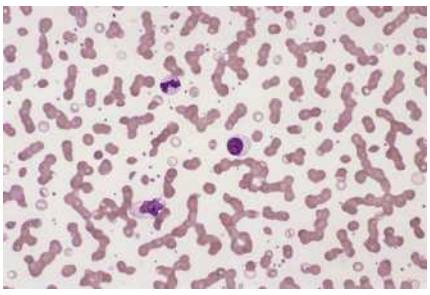

FIG. 2 Increased rouleaux formation is seen in this blood smear from a patient with a large M protein. Marked rouleaux formation is often a clue to the diagnosis of a plasma cell neoplasm but may also be observed in other conditions (Wright-Giemsa stain). (From Jaffe ES et al: *Hematopathology,* Philadelphia, 2011, WB Saunders.)

- Hypercalcemia is present in 15% of patients at diagnosis.
- Elevated blood urea nitrogen, creatinine, uric acid, and total protein.
- Urine protein immunoelectrophoresis: Proteinuria from overproduction and secretion of free monoclonal kappa or lambda chains (Bence Jones protein).
- Serum protein immunoelectrophoresis: Monoclonal spike (M spike) on protein immunoelectrophoresis in approximately 75% of patients (Fig. 3); decreased levels of normal immunoglobulins (Ig).
  1. The increased immunoglobulins are generally IgG (70%) and IgA (20%).
  2. Approximately 5% to 10% of patients have only increased light chains in the urine by electrophoresis (light chain MM).
  3. A small percentage (<2%) of patients have nonsecretory MM (no increase in immunoglobulins and no light chains in the urine) but have other evidence of the disease (e.g., positive bone marrow examination).
- Elevated serum free light chains (kappa or lambda types) with abnormally elevated or decreased kappa:lambda ratios suggestive of the presence of monoclonal light chain proteins.
- Hyponatremia, increased serum viscosity (more common with production of IgM).
- Bone marrow examination demonstrates nests or sheets of plasma cells, which comprise >10% of the bone marrow.
- Serum beta 2-microglobulin is useful for prognosis, and elevated levels indicate high tumor mass and advanced stage disease.
- Elevated serum lactate dehydrogenase at diagnosis defines a subgroup of myeloma patients with very poor prognosis.
- Nearly all patients with MM present with abnormal chromosomes (Table 3) identified by fluorescence in situ hybridization (FISH). High-risk patients (<25% of patients at diagnosis) are those with any of the following: Deletion 17p, translocation 4:14, translocation 14:16, translocation 14;20, and gain of chromosome 1q21.

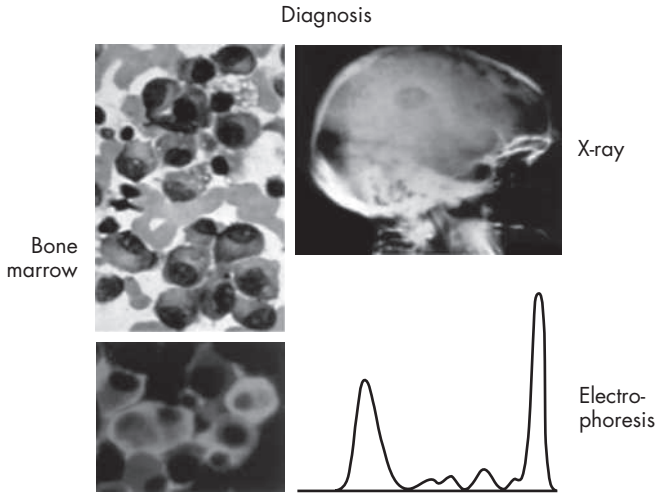

FIG. 3 Common diagnostic features in multiple myeloma. Light chain–restricted plasma cells in a bone marrow aspirate; multiple lytic lesions in a skull radiograph; large monoclonal spike in the g-globulin area in serum electrophoresis. (From Hoffman R et al: *Hematology, basic principles and practice,* ed 5, Philadelphia, 2009, Churchill Livingstone.)

IMAGING STUDIES

Imaging modalities for disease assessment in myeloma are summarized in Table 4. Radiograph films of painful areas often demonstrate punched-out lytic lesions or osteoporosis (Figs. 3, E4, E5, and E6). CT can identify rib involvement not evident on plain films and differentiate it from osteoporotic and traumatic fractures (Fig. E7). MRI is the preferred technique for suspected spinal compression or soft tissue plasmacytomas. Bone scans may not be useful because MM lesions are not blastic. Positron emission tomography scans are increasingly used for detection of osseous and extraosseous disease.

STAGING

Table 5 describes the Revised International Staging System (R-ISS) for multiple myeloma that incorporates traditional laboratory parameters alongside high-risk chromosomal abnormalities detected by FISH techniques on bone marrow samples. This system provides important prognostic assessment and classifies patients into three risk groups (high, intermediate, and standard). Risk stratification in multiple myeloma is summarized in Tables 6 and 7.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

Prevention of renal failure with adequate hydration and avoidance of nephrotoxic agents and dye contrast studies.

ACUTE GENERAL Rx

- Treatment strategy is initially related to the determination of transplant-eligible patients.
- All transplant-eligible patients should be considered for approximately 12 wk of induction chemotherapy with triplet regimens such as the VRD regimen (bortezomib, lenalidomide, and dexamethasone) or the CyBorD regimen (cyclophosphamide, bortezomib, and dexamethasone). Upon demonstration of at least a very good partial response, these patients can undergo stem cell mobilization and collection.

- All patients with high-risk features (high R-ISS stage, poor cytogenetics) should be offered autologous stem cell transplant (ASCT) subsequently, provided they have adequate cardiac, pulmonary, and hepatic function. Currently, ASCT can be safely performed in most centers in fit patients up to age 75 yr. Although recent data do not clearly demonstrate superior survival with upfront transplantation in the current era, ASCT is associated with significantly longer progression-free survival.
- Patients should be offered maintenance chemotherapy with either lenalidomide and/or bortezomib after recovery from ASCT for at least 2 yr or until disease progression. The choice of maintenance therapy depends on risk category.
- Induction chemotherapy in patients ineligible for transplantation (age >75 yr, high comorbidity index, poor performance status) can be identical to that offered transplant-eligible patients but is dose modified to allow for better tolerability. Daratumumab is a monoclonal antibody targeting CD38, which has recently been approved in combination with lenalidomide and dexamethasone in transplant-ineligible myeloma. Alternatively, less aggressive regimens (doublet regimens or single agents) can be recommended, including the following:
  1. Lenalidomide and dexamethasone (RD)
  2. Bortezomib and dexamethasone (VD)
- Therapy for relapsed and refractory myeloma can include second- or third-generation proteasome inhibitors (carfilzomib and ixazomib), immunomodulatory drugs (thalidomide, pomalidomide), and monoclonal antibodies elotuzumab (targeting signaling lymphocytic activation molecule F7 [SLAMF7]) and daratumumab. All of these agents have shown improved progression-free survival in relapsed or refractory multiple myeloma in various combinations and are useful options in this setting. The histone deacetylase inhibitor panobinostat is also approved in this setting, along with recent drug approval of nuclear protein transport inhibitor selinexor.
- If the relapse occurs more than 6 mo after conventional therapy is stopped, the initial chemotherapy regimen can be reinstituted.
- ASCT can be considered as salvage therapy in patients who had stem cells cryopreserved early in the course of the disease.
- Approximately 15% of patients with newly diagnosed MM are recognized incidentally and present without significant symptoms (asymptomatic MM, formerly known as smoldering myeloma). The rate of progression of smoldering MM to symptomatic disease is 10% per yr for the initial 5 yr, decreasing to 5% for the next 5 yr, and decreasing further to 1.5% per yr thereafter. Observation alone is reasonable in these patients because no survival advantage has been demonstrated by treating them.
- An exception to this may be in high-risk smoldering myeloma patients. Two phase III trials have shown that early treatment with lenalidomide with or without dexamethasone in patients with high-risk smoldering myeloma delays progression to active disease.

TABLE 3 Recurrent Cytogenetic Changes in Myeloma

Chromosomal Abnormality	Patients (%)	Genes Involved
Common Cytogenetic Alterations		
Hyperdiploidy	50-60	Unclear
Hypodiploid	20	Unclear
Pseudodiploid	15	Unclear
del(17p)	8	p53
t(4:14)	15	*FGFR3*, *MMSET*
t(11;14)	20	Cyclin D1
t(14;16)	3	*c-MAF*
t(14;20)	1	*MAFB*
t(6p25 or 6p21;14)	1	*IRF4* or *CCND3*
t(8;14)	5	*c-Myc*
t(9;14)	<1%	*PAX5*
del(13 or 13q)	50%	Unclear
Recently Identified Alterations		
1q+	35%	
1p–	30%	
5q+	50%	
12p–	10%	

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

CHRONIC Rx

- Promptly diagnose and treat infections. Common bacterial agents are *Streptococcus pneumoniae* and *Haemophilus influenzae.* Prophylactic therapy against *Pneumocystis jiroveci* with trimethoprim-sulfamethoxazole must be considered in patients receiving chemotherapy and high-dose corticosteroid regimens. Vaccinate against *S. pneumoniae,* influenza, and *H. influenzae.*

TABLE 4 Imaging Modalities for Disease Assessment in Myeloma

	Use	Sensitivity/Specificity	False-Negatives	False-Positives
Bone scan	• For diagnostic screening, except for multiple myeloma	Varies	• Pure osteolytic lesions	• Trauma • Inflammation • Benign tumor • Healing
X-ray	• Can clarify nonspecific findings on bone scan • Assesses risk of fracture • Possible follow-up of tumor response, but evidence of response takes considerable time to appear	Low sensitivity	• Low disease burden • Osteopenia	• Trauma • Inflammation • Benign tumor • Healing
CT	• For anatomic detail in axial skeleton • Possible follow-up of tumor response, but role is still undefined	High sensitivity	• Low disease burden	• Trauma • Inflammation • Benign tumor • Healing
MRI	• Detection of spinal cord compression • Can help distinguish benign from malignant vertebral compression fracture • Possible follow-up of tumor response, but role is still undefined	High sensitivity and specificity	• Lesion only in cortex	• Edema
PET scan	• May eventually become first-line screening test for bone metastases • Possible follow-up of tumor response, but role is still undefined	High specificity	• Lesion only in cortex	• After chemotherapy
Bone density	• Measure osteoporosis • Response to bisphosphonates	High specificity and sensitivity		• Age-related osteoporosis

CT, Computed tomography; *MRI,* magnetic resonance imaging; *PET,* positron emission tomography.

TABLE 5 Revised International Staging System (R-ISS) for Multiple Myeloma Staging System

Stage	Criteria
I	ALL of the following: • Serum β-2 microglobulin <3.5 mg/L • Serum albumin >3.5 mg/dl • no high-risk chromosomal abnormalities by FISH • Normal LDH level
II	• Fitting neither stage I nor III
III	• Serum β-2 microglobulin >5.5 mg/L *AND* either elevated LDH *OR* high-risk chromosomal abnormalities by FISH [(del 17(p) and/or translocation t(14;16) and/or translocation t(4;14)]

FISH, Fluorescence in situ hybridization; *LDH,* lactate dehydrogenase.

TABLE 6 Risk Stratification in Multiple Myeloma

Investigations Recommended for Risk Stratification
Serum albumin and β_2-microglobulin to determine ISS stage
Bone marrow examination for t(4;14), t(14;16), and del(17p) on identified PCs by FISH
LDH
Immunoglobulin type: IgA
Histology: Plasmablastic disease or plasma cell leukemia
Additional Investigations for Risk Stratification
Cytogenetics
Gene expression profiling
Labeling index
MRI/PET scan
DNA copy number alteration by CGH/SNP array

CGH/SNP, Comparative genomic hybridization/single-nucleotide polymorphism; *DNA,* deoxyribonucleic acid; *FISH,* fluorescence in situ hybridization; *IgA,* immunoglobulin A; *ISS,* International Staging System; *LDH,* lactate dehydrogenase; *MRI,* magnetic resonance imaging; *PC,* plasma cell; *PET,* positron emission tomography.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE 7 Standard Risk Factors for Multiple Myeloma and the Revised International Staging System

Prognostic Factor	Criteria
ISS stage	
I	Serum β_2-microglobulin <3.5 mg/L, serum albumin ≥3.5 g/dl
II	Not ISS stage I or III
III	Serum β_2-microglobulin ≥5.5 mg/L
CA by iFISH	
High risk	Presence of del(17p) and/or translocation t(4;14) and/or translocation t(14;16)
Standard risk	No high-risk CA
LDH	
Normal	Serum LDH below the upper limit of normal
High	Serum LDH above the upper limit of normal
A New Model for Risk Stratification for MM R-ISS stage	
I	ISS stage I and standard-risk CA by iFISH and normal LDH
II	Not R-ISS stage I or III
III	ISS stage III and either high-risk CA by iFISH or high LDH

CA, Chromosomal abnormalities; *iFISH,* interphase fluorescence in situ hybridization; *ISS,* International Staging System; *LDH,* lactate dehydrogenase; *MM,* multiple myeloma; *R-ISS,* Revised International Staging System.
From Greipp PR et al: International staging system for multiple myeloma, *J Clin Oncol* 23:3412, 2005. In Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

- Hypercalcemia is aggressively treated with IV fluids, bisphosphonates, and corticosteroids. Monthly infusions of the bisphosphonate pamidronate or zoledronate provide significant protection against skeletal complications and improve the quality of life of patients with advanced MM. The receptor activator of nuclear factor kappa B (RANK)-ligand inhibitor denosumab is effective in the treatment of hypercalcemia in this setting and in cases in which bisphosphonates are contraindicated (e.g., renal failure). Denosumab has also been studied in a large phase III study and has been shown to be noninferior to zoledronicacid.
- Control pain with analgesics; radiation therapy to treat painful bone lesions or cord compression. Perform surgical stabilization of pathologic fractures. Consider vertebroplasty or kyphoplasty for selected vertebral lesions.
- Anemia is treated with erythropoietin.

DISPOSITION

- In patients presenting at an age <60 yr, the 10-yr survival is approximately 30%. The median length of survival after diagnosis is now 7 to 8 yr and is rapidly increasing due to novel agents. Prognosis is better in asymptomatic patients with indolent or smoldering myeloma. Median survival time is approximately 10 yr in persons with no lytic bone lesions and a serum myeloma protein concentration <3 g/dl. Adverse outcome is associated with increased levels of beta-2 microglobulin, low levels of serum albumin, circulating plasma cells, plasmablastic features in bone marrow, increased plasma cell labeling index, poor cytogenetics (t (4;14) or t (14;16) translocation, deletion 17p).
- Tandem transplantation (two successive ASCT) improves survival among patients with MM who do not have a very good partial response after undergoing a single transplantation.
- Recent trials reveal that among patients with newly diagnosed myeloma, survival in recipients of a hematopoietic stem cell autograft followed by a stem cell allograft from an human leukocyte antigen (HLA)-identical sibling is superior to that in recipients of tandem stem cell autografts.

REFERRAL

To hematologist for management of disease, and bone marrow transplant specialist for transplantation options and management.

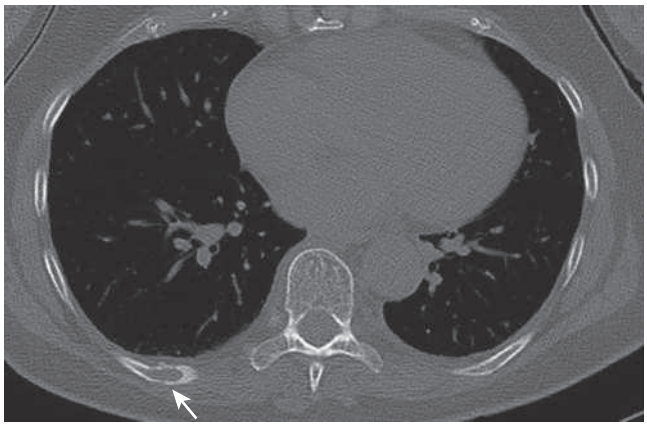

FIG. E7 Rib involvement in multiple myeloma *(arrow).* There is thinning of the cortex and enlargement of a circumscribed area of the rib. Soft tissue Hounsfield units are noted within the lesion. In contrast with osteoporotic or traumatic fractures of the rib, no callous formation is seen. In a whole-body examination, every single rib must be screened by scrolling through it posteriorly to anteriorly. (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2015, WB Saunders.)

BASIC INFORMATION

DEFINITION

Multiple sclerosis (MS) is a chronic predominantly autoimmune demyelinating disease of the central nervous system (CNS) characterized by subacute neurologic deficits correlating with CNS lesions separated in time and space, excluding other possible disease.

Subtypes include:

- **Relapsing-remitting MS (RRMS)** (82%): Relapses followed by complete or near-complete recovery, 50% to 85% of which later transition to SPMS
- **Secondary progressive MS (SPMS):** Progression of disability with few or no relapses
- **Primary progressive MS (PPMS)** (18%): Progression from the onset, rare relapses
- Progressive relapsing or relapsing progressive courses can be incorporated into PPMS or SPMS, respectively
- Relapses are defined as a subacute onset of neurologic dysfunction that lasts for at least 24 hr due to inflammatory demyelination

Classic rare MS variants include:

- **Marburg variant:** MRI reveals a tumor-like lesion with notable edema in one cerebral hemisphere. Pathology shows severe inflammation with necrosis: Typically acute onset with a fulminant, often malignant, course. May also involve peripheral nerves.
- **Balo concentric sclerosis:** Neuroimaging and pathology show alternating rings of myelination and demyelination resembling an onion bulb macroscopically and microscopically.
- **Schilder diffuse sclerosis:** Childhood onset with one to two large confluent lesions. Some cases were later found to be due to metabolic defects, and many have thus abandoned this disorder.

Neuromyelitis optica spectrum disorder (NMOSD): NMOSD is a distinct demyelinating disease with unique pathophysiology, treatment, and prognosis. Unlike MS, NMOSD usually involves extensive portions of the optic nerves and spinal cord (typically three or more spinal segments). Other areas of the CNS may also be involved, including the area postrema (presenting with intractable hiccups or nausea/vomiting), the brainstem, or the cerebral cortex. Additionally, patients may present with symptomatic narcolepsy. The lesions look very different on MRI than typical MS demyelinating lesions. The majority of patients are aquaporin-4 receptor Ab positive (NMO immunoglobulin G [IgG] positive) while some are antibody negative or are myelin oligodendrocyte glycoprotein Ab positive (MOG-IgG positive), which has a better prognosis. The actual diagnostic criteria for NMOSD vary depending on the patient's aquaporin-4 receptor antibody status. Prognosis is typically worse than MS, and this condition does not respond to MS-specific therapies. Steroids, plasma exchange, rituximab, mycophenolate mofetil, and azathioprine are among the treatments that may be used.

SYNONYMS

MS
Disseminated sclerosis

ICD-10CM CODE
G35 Multiple sclerosis

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: 20 to 40 yr in two thirds of patients; it is the most common permanently disabling disorder of the central nervous system in young adults; mean age of onset is 30 yr, range is infancy to 70 yr.

PREVALENCE: More common in people raised in northern latitudes and in certain genetic clusters. Prevalence per 10,000 varies from 20 in southern Europe to 150 to 180 in Canada, northern United States, and northern Europe; and <10 in Asia, Central America, and most of Africa.

PREDOMINANT SEX & AGE: Female/male ratio is 2 to 3:1.

GENETICS: Frequency of MS in dizygotic twins and siblings is 3% to 5%, and 20% to 40% in monozygotic twins. Most common associations include human leukocyte antigen classes I and II *(DRB1*1501, DQA1*0102, DQB1*0602),* (*DRB1*0405-DQA1*0301-DQB1*0302* in Mediterranean population). A notable epigenetic interaction between vitamin D and the main MS-linked HLA-DRB1*1501 allele has been elucidated.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Findings depend on the location of the CNS lesion(s) and may include the following:

- Common: Nonspecific complaints such as fatigue, blurred vision, diplopia, vertigo, falls, hemiparesis, paraparesis, monoparesis, numbness, paresthesias, ataxia, cognitive deficits, depression, sexual dysfunction, and urinary dysfunction
- Visual abnormalities: Horizontal nystagmus, visual field defects, ***Marcus Gunn pupil*** (i.e., relative afferent papillary defect—normal direct and consensual light reflexes; however, when swinging flashlight from one eye to the other, direct light causes dilatation of pupil of affected eye), ***internuclear ophthalmoplegia*** (paresis of the adducting eye on conjugate lateral gaze with horizontal nystagmus of the abducting eye) (Fig. 1)
- Corticospinal tract(s) involvement: Leads to upper motor neuron signs such as spasticity, hyperreflexia, clonus, extensor plantar responses, and upper motor neuron pattern of weakness
- Sensory loss: May include partial or full dermatomal loss of pain and temperature, loss of vibration (common) and position sense, or a thoracic band of sensory loss
- Ataxia: Intention tremor, dysmetria, dysdiadochokinesis, titubation, inability to tandem gait
- Bladder dysfunction: Detrusor hyperreflexia (urge incontinence), flaccidity (neurogenic bladder), and dyssynergia (bladder contracts against a closed sphincter)
- ***Lhermitte* sign:** Flexion of the neck elicits an electrical sensation extending down the spine and occasionally into the extremities
- ***Uhthoff* phenomenon:** Transient worsening of preexisting symptoms with small elevations in body temperature (e.g., during exercise or warm bathing)

ETIOLOGY

Remains unknown but multifactorial with evidence for autoimmunity (autoreactive T and B cells), environmental factors, and genetics (Mendelian and epigenetic). Environmental risk factors during childhood include certain viruses (e.g., Epstein-Barr virus and human herpes virus 6), low UV exposure, and month of birth (higher in spring). Other risk factors include low vitamin D level and smoking.

DIAGNOSIS

- MS: Based on revised 2017 McDonald criteria (Table 1)
- RRMS: See Table 1
- PPMS: Insidious progression of disability for at least 1 yr with a positive CSF and MRI evidence of >1 brain or >2 spinal cord MS-like lesions

DIFFERENTIAL DIAGNOSIS (TABLE 2)

- Autoimmune: Acute disseminated encephalomyelitis (ADEM), postvaccination encephalomyelitis, neuromyelitis optica spectrum disorder
- Degenerative: Subacute combined degeneration of the cord (vitamin B_{12} deficiency), amyotrophic lateral sclerosis, primary lateral sclerosis
- Infections: Lyme disease, neurosyphilis, HIV, tropical spastic paraparesis, progressive multifocal leukoencephalopathy, Whipple disease, acute flaccid myelitis, CNS tuberculosis, or fungal disease

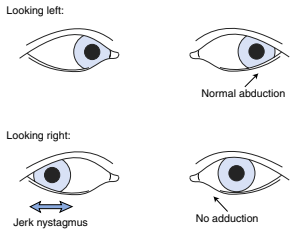

FIG. 1 Internuclear ophthalmoplegia. When the patient in the figure looks to the left (*top* row), both eyes move normally, but when the patient looks to the right (*bottom* row), the left eye fails to adduct ("weak" medial rectus) and the contralateral eye develops a jerk nystagmus. The finding is named for the side with weak adduction (i.e., in this example, a *left* internuclear ophthalmoplegia), and the lesion is in the *ipsilateral* medial longitudinal fasciculus (i.e., *left* medial longitudinal fasciculus in this example). See the text. (From McGee S: *Evidence-based physical diagnosis,* ed 4, Philadelphia, 2018, Elsevier.)

TABLE 1 Summary of Revised 2017 McDonald Criteria for Diagnosis of Multiple Sclerosis

RRMS/Clinical Attacks	Clinical Lesions	Paraclinical Testing Needed
2	2	None
2	1	MRI dissemination in space *or* a second clinical attack at a different CNS site
1	2	MRI dissemination in time *or* CSF-specific oligoclonal bands
1	1	1. Additional clinical attack at a different CNS site or MRI dissemination in space 2. MRI dissemination in time or CSF-specific oligoclonal bands

Evidence of clinical lesions by physical examination or evoked potentials.
CNS, Central nervous system; *CSF,* cerebrospinal fluid; *MRI dissemination in space,* ≥1 T2 lesions in 2 of the 4 typical areas for MS lesions—periventricular, juxtacortical, infratentorial, or spinal cord; *MRI dissemination in time,* a new lesion at follow-up MRI at any time, or presence of both an enhancing and nonenhancing lesion at any time; *RRMS,* relapsing-remitting multiple sclerosis.

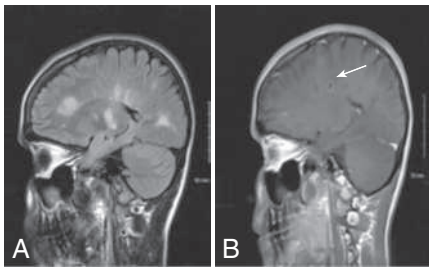

FIG. 2 Multiple sclerosis. A, Sagittal fluid-attenuated inversion recovery (FLAIR) image magnetic resonance scan shows multiple lesions in corpus callosum, "Dawson fingers" (periventricular finger-like lesions oriented toward the ventricles), along with ovoid and punctuate lesions in the deep white matter. **B,** Gadolinium-enhanced scan shows an enhancing lesion *(arrow).*

TABLE 2 Conditions that Can Be Mistaken for Multiple Sclerosis and Other Diseases of Myelin

Vascular Disease
Small-vessel cerebrovascular disease
Vasculitis
CADASIL
Antiphospholipid antibody syndrome

Structural Lesions
Craniocervical junction, posterior fossa, or spinal tumors
Cervical spondylosis or disc herniation
Chiari malformation or syrinx

Degenerative Diseases
Hereditary myelopathy
Spinocerebellar degeneration

Infections
HTLV-1 infection
HIV myelopathy or HIV-related cerebritis
Neuroborreliosis (e.g., Lyme disease)
John Cunningham (JC) JC virus/progressive multifocal leukoencephalopathy
Neurosyphilis

Other Inflammatory Conditions
Systemic lupus erythematosus
Sjögren syndrome

Sarcoidosis
Monofocal or Monophasic Demyelinating Syndromes
Neuromyelitis optica spectrum disorder
Acute disseminated encephalomyelitis

Other Conditions
Hashimoto thyroiditis with or without encephalopathy
Nonspecific MRI abnormalities related to migraine, aging, or trauma

CADASIL, Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; *HTLV,* human T-cell lymphotropic virus.
From Goldman L, Schafer AI: *Goldman's cecil medicine,* ed 24, Philadelphia, 2012, Saunders.

- Inflammatory: Systemic lupus erythematosus, vasculitis, sarcoidosis, Sjögren disease, Behçet disease, celiac disease
- Inherited metabolic disorders: Leukodystrophies
- Mitochondrial: Leber hereditary optic neuropathy, mitochondrial encephalopathy, lactic acidosis, and strokelike episodes (MELAS)
- Neoplasms: CNS lymphoma, metastases
- Vascular: Subcortical infarcts, Binswanger disease

WORKUP

- Lumbar puncture for cases that are atypical and to evaluate for mimics of MS. Typical CSF abnormalities may include increased protein (less than 100 mg/dl), mild elevation of mononuclear white blood cells, and increased IgG synthesis rate. 70% of clinically definite MS (CDMS) have elevated CSF IgG index, and 90% have CSF oligoclonal bands. (Serum for a serum protein electrophoresis needs to be sent to lab simultaneously with CSF for both tests.) False-positive results with IgG index and rarely with positive OCBs can be seen in CNS infections, parainfections, vasculitis, and CNS lymphoma.
- Serum: Complete blood count (CBC), chemistry panel, liver function tests, vitamin B_{12}, 25-OH vitamin D_3.
- Consider in the proper clinical setting: Aquaporin-4 IgG, MOG-IgG, antinuclear antibody (ANA), ACE (a test with low specificity and sensitivity for sarcoidosis) thyroid stimulating hormone (TSH), free T_4, very-long-chain fatty acids, arylsulfatase A.
- Consider optical coherence tomography or evoked potentials (visual, somatosensory, and brain stem auditory evoked response).

IMAGING STUDIES

Brain MRI with and without gadolinium is recommended in all cases. Fig. 2 illustrates imaging features of MS. MRI with and without contrast of the cervical (Fig. E3) and thoracic spine can be helpful. MRI assesses acute and chronic lesions as well as atrophy. A normal MRI of the brain does not conclusively exclude early MS but makes it extremely unlikely.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

Patient education regarding disease characteristics, treatment options, risks and benefits of treatment, and prognosis. Often patients need intermittent rest periods on a daily basis and when physically active, and avoid exposure to heat, which typically worsens symptoms (not the disease).

Recommend physical therapy for new or worsening weakness, incoordination, or spasticity.

ACUTE GENERAL Rx

Relapses: High-dose IV methylprednisolone (3-5 days of 1 g/day), often followed by a 7- to 10-day prednisone or methylprednisolone taper. High-dose corticosteroids do not alter the long-term course of disease. May consider plasmapheresis for refractory cases.

CHRONIC Rx

- The vast majority of FDA-approved therapies are only for relapsing MS; the FDA-approved ocrelizumab is the first medication for primary progressive MS.
- Disease-modifying injection therapy includes interferon beta-1a (intramuscular injection [IM Avonex, IM] Plegridy, subcutaneous [SC] Rebif), interferon beta-1b (SC Betaseron, SC Extavia), and glatiramer acetate (SC Copaxone, SC Glatopa). These medications have a low risk of side effects but are not as efficacious in preventing future relapses. Common side effects for interferons include flulike symptoms, depression, liver toxicity, and leukopenia; CBC and Liver function tests (LFTs) (initially q1mo, then q3mo). Common side effects for glatiramer acetate include injection site reactions and benign chest tightness; no serum studies are needed.
- Disease-modifying oral therapy: These medications are newer and more efficacious in preventing multiple sclerosis relapses; however, they have a higher risk of serious side effects and infections. Consider baseline pregnancy test and infectious tests for all oral therapies, although not required by the FDA, such as VZV Ab, Lyme Ab, tuberculosis (TB) test, JC virus Ab, hepatitis Ab panel. Also review general risk of infections (hx UTIs, kidney stones, smoking, diabetes, bronchitis, disability, pulmonary function, and age). Typically monthly CBC and liver function tests for 6 mo then q3mo; pregnancy test.

1. Fingolimod (Gilenya), a sphingosine-1-phosphate receptor modulator and lymphocyte sequester. Possible side effects: Liver toxicity, bradycardia with first dose (requiring cardiac monitoring and ECG for at least 8 hr after administration of first dose), arrhythmia, pancytopenia, macular edema (ophthalmologic exam at baseline, at 3 mo, and thereafter for those with hx DM or uveitis), and reduced pulmonary function. Obtain varicella-zoster virus (VZV) serology.
2. Teriflunomide (Aubagio), reversible inhibitor of pyrimidine synthesis (enzyme dihydroorotate dehydrogenase). Possible side effects: Diarrhea, abnormal liver function tests, nausea, and hair loss; pregnancy category X. Men should not impregnate their partners while on teriflunomide. Serum levels can be measured, and drug can be eliminated by charcoal or cholestyramine. Obtain TB test.
3. Dimethyl fumarate (Tecfidera), mechanism includes inhibition of transcription of Nuclear factor-κB NF-κB. Frequent side effects include nausea, abdominal discomfort, and flushing—especially during the first month—and rarely leukopenia.
4. Siponimod (Mayzent): A selective sphingosine-1-phosphate receptor modulator and lymphocyte sequester. This is the only drug approved not only for relapsing forms of MS but also for secondary progressive MS. Possible side effects: Liver toxicity but does not cause first-dose bradycardia and requires observation. Obtain VZV serology.
5. Cladribine (mavenclad) is a purine antimetabolite recently FDA approved for oral treatment of adults with relapsing form of MS who cannot tolerate or have had an inadequate response to other MS treatments.

- Disease-modifying IV therapy: These medications are newer and more efficacious in preventing multiple sclerosis relapses; however, they have a higher risk of serious side effects and infections.
  1. Natalizumab (Tysabri) is a monoclonal humanized Ab that binds integrin-α4 interfering with binding to VCAM-1. It has been associated with a *higher* risk of progressive multifocal leukoencephalopathy (JC virus) than other immunomodulatory therapies. Test for JC virus Ab at least annually because conversion to a positive antibody occurs at increased frequency while on this drug. If positive, progressive multifocal leukoencephalopathy (PML) is still rare, but risk increases with increased length of therapy (>2 yr), history of chemotherapy, and concomitant immunosuppressants.
  2. Alemtuzumab (Lemtrada): An anti-CD52 humanized monoclonal antibody and second-line therapy for patients who have failed at least two FDA-approved MS therapies. The medication is delivered in two treatment courses. After an initial series of five daily infusions, the medication is administered 1 yr later for 3 days. Serious side effects include the development of autoimmune conditions (34% developed autoimmune thyroid disorders), infusion reactions, and certain cancers. The medication is only available through a restricted access program.
  3. Ocrelizumab (Ocrevus): A first-line therapy that is a humanized monoclonal antibody to CD20+ B cells. This is the only drug approved not only for relapsing forms of MS but also for primary progressive MS. Infections are the most common side effects.
- Symptomatic therapy:
  1. Dalfampridine (Ampyra) is a potassium channel blocker recently approved to improve walking speed in patients with MS. This medication is contraindicated in patients with epilepsy.
  2. Treat spasticity with baclofen or tizanidine. Onabotulinum toxin type A injection for focal intractable spasticity. Intrathecal baclofen pump for generalized intractable spasticity. Acute worsening may be due to infections such as urinary tract infection (UTI), injury, recent surgery, or colder temperatures.
  3. Treat urge incontinence with anticholinergic/muscarinic therapy such as oxybutynin, tolterodine, or solifenacin. Treat urinary retention with tamsulosin. In both cases, rule out a bladder infection.
  4. Treat dysesthesias with gabapentin or pregabalin.
  5. Fatigue: Consider amantadine 100 mg bid, modafinil, or a stimulant.
  6. Tremor: Clonazepam, propranolol, or gabapentin.
  7. Depression and anxiety are common. Consider referring to both a counselor and psychiatrist.

DISPOSITION

Most patients have complete or near-complete recovery weeks to months after a relapse. Typically, two relapses occur in RRMS patient per yr (75% will have >1 relapse). Although the rate of disease progression is highly variable, there is higher risk of greater long-term disability with higher relapse rate during the first 2 to 5 yr, poor recovery from initial relapses, older age of onset, involvement of multiple systems, male sex, African American, and primary progressive disease.

Disease-modifying treatment has improved, and the current treatment goal is no relapses and no disease progression on imaging.

REFERRAL

- Referral to neurologist is highly recommended. Referral to MS specialist should be considered in cases of poor response to therapy and/or if there is concern about complications of therapies.
- Consider referrals for physical, speech, and occupational therapy.
- Consider referral to urology if bladder-sphincter dyssynergia is possible or if not responsive to treatment.

PEARLS & CONSIDERATIONS

- Clinically isolated syndrome (CIS): Isolated demyelinating event and assessing risk of CDMS 1) in optic neuritis, if brain MRI is completely normal, there is 20% to 25% chance of CDMS over 15 yr. 2) In CIS, if there are >1 T2 hyperintensity on brain MRI, there is 84% risk, and if there are >2 Gd + lesions there is a 96% risk of CDMS over 18 mo.
- Pseudorelapses may occur with heat, fever, or infections (urinary tract infections common in patients with MS).
- Headache, fever, altered mental status, elevated CSF WBCs, or recurrent relapses over days to weeks raises concern for CNS infection or ADEM.

Multiple System Atrophy

BASIC INFORMATION

DEFINITION

Multiple system atrophy (MSA) is an adult-onset (>30 yr) fatal neurodegenerative disorder characterized by autonomic failure associated with parkinsonism and/or cerebellar symptoms.

MSA is further subdivided into two main types:

- MSA-P (parkinsonism subtype), previously *striatonigral degeneration*
- MSA-C (cerebellar subtype), previously *olivopontocerebellar atrophy*

SYNONYMS

MSA
Atypical parkinsonism
Synucleinopathy
Shy-Drager syndrome
Olivopontocerebellar atrophy
Striatonigral degeneration

ICD-10CM CODES
G23.2 Striatonigral degeneration
G23.8 Olivopontocerebellar degeneration

EPIDEMIOLOGY & INCIDENCE

INCIDENCE: Estimated mean incidence is 0.6 to 0.7 cases per 100,000 persons per yr, with a range of 0.1 to 2.4 cases.

PREVALANCE:

- Estimated point prevalence is 4.4 cases per 100,000 patients
- Rises to about 7.8 cases per 100,000 for age >40 yr
- Subtype distribution:
  1. MSA-P: 68% of cases
  2. MSA-C: 32% of cases

PREDOMINANT SEX & AGE:

- Male:female ratio is 1.3:1
- Mean age of onset is 57.8 yr
- In Japan, the predominant subtype is MSA-C and mean survival is short

RISK FACTORS: People with MSA perform some activities more often than the general population, such as drinking alcohol and tea, eating seafood, taking aspirin, and working in plant and machine operations. However, it is not clear if these behaviors are risk factors or coincidence.

GENETICS: A large, genome-wide association study found no significant loci, including no association with the *SNCA* and *COQ2* gene variants that previously had been suggested.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Parkinsonism (see "Parkinson Disease"):
  1. Tremor: Resting tremor in MSA is more likely to be a jerky tremor or myoclonic tremor. It is usually faster and symmetrical.
  2. Rigidity: Usually symmetric.
  3. Postural instability: Seen early in the disease, usually within 1 to 3 yr of onset, and is rapidly progressive, with patients being wheelchair dependent within 5 yr. Falls are common early in MSA (within 3 yr) and are more common in MSA-C.
- Dysautonomia:
  1. Hallmark of MSA, present in both subtypes (99% of patients).
  2. Orthostatic hypotension is symptomatic in 75% of the patients with lightheadedness or dizziness, especially in early morning and when quickly getting up after prolonged sitting. Drop in blood pressure of 30/15 mm Hg within in 3 min of standing is required for diagnosis.
  3. Erectile dysfunction is seen in 84% of males with MSA.
  4. Cold hands or feet with red hand sign due to Raynaud phenomenon.
  5. Respiratory dysfunction with inspiratory stridor or sighs.
- Sleep-related breathing disorders: More commonly obstructive sleep apnea and stridor. This results from airway obstruction and vocal cord restriction (in >50%). Nocturnal stridor and snoring and later daytime stridor are common.
- Urine incontinence (73% of patients).

ETIOLOGY

- Etiology of MSA is unclear. It is generally considered a sporadic disease. Many different factors have been proposed, including environmental toxins such as formaldehyde, malathion, diazinon, benzene, hexane, ketone, and pesticides.
- MSA is a synucleinopathy similar to Parkinson disease (PD) and Lewy body disease. Deposition of alpha-synuclein is seen in cerebellar subcortical white matter and early on in cerebellar brain stem projections with gradual spread.

DIAGNOSIS

- Definitive diagnosis of MSA requires pathologic confirmation on autopsy.
- Possible and probable diagnoses of MSA are based on clinical findings (Table E1).

DIFFERENTIAL DIAGNOSIS

- Progressive supranuclear palsy: Atypical parkinsonism that presents with early falls and postural instability and can be differentiated by lack of tremors, supranuclear ocular palsy, lack of myoclonus, and, most important, less frequent dysautonomia.
- PD: PD can develop mild dysautonomia and postural instability. Key in differentiation is timing of onset of these symptoms (much later for PD), levodopa responsiveness, asymmetry of PD, and much slower progression of PD.
- Corticobasal syndrome: Atypical parkinsonism that can present with early falls and postural instability and can have myoclonus. Differentiated due to marked asymmetry of the disease, early cognitive involvement, and presence of apraxia.
- Secondary parkinsonism: Usually lacks the presence of dysautonomia and may be more slowly progressive.
- Main differential diagnosis of MSA-C includes sporadic late-onset ataxias and autosomal dominant spinocerebellar ataxias (SCA).
- Fragile X associated tremor ataxia syndrome (FXTAS) must be distinguished from MSA and can be present in up to 5% of adult-onset progressive cerebral ataxia.

WORKUP

Autonomic failure early in disease can differentiate MSA and can be determined with:

- Thermoregulatory testing
- Thermal skin sweat test
- Tilt table test
- Ambulatory 24-hour blood pressure monitoring

LABORATORY TESTS

- No routine laboratory tests are indicated.
- It is important to work up for secondary causes of parkinsonism and dysautonomia as appropriate.

TABLE E1 Diagnostic Criteria for Multiple System Atrophy (MSA)

Possible MSA	A sporadic, progressive, **adult (>30 yr)** onset disease characterized by • Parkinsonism or cerebellar syndrome • At least one feature of autonomic or urogenital dysfunction • At least one of the additional features	Additional Features: • Stridor • Babinski sign • Rapidly progressive parkinsonism • Poor response to levodopa • Postural instability within 3 yr • Cerebellar ataxia • Dysphagia within 5 yr • MRI changes suggestive of MSA
Probable MSA	A sporadic, progressive, **adult (>30 yr)** onset disease characterized by • Autonomic failure involving urinary dysfunction • Poorly levodopa-responsive parkinsonism or cerebellar dysfunction	
Definitive MSA	A sporadic, progressive, **adult (>30 yr)** onset disease pathologically confirmed by presence of high-density glial cell inclusions in association with degenerative changes in striatonigral and olivopontocerebellar pathways	

MRI, Magnetic resonance image.

IMAGING STUDIES

Some changes have been described on MRI of the brain in MSA, although they are not common or exclusive.

- Hot cross bun sign or T2 hyperintensity in a crosslike fashion in the *basis pontis.*
- T2 linear hyperintensities on the outer margin of the putamen.
- Middle cerebellar peduncle atrophy and infratentorial atrophy.
- Changes in diffusion tensor imaging in putamen and middle cerebellar peduncle.
- Ancillary neuroimaging tests include FDG-PET, transcranial ultrasonography, F-DOPA PET, ^{18}F-fluorodopamine PET, and ^{123}I-IBZM SPECT.

Rx TREATMENT

- Parkinsonism in MSA may respond to levodopa in 60% patients; however, <10% have an excellent response and the best response is usually seen at higher doses. This improvement is transient in >90% patients, usually 2 to 3 yr on average.
- Parkinsonism in MSA does NOT respond to deep brain stimulation (DBS) surgery and is a diagnosis of exclusion for DBS surgery. Currently, there is no surgical treatment for parkinsonism in MSA.
- Antiaggregation and truncation of alpha-synuclein is under investigation as a treatment strategy.

NONPHARMACOLOGIC THERAPY

Most often, the initial treatment for orthostatic hypotension includes physical and supportive countermeasures to raise blood pressure, such as:

- Crossed leg stance with leaning against the wall
- Elastic stockings
- Correcting volume depletion and anemia
- Avoiding dehydration
- Liberal salt use

ACUTE GENERAL Rx

ORTHOSTATIC HYPOTENSION:

- Second FDA-approved medication for neurogenic orthostatic hypotension is *Droxidopa* (with midodrine being the only other medication).
- Recently approved droxidopa is a synthetic amino acid prodrug of norepinephrine that is orally bioavailable and has limited crossover through the blood-brain barrier and increases norepinephrine levels in brain.
- Other medications are used frequently to treat orthostatic hypotension (generally before droxidopa), including pyridostigmine, fludrocortisone, midodrine, and octreotide (Table E2).

CHRONIC Rx

- Bladder dysfunction: Medication used includes oxybutynin, tolterodine, solifenacin, darifenacin, tamsulosin, prazosin, and moxisylyte (specific antagonist of bladder α-adrenergic receptors), and use of botulinum toxin for bladder spasticity and urgency.
- Erectile dysfunction: Medication used includes sildenafil and tadalafil.
- Constipation: Medications include polyethylene glycol, bisacodyl, magnesium sulphate, macrogol, lubiprostone, and botulinum toxin. Long-term use of polyethylene glycol is safe in parkinsonian patients and is the recommended treatment of choice in PD.
- Sleep apnea: Usually treated with continuous positive airway pressure or bilevel positive airway pressure.
- Stridor: Continuous positive airway pressure is first-line therapy, but tracheostomy may be required for persistent and severe stridor.

COMPLEMENTARY & ALTERNATIVE MEDICINE

No evidence-based therapy. Patients with parkinsonism use *Mucuna pruriens* powder and fava beans. Both of them have levodopa in varying concentration and are not known to be any superior to *carbidopa/levodopa.*

DISPOSITION

MSA is a relentlessly and rapidly progressive disabling disease. Mean survival in both subtypes is 7 to 9 yr; sudden death and pneumonia are the two most common causes of death. Older age of onset and early autonomic dysfunction are predictive factors for rapid progression with shorter disease survival.

REFERRAL

- Neurology consultation is important to make the distinction between MSA and other causes of parkinsonism. Yearly evaluation for diagnosis may be needed. Reliability of diagnosis by a movement disorders expert is superior to that from a general neurologist (95% vs. 70%).
- Due to high incidence of nonmotor complications, a close coordination by different care providers is needed.

TABLE E2 Medications for Orthostatic Hypotension in Parkinsonism

Medication	Mechanism of Action	Suggested Dosage	Common/Serious Side Effects
Fludrocortisone*,† (9 alpha-fluoro-17-hydroxy-corticosterone)	A synthetic corticosteroid with mineralocorticoid effect on the kidney (inducing permease), enhancing Na+ reabsorption and increasing K+ excretion	0.1-0.5 mg per day	Acute withdrawal adrenal insufficiency, edema, hypokalemia, interaction with lithium and through CYP450.
Midodrine*,† (2-amino-N-[dimethoxyphenyl-hydroxyethyl]-acetamide)	Midodrine is converted to active metabolite desglymidodrine by that selectively binds to and activates alpha-1-adrenergic receptors of vasculature	5-10 mg per day	Contraindicated in patients with severe organic heart disease, acute renal disease, urinary retention, pheochromocytoma, or thyrotoxicosis.
Droxidopa*,† (D,L Threo 3,4-Dihydroxy-phenylserine)	An orally active synthetic precursor of epinephrine that crosses blood-brain barrier and increases brain epinephrine levels	200-2000 mg per day	Headache, dizziness, and nausea. No significant known toxicity.
Mestinon† (hydroxymethyl-pyridinium bromide dimethyl-carbamate)	Binds reversibly to acetyl-cholinesterase in PNS and increases ACH, leading to muscarinic effects of contraction of bronchial and intestinal smooth muscles, exocrine gland secretions, and nicotinic effect of skeletal muscle contraction	120 to 660 mg per day in divided doses (usually QID)	Toxicity with confusion, ataxia, seizures; generalized weakness, fatigue and twitching, nausea, vomiting and cramps. Coma and death can occur. Antidote is atropine.
Octreotide‡ (pentaoxo-dithia-pentazacycloicosane-4-carboxamide)	A synthetic somatostatin analogue; even more potent inhibitor of growth hormone, glucagon, and insulin	100-1500 μg per day subcutaneously	Abdominal pain, decreased appetite, diarrhea

ACH, Acetylcholine; *CYP450,* cytochrome P450; *PNS,* peripheral nervous system; *QID,* four times daily.
*Drug warning: Potentially serious side effect of marked elevation of supine blood pressure.
†FDA Pregnancy Risk Category C.
‡FDA Pregnancy Risk Category B.

PEARLS & CONSIDERATIONS

Red flags for MSA in patient presenting with parkinsonism:

- Early postural instability, especially if wheelchair bound within 5 yr
- Rapid progression
- Abnormal postures, such as Pisa syndrome
- Severe bulbar dysfunction
- Respiratory dysfunction: Inspiratory stridor or inspiratory signs
- Emotional lability

BASIC INFORMATION

DEFINITION

Mumps is an acute generalized viral infection that is usually characterized by nonsuppurative swelling and tenderness of one or both parotid glands. It is caused by mumps virus, a single-stranded RNA paramyxovirus, of which humans are the only natural host.

SYNONYMS

Viral parotitis
Parotitis

ICD-10CM CODES

B26.0	Mumps orchitis
B26.1	Mumps meningitis
B26.2	Mumps encephalitis
B26.3	Mumps pancreatitis
B26.81	Mumps hepatitis
B26.82	Mumps myocarditis
B26.83	Mumps nephritis
B26.84	Mumps polyneuropathy
B26.85	Mumps arthritis
B26.89	Other mumps complications
B26.9	Mumps without complication

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- In 2016 there were 6369 cases in the U.S., and in 2017 there were 5629 cases in the U.S., which was the highest in a decade. Sporadic outbreaks still occur in schools, colleges, military posts, or summer camps started by an unvaccinated person.
- Recent mumps outbreaks in the U.S.: At an Ohio university in 2014 (386 cases), at a California university in 2011 (29 cases).
- More than 150,000 cases/yr before licensure of mumps vaccine in 1967.

PREDOMINANT SEX: Males = females
PREDOMINANT AGE: 75% of disease in teenage years
PEAK INCIDENCE: Late winter and early spring months
GENETICS:

- Congenital infection:
  1. First-trimester infection is associated with excessive fetal deaths.
  2. Second- and third-trimester infection is not associated with increased fetal mortality.
- Neonatal infection:
  1. Uncommon
  2. Uncommon in infants <1 yr because of passive immunity conferred by placental transfer of maternal antibody

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Prodromal period: Includes low-grade fever, malaise, anorexia, and headache
- Parotid swelling and tenderness; often the first signs of infection:
  1. Progresses over 2 to 3 days, then opposite side may become involved
  2. Unilateral parotitis in 25% of cases
  3. Considerable pain with parotid swelling, causing trismus and difficulty with mastication and pronunciation
  4. Pain exacerbated by eating or drinking citrus and other acidic foods
  5. Possible fever with parotid swelling, ranging up to 40° C (104° F)
  6. Parotid swelling, usually resolving within 1 wk
- Central nervous system involvement:
  1. May occur from 1 wk before to 2 wk after the onset of parotitis or even in its absence
  2. Meningitis:
     a. Occurs in 1% to 10% of patients with mumps parotitis
     b. Occurs three times more often in males than females
     c. Symptoms: Headache, fever, nuchal rigidity, and vomiting
     d. Full recovery with no sequelae
  3. Encephalitis:
     a. May develop early, as a result of direct viral invasion of neurons, or late, around the second wk after onset of parotitis, and is a postinfectious demyelinating process.
     b. Mumps accounted for only 0.5% of viral meningitis.
     c. Symptoms: Fever, alterations in the level of consciousness, possible seizures, paresis or paralysis, and aphasia. Fever can be quite high (40° to 41° C; 104 to 105.8° F).
     d. Cerebellitis and hydrocephalus are serious complications of mumps encephalitis.
     e. May result in permanent sequelae or death.
  4. Other rare neurologic complications include cerebellar ataxia, transverse myelitis, Guillain-Barré syndrome, and facial palsy.
- Epididymoorchitis:
  1. Most common extrasalivary gland complication of mumps in adult men
  2. Occurs in 38% of postpubertal males who have mumps
  3. Most often unilateral but is bilateral in 30% of males who develop this complication
  4. May precede development of parotitis and may be only manifestation of mumps
  5. Two thirds of cases develop during first week of parotitis
  6. Symptoms:
     a. Severe pain, swelling, and tenderness of the testes and scrotal erythema
     b. Fever and chills
  7. Some degree of testicular atrophy in 50% of cases, mo to yr later
  8. Sterility from bilateral orchitis is rare
- Involvement of pancreas and ovaries:
  1. Pancreas: Abdominal pain, fever, and vomiting
  2. Ovaries: Oophoritis
     a. Occurs in 5% of postpubertal women with mumps
     b. Symptoms include fever, nausea, vomiting, and lower abdominal pain
     c. May rarely result in decreased fertility and premature menopause
- Transient renal impairment: Common and manifested by hematuria and polyuria
- Joint involvement:
  1. Migratory polyarthritis is most frequent
  2. Infrequently affects adults with mumps
  3. Occurs rarely in children
  4. Self-limited, with complete resolution
- Deafness:
  1. Most often unilateral, involving high frequencies; may rarely cause bilateral involvement
  2. Most patients recover
  3. Permanent unilateral deafness reported in 1 in 20,000 cases
  4. Labyrinthitis and end lymphatic hydrops also reported
- Myocardial involvement:
  1. Uncommon
  2. Rarely causes progressive and fulminant fatal myocarditis with dilated cardiomyopathy
  3. Refractory arrhythmia and congestive heart failure
  4. Coronary artery involvement
- Eye involvement:
  1. Corneal endotheliitis following mumps parotitis

ETIOLOGY

- Virus is spread via direct contact, droplet nuclei, fomites, or oral or nasal secretions.
- Patients are contagious from 48 hr before to 9 days after parotid swelling.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other viruses that may cause acute parotitis:
  1. Parainfluenza types 1 and 3
  2. Coxsackie viruses
  3. Influenza A
  4. Cytomegalovirus
- Suppurative parotitis:
  1. Most often caused by *Staphylococcus aureus*
  2. May be differentiated from mumps
     a. Extreme indurations, tenderness and erythema overlying the gland
     b. Ability to express pus from Stensen duct or massage of parotid
- Other conditions that may occur with parotid enlargement or swelling:
  1. Sjögren syndrome
  2. Leukemia
  3. Diabetes mellitus
  4. Uremia
  5. Malnutrition
  6. Cirrhosis
- Drugs that cause parotid swelling:
  1. Phenothiazines
  2. Phenylbutazone
  3. Thiouracil
  4. Iodides

- Conditions that cause unilateral swelling:
  1. Tumors
  2. Cysts
  3. Stones causing obstruction
  4. Strictures causing obstruction

WORKUP

- Diagnosis based on history of exposure and physical finding of parotid tenderness with mild to moderate constitutional symptoms.
- Diagnosis is confirmed by a variety of serologic tests or isolation of the virus.

LABORATORY TESTS

- Diagnosis is confirmed by reverse transcriptase polymerase chain reaction (RT-PCR) performed on serum or on buccal or oral swab with the same specimen also being used to perform viral culture, or by a positive IgM mumps antibody that generally stays elevated for 4 wk. However, serologic mumps testing is particularly unhelpful in some vaccinated individuals who can have mumps without having the usual immunoglobulin M (IgM) spike. Serologic tests cannot distinguish between vaccination and prior true mumps exposure.
- Virus can be isolated from the saliva, usually from 2 to 3 days before to 4 to 5 days after the onset of parotitis. Researchers have shown that many cases labeled as "parotitis" are actually caused by other viruses (EB virus, human herpesvirus 6B, human herpesvirus 6B, human parainfluenza virus).[1]
- Virus can be cultured from cerebrospinal fluid (CSF) in patients with meningitis during the first 3 days of meningeal findings. More rapid confirmation of mumps in the CSF is done through the RT-PCR.
- Virus can be detected in urine during the first 2 wk of infection.
- White blood count (WBC):
  1. May be normal or possible mild leukopenia with a relative lymphocytosis
  2. Leukocytosis with left shift with extrasalivary gland involvement, such as meningitis, orchitis, or pancreatitis
- Serum amylase:
  1. Elevated in the presence of parotitis
  2. May remain elevated for 2 to 3 wk
  3. May be differentiated from mumps and parotids by isoenzyme analysis or serum pancreatic lipase
- Mumps meningitis:
  1. CSF WBCs from 10 to 2000 WBC/mm^3 with a predominance of lymphocytes
  2. In 20% to 25% of patients, predominance of polymorphonuclear cells
  3. CSF protein normal or mildly elevated
  4. CSF glucose low, <40 mg/dl, in 6% to 30% of patients

[1] Barshey AE et al: Viruses detected among sporadic cases of parotitis, United States 2009-2011, *J Infect Dis* 208:1979, 2013.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Supportive treatment
- Adequate hydration and nutrition

ACUTE GENERAL Rx

- Analgesics and antipyretics to relieve pain and fever
- Narcotic analgesics, along with bed rest, ice packs, and a testicular bridge, to relieve pain associated with mumps orchitis
- IV fluids for patients with frequent vomiting associated with mumps pancreatitis or meningitis

DISPOSITION

Most patients recover without incident.

REFERRAL

- To a neurologist if significant neurologic complications develop during or following mumps (myelitis, encephalitis, cranial nerve involvement, cerebellar ataxia, etc.)
- To a cardiologist if viral perimyocarditis develops
- To a urologist if orchitis develops

PEARLS & CONSIDERATIONS

COMMENTS

Prevention:

- Attenuated live mumps virus vaccine has been available since 1967.
  1. Usually given in combination with measles and rubella vaccines (MMR) or as a measles-mumps-rubella-varicella vaccine (MMRV). A monovalent mumps vaccine is no longer available.
  2. Either vaccine should be given at 12 to 15 mo of age and again at 4 to 6 yr of age.
  3. Seroconversion in about 100% of infants given the vaccine.
  4. Contraindicated in pregnant women and immunocompromised patients.
  5. Patients with asymptomatic HIV infection and patients with symptomatic HIV infection, in the absence of severe immunosuppression, can safely receive the MMR vaccine.
  6. Adverse events of vaccination include local pain, indurations, thrombocytopenic purpura, Guillain-Barré syndrome, and cerebellar ataxia.
  7. Adults born before 1957 are considered immune. Those born after 1957 who lack documentation of immunization are considered susceptible. Adults can receive two doses 1 mo apart.
- The CDC and American Academy of Pediatrics (AAP) recommend that patients with mumps stay home from work or school for 5 days after onset of clinical symptoms.
- Because virus may be shed before the onset of parotid swelling, isolation possibly not of great value in limiting spread of infection. Use droplet precautions as per CDC and AAP.
- Mumps is a notifiable disease in all U.S. states.

BASIC INFORMATION

DEFINITION

Muscular dystrophy (MD) refers to a heterogeneous group of inherited disorders resulting in characteristic patterns of muscle weakness, some with cardiac involvement. Only disorders with childhood or adult onset are considered here (i.e., excluding congenital myopathies).

SYNONYM

MD

ICD-10CM CODE
G71.0 Muscular dystrophy

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- Most common childhood MD is Duchenne muscular dystrophy (DMD) with an incidence of 1/3500 male births.
- Most common adult MD is myotonic dystrophy with an incidence as high as 1/8000.

GENETICS:

- **Dystrophinopathies:** X-linked recessive defect in dystrophin gene resulting in either absence (DMD) or reduced/defective (Becker MD [BMD]) dystrophin
- **MD:** Autosomal dominant (AD) CTG trinucleotide repeat (see "Myotonia")
- **Limb-girdle muscular dystrophy (LGMD):** The majority are autosomal recessive, also autosomal dominant forms. Associated with deficiencies identified in multiple proteins (sarcoglycan, calpain, dystroglycan, and dysferlin may be most common; also may involve telethonin, lamin A/C, myotilin, and caveolin-3)
- **Emery-Dreifuss MD:** X-linked recessive defect in nuclear protein emerin or AR/AD defect in inner nuclear lamina proteins lamin A/C
- **Facioscapulohumeral MD:** AD; genetic mutation causes deletion of 3.3 kb repeat
- **Oculopharyngeal DM:** AD GCG trinucleotide repeat resulting in deficient mRNA transfer from nucleus

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- **Dystrophinopathies:** Proximal arm and leg weakness with hypertrophic calf muscles (Fig. E1), delayed motor milestones, cognitive impairment, cardiac involvement (Fig. E2), progressive course resulting in respiratory complications and respiratory failure.
  1. DMD onset at 2 to 3 yr old, typically wheelchair-bound by 12 yr
  2. BMD onset at 5 to 15 yr old, ambulatory beyond age 15 yr
- **Myotonic dystrophy:** Variable age of onset and severity manifesting as predominantly distal weakness with long face, percussion and grip myotonia, temporalis and masseter wasting, ptosis, hypersomnolence, cognitive impairment, and cardiac conduction defects. May be associated with frontal balding, cataracts, impaired glucose tolerance, and male infertility.
- **LGMD:** Phenotypically and genetically heterogenous characterized by proximal hip and shoulder girdle weakness, some genotypes featuring cardiac involvement. Extraocular muscles are spared, and usually facial muscles and intellect are spared. With LGMD, less severe forms can emerge during the first three decades, leading to loss of ambulation after 30 yr of age. The most severe forms start at 3 to 5 yr of age and progress rapidly.
- **Emery-Dreifuss MD:** Early adulthood onset with predominantly humeroperoneal weakness, early contractures, and cardiac dysfunction
- **Facioscapulohumeral MD:** Onset typically in late childhood or adolescence with weakness mostly in face and shoulder girdle musculature (Fig. E3) and possible later, mild involvement of lower extremities
- **Oculopharyngeal MD:** Symptom onset typically in mid-adult life with ptosis, ophthalmoparesis usually without diplopia, dysphagia, dysarthria, and proximal muscle weakness
- Table E1 shows a classification of muscular dystrophies. Fig. E4 illustrates the Gower maneuver in a patient with Becker muscular dystrophy.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Spinal muscular atrophy, myasthenia gravis, inflammatory myopathy, metabolic myopathy,

FIG. E1 A, Calf pseudohypertrophy in an 8-year-old male with Duchenne muscular dystrophy. **B,** Becker muscular dystrophy in a 24-year-old male. Dystrophy of the shoulder girdle and calf pseudohypertrophy is evident. (**A,** Courtesy Dr. Laurence E. Walsh; **B,** courtesy Dr. Robert M. Pascuzzi. A

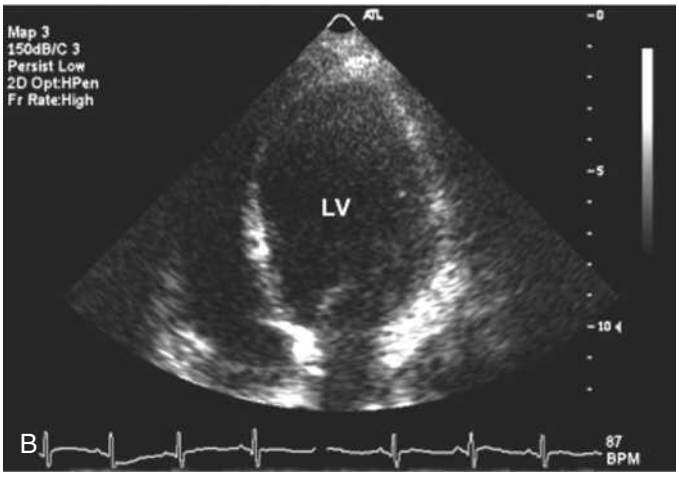

FIG. E2 Dilated cardiomyopathy in a 19-year-old man with Duchenne muscular dystrophy. A, Electrocardiogram showing a QRS complex that is typical of Duchenne dystrophy, with tall R waves in lead V1 and deep narrow Q waves in leads I and aVL. **B,** Two-dimensional echocardiogram (parasternal four-chamber view) showing a dilated, thinned left ventricle *(LV). aVF,* Augmented vector foot; *aVL,* augmented vector left; *aVR,* augmented vector right. (From Mann DL et al: *Braunwald's heart disease,* ed 10, Philadelphia, 2015, Elsevier.)

endocrine myopathy, toxic myopathy, mitochondrial myopathy

WORKUP

- Creatine kinase
- ECG, Holter monitor, echocardiography
- Electromyography
- Muscle biopsy with immunohistochemistry useful for diagnosis of dystrophinopathies and LGMD
- DNA testing: Single gene or panel depending on suspicion
- Assessment of respiratory parameters, including forced vital capacity (FVC)

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Genetic counseling
- Physical, occupational, respiratory, speech therapy as symptoms dictate
- Screening for sleep-disordered breathing with overnight polysomnogram (PSG) if clinically indicated
- Pacemaker placement may be necessary if cardiac conduction defect present

ACUTE GENERAL Rx

- Prednisone may modestly prolong ambulation in DMD. A dose of 0.75 mg/kg/day may improve muscle strength and function over 6 mo to 2 yr. These short-term benefits must be weighed against the side effects of long-term steroid therapy. Deflazacort could be an alternative treatment.
- Eteplirsen has recently been approved for treatment of DMD specifically caused by mutations in the dystrophin gene amenable to exon 51 skipping. Other specific gene therapy drugs are also in development.

FIG. E3 Clinical photograph showing bilateral winging of the scapulae in a patient with facioscapulohumeral muscular dystrophy. (From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.)

CHRONIC Rx

Vigilance to avoid cardiac and respiratory complications, joint contractures

DISPOSITION

Variable course, because severity of phenotype is contingent upon both diagnosis and genotype

REFERRAL

- Surgical referral for correction of scoliosis or contractures may be necessary
- Assessment and follow-up in an MD specialty clinic

PEARLS & CONSIDERATIONS

Formal evaluation by anesthetist is recommended before any operation with general anesthesia in patients with dystrophinopathy.

TABLE E1 Classification of Muscular Dystrophies

Disease	Genetic Locus	Inheritance	Protein	Outcome/Distinguishing Characteristics
Duchenne/Becker		XR	Dystrophin	Lethal
Emery-Dreifuss		XR	Emerin, lamins A and C	40% lethality
Limb-Girdle Muscular Dystrophies				
LGMD 1A	5q31	AD	Myotilin	
LGMD 1B	1q11-q21	AD	Laminin A/C	Most common AD LGMD Common cardiac involvement requiring pacemaker
LGMD 1C	3p35	AD	Caveolin	Associated with rippling muscle disease
LGMD 1D	6q23	AD	DNAJB6	
LGMD 1E	7q	AD	Desmin	Cardiac
LGMD 1F	7q32	AD	Transportin 3	
LGMD 1G	4p21	AD	HNRNPDL	
LGMD 1H	3p25.1-p23	AD	—	
LGMD 2A	15q15.1-q21.1	AR	Calpain 3	Most common LGMD (15%-40%). Scapular winging, abdominal laxity
LGMD 2B	2p13	AR	Dysferlin	Second most common LGMD (5%-35%) Common distal involvement
LGMD 2C	13q12	AR	γ-Sarcoglycan	
LGMD 2D	17q12-q21.33	AR	α-Sarcoglycan	
LGMD 2E	4q12	AR	β-Sarcoglycan	
LGMD 2F	5q33-q34	AR	δ-Sarcoglycan	
LGMD 2G	17q11-q12	AR	Telethonin	
LGMD 2H	9q31-q34.1	AR	E3-Ubiquitin ligase (TRIM32)	
LGMD 2I	19q13.3	AR	Fukutin-related protein	More frequent Cardiomyopathy, may look like Duchenne
LGMD 2J	2q24.3	AR	Titin	
LGMD 2K	9q34	AR	Protein O-mannosyltransferase	Cognitive involvement
LGMD 2L		AR	Anoctamin 5	Adult onset 20-50 years old 25% wheelchair
LGMD 2M		AR	Fukutin	
CMDs with CNS Involvement				
Fukuyama CMD	9q31	AR	Fukutin	LE, 11-16 yr
Walker-Warburg CMD	1p32	AR	O-Mannosyltransferase	LE, <3 yr
Muscle-eye-brain CMD	1p32-34	AR	O-MNAGAT	LE, 10-30 yr
CMDs without CNS Involvement				
Merosin-deficient classic type	6q2	AR	Merosin (laminin A_2)	Many patients never walk; others have an LGMD pattern
Merosin-positive classic type	4p16.3	AR	Selenoprotein N1, collagen VI α_2	Course stabilizes in late childhood; many continue to walk into adulthood
Integrin-deficient CMD	12q13	AR	Integrin α7	Presents early in infancy with hypotonia and delayed milestones
Other Dystrophies				
Facioscapulohumeral	4q35	AD	DUX4	20% wheelchair bound
Oculopharyngeal	14q11.2-q13	AD/AR	Polyadenylate binding protein nuclear 1	Onset: ≈48 yr, 100% symptomatic by age 70
Myotonic dystrophy	19q13.3	AD	DMPK, CCHC-type zinc finger and CNBP	Onset: 50% show signs by age 20; variable severity

AD, Autosomal dominant; *AR,* autosomal recessive; *CCHC,* cysteine and histidine amino acid sequence in this class of zinc finger; *CMD,* congenital muscular dystrophy; *CNBP,* cellular nucleic acid–binding protein; *CNS,* central nervous system; *DMPK,* dystrophia myotonica-protein kinase; *DUX4,* double homeobox protein 4; *LE,* life expectancy; *LGMD,* limb-girdle muscular dystrophy; *O-MNAGAT,* O-mannose β-1,2-*N*-acetylglucosaminyl transferase; *XR,* X chromosome related.

Mushroom Poisoning PTG

BASIC INFORMATION

DEFINITION

Mushroom poisoning is intoxication resulting from ingestion of poisonous mushrooms.

ICD-10CM CODE

T62.0X1A Toxic effect of ingested mushrooms, accidental (unintentional), initial encounter

EPIDEMIOLOGY & DEMOGRAPHICS

- 5% of all mushrooms are poisonous. Distinction between poisonous and edible mushrooms may be difficult even by experienced persons.
- Common poisonous species include *Amanita, Russula, Gyromitra,* and *Omphalotus* (see Table E1). *Amanita phalloides,* colloquially known as the "death cap," belongs to the *Phalloideae* section of the *Amanita* family of mushrooms and is responsible for most deaths following ingestion of foraged mushrooms worldwide.
- Identification of syndromes is more important than knowing the associated species (Table 2).

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- *Russula* causes confusion, delirium, visual disturbance, tachycardia, and diarrhea within a few hours of ingestion. Prognosis: Spontaneous recovery (mortality rate >1%).
- *Amanita* and *Gyromitra* intoxication begins with symptoms of gastroenteritis (nausea, vomiting, diarrhea, and abdominal cramps) approximately 10 hr after ingestion. *Amanita* then causes cardiomyopathy and hepatic and renal failure. *Gyromitra* produces jaundice and seizures. Both mushrooms are associated with a 50% mortality rate.
- *Omphalotus* causes symptoms of gastroenteritis that subside spontaneously within 24 hr.

ETIOLOGY

- *Amanita* contains cytotoxic substances and isoxazoles that are gamma-aminobutyric acid neurotransmitter analogs. Amatoxins, consisting of alpha-, beta-, and gamma-amanitin, account for >90% of deaths related to mushroom poisoning. The amanitas are heat stable and not inactivated by cooking.
- *Gyromitra* contains a pyridoxine antagonist that disrupts the gastrointestinal mucosa and causes hemolysis.
- *Russula* contains a cholinergic substance.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Food poisoning
- Overdose of prescription or illegal drug
- Other intoxications
- See topic on specific organ failure (e.g., renal or hepatic failure) for differential diagnosis of those conditions

WORKUP

- History
- Inspection and identification of suspected mushrooms
- Mushroom or gastric content analysis (by thin-layer chromatography or radioimmunoassay)

TREATMENT

- Gastric lavage.
- Repeated administration of activated charcoal.
- Penicillin G or silibinin can be used for *Amanita* mushroom intoxication. Silibinin interferes with hepatic uptake of alpha-amanitin. IV silibinin is not currently available in the U.S. Where available, it is given at a rate of 5 mg/kg IV over 1 hr, followed by 20 mg/kg/day. An oral form of silibinin is available in health food stores as an extract from milk thistle called silymarin. Dose is 1 g PO qid. IV benzyl penicillin reduces hepatocyte uptake of amatoxin.
- Supportive care as needed (may require respiratory assistance, hemodialysis, or emergency liver transplantation) in the event of irreversible fulminant liver failure.
- In patients with severe *Amanita* poisoning, early contact with the nearest liver transplant center is recommended.
- Box E1 summarizes the general management of mushroom poisoning.

Mushroom Poisoning (Patient Information)

AUTHOR: **Fred F. Ferri, MD**

TABLE 2 Summary Common Mushroom-Associated Syndromes

Syndrome	Clinical Course	Toxin(s)	Typical Causative Mushroom(s)
Delayed gastroenteritis followed by hepatorenal syndrome	Stage 1: 24 hr after ingestion: onset of nausea, vomiting, profuse cholera-like diarrhea, abdominal pain, hematuria Stage 2: 12-48 hr after ingestion: apparent recovery; levels of hepatic enzymes are rising during this stage Stage 3: 24-72 hr after ingestion: progressive hepatic and renal failure, coagulopathy, cardiomyopathy, encephalopathy, convulsions, coma, death	Cyclopeptides, principally amatoxins	"Deadly *Amanitas*," *Galerina* species
Hyperactivity, delirium, coma	30 min to 2 hr after ingestion: delirium, hallucinations, and coma	Muscimol, ibotenic acid	*Amanita muscaria, Amanita pantherina*
Delayed gastroenteritis with central nervous system abnormalities	6-24 hr after ingestion: nausea, vomiting, diarrhea, abdominal pain, muscle cramps, delirium, convulsions, coma; hemolysis and methemoglobinemia may occur	Gyromitrin	*Gyromitra esculenta* ("false morel")
Cholinergic syndrome	30 min to 2 hr after ingestion: bradycardia, bronchorrhea, bronchospasm, salivation, perspiration, lacrimation, convulsions, coma	Muscarine	*Boletus* species, *Clitocybe* species, *Inocybe* species, *Amanita* species
Disulfiram-like reaction with ethanol	30 min after drinking ethanol (may occur up to 1 wk after eating coprine-containing mushrooms): flushing of skin of face and trunk, hypotension, tachycardia, chest pain, dyspnea, nausea, vomiting, extreme apprehension	Coprine	*Coprinus atramentarius*
Hallucinations	30 min to 3 hr after ingestion: hallucinations, euphoria, drowsiness, compulsive behavior, agitation	Psilocybin and psilocin	*Psilocybe* species
Delayed gastritis and renal failure	Abdominal pain, anorexia, vomiting starting over 30 hr after ingestion, followed by progressive renal failure 3-14 days later	Orelline, orellanine	*Cortinarius* species
Immune-mediated hemolytic anemia	Syncope, gastroenteritis, oliguria, hemoglobinuria, back pain, hemolysis	Immunoglobulin mediated	*Paxillus involutus*
General gastrointestinal irritants	30 min to 2 hr after ingestion: nausea, vomiting, abdominal cramping, diarrhea; may recover without treatment	Unidentified, probably multiple	*Chlorophyllum molybdites,* backyard mushrooms ("little brown mushrooms"), many others

From Brent J et al (eds): *Haddad and Winchester's clinical management of poisoning and drug overdose,* ed 4, Philadelphia, 2007, WB Saunders, Table 23-1.

BOX E1 General Management of Mushroom Ingestion

1. Determine history of ingestion: How many types of mushrooms ingested, what time, if anyone else ate them, and what symptoms are present.
2. Attempt to determine which of the possible syndromes (see Table 2) the patient may have. For example, gastrointestinal symptoms occurring more than 6 hr after ingestion strongly suggest cyclopeptide, gyromitrin, or *Cortinarius* poisoning.
3. Administer activated charcoal. If the patient has diarrhea, do not give a cathartic. If a cathartic is used, give it only with the first dose of activated charcoal. Use repeated doses of activated charcoal for suspected amatoxin poisonings.
4. If feasible and when indicated, send gastric aspirate or emesis, along with any remaining mushrooms, to a mycologist for identification.
5. Try to perform a preliminary identification of mushroom and spores. Start to develop a spore print as soon as possible.
6. Maintain supportive measures, including airway support, intravenous fluids, and vasopressors (if needed). Monitor volume status.
7. Avoid antispasmodics for gastrointestinal symptoms.
8. Anticipate the clinical course.

From Brent J et al (eds): *Haddad and Winchester's clinical management of poisoning and drug overdose,* ed 4, Philadelphia, 2007, WB Saunders, Box 23.1.

TABLE E1 Mushroom Groups

Group/Toxin	Representative Example	Clinical Effects
Early Onset of Symptoms		
Coprine	*Coprinus atramentarius*	Disulfiram reaction with alcohol
GI toxin	Many species	Nausea, vomiting, diarrhea, abdominal pain
Ibotenic acid and muscimol	*Amanita muscaria*	Diverse CNS effects, including hallucinations, seizures, delirium, coma, agitation
Muscarine	*Clitocybe dealbata*	Peripheral cholinergic toxidrome
Psilocybin	*Psilocybe cubensis*	CNS effects, including hallucinations and euphoria
Late Onset of Symptoms		
Cyclopeptides	*Amanita phalloides*	GI effects followed by hepatotoxicity
Gyromitrin	*Gyromitra esculenta*	GI effects followed by seizures
Orellanine	*Cortinarius orellanus*	GI effects followed by renal toxicity

CNS, Central nervous system; *GI,* gastrointestinal.
From Marx J: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, Philadelphia, 2010, Elsevier.

SUGGESTED READING

BASIC INFORMATION

DEFINITION

Myasthenia gravis (MG) is an autoimmune disorder affecting postsynaptic neuromuscular transmission, most commonly mediated by antibodies directed against the nicotinic acetylcholine receptor (AChR) of the neuromuscular junction. Anti-AChR antibodies cause a decrease in functional postsynaptic ACh receptors, resulting in fatigable weakness. A small percentage of MG patients lack AChR antibodies, and a subset of these patients possess antibodies against muscle-specific tyrosine kinase (MuSK), impacting both pre- and postsynaptic function of the neuromuscular junction. A classification of MG is described in Table 1.

SYNONYM

MG

ICD-10CM CODES

G70.00	Myasthenia gravis without (acute) exacerbation
G70.01	Myasthenia gravis with (acute) exacerbation
P94.0	Transient neonatal myasthenia gravis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 8 to 10 cases annually per 1 million persons. It is the most common disorder of neuromuscular junction transmission.
PREVALANCE (IN U.S.): 150 to 250 cases per 1 million
PREDOMINANT SEX: Females are affected more often than males (3:2) in adults; they are equally affected in the elderly.
PEAK INCIDENCE: Female, second to third decades; male, sixth to eighth decades
GENETICS: Increased frequency of HLA-B8, DR3

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The hallmark of MG is weakness worsened with exercise and improved with rest.
- Generalized weakness involving proximal muscles, diaphragm, and neck extensors is common.
- Weakness is confined to eyelids and extraocular muscles in approximately 15% of patients (Fig. 1).
- Bulbar symptoms of ptosis, diplopia, dysarthria, and dysphagia are common.
- Reflexes, sensation, and coordination are normal.

ETIOLOGY

Antibody-mediated decrease in nicotinic AChR in the postsynaptic neuromuscular junction resulting in defective neuromuscular transmission and subsequent muscle weakness and fatigue. Early-onset MG is associated with *HLA-DR3, HLA-B8,* and non-*HLA* genes. Late-onset MG is associated with *HLA-DR2, HLA-B27,* and *HLA-DRB1*. MuSK antibodies have been recognized since 2001 and present with a similar syndrome to AChR MG although they may have more bulbar weakness, proximal muscle atrophy, and either lack of or paradoxical response to pyridostigmine. Serologic and clinical presentation of myasthenia gravis subgroups are summarized in Table 2.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Lambert-Eaton myasthenic syndrome, botulism, medication-induced myasthenia, chronic progressive external ophthalmoplegia, congenital myasthenic syndromes, thyroid disease, basilar meningitis, intracranial mass lesion with cranial neuropathy, Miller-Fisher variant of Guillain-Barré syndrome

WORKUP

- Edrophonium (Tensilon) test (Fig. 2): Useful in MG patients with ocular symptoms, although uncommonly used now. Cardiac monitoring and atropine ready at the bedside are essential. Patients with MG may also have a positive ice pack test (Fig. E3).
- Repetitive nerve stimulation: Successive stimulation shows decrement of muscle action potential in clinically weak muscle; may be negative in up to 50%.
- Single-fiber electromyography: Highly sensitive; abnormal in up to 95% of patients.
- Serum AChR antibodies found in up to 90% of patients.
- A subset of patients with seronegative MG may have MuSK antibodies.

LABORATORY TESTS

- Forced vital capacity (FVC) is the most useful test for assessing neuromuscular respiratory status. Patients with an FVC of <20 ml/kg are at high risk of respiratory failure and should be monitored in an ICU setting. Although the decision of when to intubate is a clinical one, FVC falling below 10 to 15 ml/kg generally requires intubation.
- CT scan with contrast of anterior chest to look for thymoma or residual thymic tissue. 10% of patients with MG have a thymoma and the prevalence increases with age.
- Thyroid-stimulating hormone, free T_4 to rule out thyroid disease.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Patient education to facilitate recognition of worsening symptoms and impress need for medical evaluation at onset of clinical deterioration
- Avoidance of selected drugs (Table 3) known to provoke exacerbations of MG (beta-blockers, aminoglycoside and quinolone antibiotics, penicillamine, interferons, class I antiarrhythmics [procainamide, quinidine, etc.])

TABLE 1 Osserman Classification Used by the Myasthenia Gravis Foundation of America to Standardize Clinical Symptoms[1]

Class I	Any ocular muscle weakness
Class II	Ocular muscle weakness of any severity, MILD limb weakness
Class IIa	Predominantly limb and/or axial muscle weakness
Class IIb	Predominantly bulbar and/or respiratory muscle weakness
Class III	Ocular muscle weakness of any severity, MODERATE weakness of other muscles
Class IIIa	Predominantly limb and/or axial muscle weakness
Class IIIb	Predominantly bulbar and/or respiratory muscle weakness
Class IV	Ocular muscle weakness of any severity, SEVERE weakness of other muscles
Class IVa	Predominantly limb and/or axial muscle weakness
Class IVb	Predominantly bulbar and/or respiratory muscle weakness
Class V	Intubation with or without mechanical ventilation

[1]Jaretzki A et al: Myasthenia gravis: recommendations for clinical research standards. Task Force of the Medical Scientific Advisory Board of the Myasthenia Gravis Foundation of America, *Neurology* 55:16-23, 2000.
From Parrillo JE, Dellinger RP: *Critical care medicine: principles of diagnosis and management in the adult,* ed 5, Philadelphia, 2019, Elsevier.

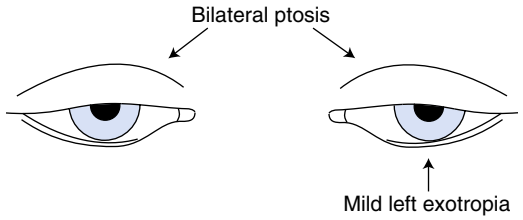

FIG. 1 Myasthenia gravis. Myasthenia gravis may mimic any ocular disorder causing diplopia, although most often it mimics weakness of the superior rectus muscle or medial rectus muscle (i.e., difficulty with sustained elevation or adduction of the eye, respectively). Clues to the diagnosis of myasthenia gravis are associated ptosis, fluctuating course, and normal pupils. (From McGee S: *Evidence-based physical diagnosis,* ed 4, Philadelphia, 2018, Elsevier.)

TABLE 2 Serologic and Clinical Presentation of Myasthenia Gravis Subgroups[1-7]

	AChR Antibody	MuSK Antibody	Striated Muscle Antigens Titin Antibody RyR Antibody	Age at Onset Sex	Clinical Findings	Response to Therapy	Response to Thymectomy	Prognosis
Ocular MG	50%-75%	None	None	Older Male	Ocular	Good	Good	Good (but 50% can develop generalized MG in 2 yr)
Early-onset generalized MG	80%-85% (high titer)	None	None-rare	<50 yr	General	Rarely needs immunosuppression	Good	Less severe Low mortality
Late-onset generalized MG	None-rare	None	50% 54% titin 33% RyR	≥50 yr	General	Often requires immunosuppression	Poor	Severe
Thymomatous-associated MG	Positive, nearly 100% (low titer)	None	95% 50% titin 47% RyR	Ranges: Older but <40 yr if RyR	General If RyR: Ocular, bulbar, respiratory weakness	Often requires immunosuppression	Fair	RyR: Invasive, malignant thymoma Severe Higher mortality
Generalized MG MuSK positive	None	100%	None	Younger Female	Facial, bulbar, neck, respiratory weakness paraspinal, esophageal muscles	Poor response to AChE inhibitors	Poor (no thymic changes)	Severe, progressive course
MG with thymic hyperplasia	89%	None	None	Younger Female	General	Good	Good	Good
ACh antibody negative	Negative	Negative	Present	Younger Female	General	Poor		Fair

TABLE 3 Medications to Avoid in Myasthenia Gravis[1]

Medications to Avoid	Examples	Recommendation for Avoidance	Mechanism of Weakness
Antibiotics			
Aminoglycosides	Gentamycin Streptomycin	Contraindicated	Blocks ACh receptor, prevents release of ACh
	Tobramycin Amikacin	Less likely problematic	
Antimalarials	Quinine Chloroquine	Contraindicated	Presynaptic blockage of voltage-dependent sodium channels and postsynaptic potentiation of depolarization
Macrolides	Erythromycin, Tetracycline Azithromycin	Relative	Affects presynaptic transmission
Fluoroquinolones	Moxifloxacin Ciprofloxacin Levofloxacin Ofloxacin	FDA black box warning	Unknown
Ketolide	Telithromycin	FDA black box warning	Unknown
	Polymyxins	Contraindicated	Presynaptic and postsynaptic effects
Cardiovascular			
Antiarrhythmics	Procainamide Propafenone	Contraindicated	Decreases the release of ACh Sodium influx blocker
β-Blockers	Propranolol Atenolol Ophthalmic timolol	Relative	Unclear—may be at the neuromuscular junction or muscle membrane
Calcium channel blocker	Verapamil Amlodipine	Relative	Presynaptic and postsynaptic blockade of L-type calcium channels
Anticonvulsants			
	Phenytoin	Relative	Depressed postsynaptic response to ACh; inhibition of calcium channel; increase in muscle membrane threshold
	Carbamazepine	Relative	Triggers immune response
	Gabapentin	Relative	Binds voltage-gated calcium channel
Chemotherapeutic Agents			
	Doxorubicin Etoposide Cisplatin	Relative	Unknown
Others			
	Interferon	Relative	Autoantibody production
Neuromuscular blocking agents	Atracurium Cisatracurium Vecuronium	Relative	Blocks ACh receptors
Statins		Relative	Unknown
Corticosteroids		Relative	Direct blocking of ACh receptor through ionic channels
Botulinum toxin		Contraindicated	Impairs synaptic transmission
Magnesium		Relative	Impairs synaptic transmission
Penicillamine		Contraindicated	Binds the ACh receptor; induces antibodies to receptor

- Prompt treatment of infections, diet modification, and speech evaluation with dysphagia

ACUTE GENERAL Rx

- Symptomatic treatment with acetylcholinesterase inhibitors:
  1. Pyridostigmine 30 to 60 mg PO q4 to 6h initially; onset of effects is 30 min, duration 4 hr. May be titrated up to 120 mg every 4 hr. GI upset is not uncommon with higher doses and may respond to hyoscyamine.
- Immunosuppressive treatment with corticosteroids and azathioprine is first-line treatment:
  1. Prednisone initiated at 10 to 20 mg qd titrated by 5-mg increments to effect or dose of 1 mg/kg/day with improvement in 2 to 4 wk and maximal response by 3 to 6 mo.
  2. Azathioprine initiated at 50 mg qd titrated to 2 to 3 mg/kg/day with clinical effect in 6 to 12 mo. Azathioprine is not recommended in patients with no thiopurine methyltransferase activity.
- Alternative secondary agents:
  1. Eculizumab, a first-in-class compliment inhibitor, is FDA-approved for adult patients who are acetylcholine-antibody positive and continue to suffer from severe symptoms despite current immunotherapy use.
  2. Cyclosporine initiated at 5 mg/kg/day with clinical effect within 1 to 2 mo.
  3. Mycophenolate mofetil 500 mg twice a day titrated to 2 g/day with clinical effect in 3 to 6 mo, but can be up to 12 mo.
  4. Rituximab.
- Plasmapheresis and IV immunoglobulin are short-term options for immunotherapy during an exacerbation. There is no significant difference in efficacy between intravenous immunoglobulin (IVIG) and plasmapheresis.
- Mechanical ventilation is lifesaving in setting of a myasthenic crisis. Consider elective intubation if forced vital capacity <10 to 15 ml/kg.

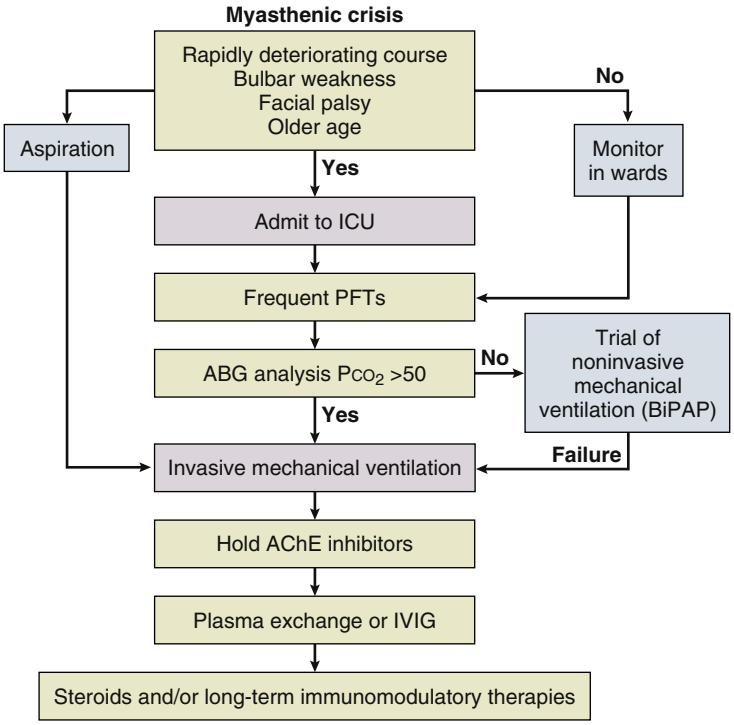

FIG. 4 Clinical flowchart for the management of myasthenic crisis. *ABG,* Arterial blood gas; *AChE,* acetyl cholinesterase; *BiPAP,* bilevel positive airway pressure; *ICU,* intensive care unit; *IVIG,* intravenous immunoglobulin; *PFT,* pulmonary function test. (From Parrillo JE, Dellinger RP: *Critical care medicine, principles of diagnosis and management in the adult,* ed 4, Philadelphia, 2014, Elsevier.)

- Fig. 4 illustrates a flowchart for the management of myasthenic crisis.

SURGICAL Rx

- In thymomatous MG, thymectomy is indicated in all patients. If the tumor cannot be surgically resected, chemotherapy can be considered for prevention of local invasion and symptom relief.
- For nonthymomatous autoimmune MG, thymectomy improves clinical outcomes and reduces the need for steroids sustained over at least a 5-yr period. Surgical referral should be considered in patients <60 yr old without significant medical comorbidities even if no frank thymic tissue seen on imaging, especially if they are refractory to therapy.
- MuSK myasthenia is not associated with thymic pathology.

DISPOSITION

Course of disease is highly variable. Mortality rate has decreased from 75% to 4.5% over the past four decades.

REFERRAL

- Referral to a general neurologist or neuromuscular specialist is appropriate.
- Surgical referral for thymectomy in selected cases (see "Surgical Rx").

PEARLS & CONSIDERATIONS

- Sustained upward or lateral gaze and arm abduction for 120 sec may be necessary to elicit subtle signs on examination.
- Myasthenic patients can worsen rapidly and warrant careful observation during an exacerbation or when ill.

Mycosis Fungoides ALG

BASIC INFORMATION

DEFINITION

Mycosis fungoides is an epidermotropic cutaneous T-cell lymphoma characterized by a proliferation of small- to medium-size T lymphocytes with cerebriform nuclei with skin as their primary site.

SYNONYMS

Cutaneous T-cell lymphoma
MF

ICD-10CM CODES

C84.00	Mycosis fungoides, unspecified site
C84.01	Mycosis fungoides, lymph nodes of head, face, and neck
C84.02	Mycosis fungoides, intrathoracic lymph nodes
C84.03	Mycosis fungoides, intra-abdominal lymph nodes
C84.04	Mycosis fungoides, lymph nodes of axilla and upper limb
C84.05	Mycosis fungoides, lymph nodes of inguinal region and lower limb
C84.06	Mycosis fungoides, intrapelvic lymph nodes
C84.07	Mycosis fungoides, spleen
C84.08	Mycosis fungoides, lymph nodes of multiple sites
C84.09	Mycosis fungoides, extranodal and solid organ sites

EPIDEMIOLOGY & DEMOGRAPHICS

- The annual incidence of cutaneous lymphomas in the U.S. is about 0.6 to 1.0 per 100,000, and mycosis fungoides constitutes about 50% of the cutaneous lymphomas.
- More commonly affects males than females (2:1).
- The majority of patients are Caucasian (70%).
- Median age of diagnosis is 55 to 60 yr but it can also be seen in young adults and children.

CLINICAL PRESENTATION

Mycosis fungoides usually presents in the skin with erythematous patches, plaques, and, less frequently, tumors. Scaling is often found on patch and plaque lesions. The lesions are usually pruritic and patients may have alopecia. Rarely, lesions are atrophied and dyspigmented. Some patients of mycosis fungoides develop erythroderma later in the course of the disease.

Mycosis fungoides usually has an indolent clinical course with slow progression over years and sometimes over decades from patches to more infiltrative plaques and eventually to tumors. The initial skin lesions have predilection for the buttocks and other sun-protected areas ("bathing suit" areas). Patients with tumor-stage MF characteristically show a combination of patches, plaques, and tumors, which often show ulceration. If only tumors are present, without preceding or concurrent patches or plaques, a diagnosis of MF is highly unlikely and another type of cutaneous T-cell lymphoma should be considered.

Sézary syndrome (SS) is considered in patients with erythroderma, circulating T cells, and with or without associated lymphadenopathy.

STAGING

Staging patients with mycosis fungoides (Table E1) is helpful in guiding therapy and it has prognostic value too. The lesions of mycosis fungoides are classified into four tumor (T) groups, T_1-patches and plaques affecting less than 10% of body surface area, T_2-patches and plaques affecting more than 10% of body surface area, T_3-presence of tumors (i.e., raised, dome-shaped lesions >1 cm in diameter), and T_4-erythroderma affecting more than 80% of body surface area.

Because patients with extensive mycosis fungoides lesions (T_2 or T_3 disease) can have substantial blood involvement in the absence of erythroderma, blood assessment is needed in these patients.

- Stage I_A disease is defined as a patch or plaque skin disease involving <10% of the skin surface area and with absence of blood involvement or with low blood tumor burden (<5% of atypical T cells [Sézary cells] in the peripheral blood).
- Stage I_B disease is defined as a patch or plaque skin disease involving ≥10% of the skin surface area (Fig. E1) with absence of blood involvement or low blood tumor burden (<5% Sézary cells).
- Stage II_A and stage II_B diseases are defined by the presence of tumors with or without clinically abnormal peripheral lymph nodes with absence of blood involvement or low blood tumor burden. In approximately 5% of cases of mycosis fungoides, the presentation may be a diffuse, painful, pruritic erythroderma with Sézary cells (Fig. E2) in the peripheral blood (known as Sézary syndrome) (Fig. E3).
- Stage III disease is defined by the presence of generalized erythroderma from the spread of cancer cells through the skin but not yet to the lymph nodes.
- Stage IV_A disease is defined by a lymph node biopsy showing large clusters of atypical cells, more than six cells, or total effacement by atypical cells.
- Stage IV_B disease is defined by the presence of visceral involvement.

ETIOLOGY

Several etiologies have been postulated for mycosis fungoides. There is a supporting role of the skin microenvironment in the pathogenesis, as MF is thought to arise in the background of chronic inflammation. Extravasation and migration of malignant T cells are facilitated by chemokines, cytokines, and adhesion molecules. Th1 and Th2 cytokines are both involved in different stages of the course of MF.

DIAGNOSIS

The diagnosis of mycosis fungoides is established by skin biopsy. This may be difficult to differentiate from other skin lesions in the early phases of the disease (e.g., premycotic patch or early plaque lesions); therefore the diagnosis can only be suspected.

The biopsy of the skin lesions in mycosis fungoides usually shows superficial band like or lichenoid infiltrate, mainly consisting of lymphocytes and histocytes. Atypical T cells of small to regular size with irregular (cerebriform) nuclei are frequently present on or within the epidermis (epidermotropism). The presence of intraepidermal collection of atypical cells (Pautrier microabscesses) is sometimes present and they are a fairly specific but insensitive histologic marker for mycosis fungoides. Because histologic findings are often nondiagnostic, especially in patch stage disease, serial biopsies are frequently needed for the confirmation of diagnosis.

Immunohistochemical staining generally shows atypical CD4+ T cells along with demonstration of aberrant T-cell phenotype (e.g., loss of T-cell antigens). Clonal T-cell gene rearrangements are detected in most cases of mycosis fungoides. These findings help in the diagnosis of mycosis fungoides but they are not very specific.

The diagnosis of early mycosis fungoides often needs integration of clinical, histologic, and molecular features since it can be confused with benign eczematous skin disease.

DIFFERENTIAL DIAGNOSIS

- Contact dermatitis
- Atopic dermatitis
- Nummular dermatitis
- Parapsoriases
- Superficial fungal infections
- Drug eruptions
- Psoriasis
- Photodermatitis
- Alopecia mucinosa
- Lymphomatoid papulosis

WORKUP

Any patient who is suspected of having mycosis fungoides should have a staging workup. Prognosis in patients with mycosis fungoides depends on the type of skin lesions and the extent of disease. The workup should focus on:

- Complete physical examination:
  1. The type of skin lesion and the extent of skin involvement of the body (e.g., skin involvement is >10% or <10% of the skin surface)
  2. Identification of palpable lymph node (especially those >1.5 cm in largest diameter)
  3. Identification of organomegaly (e.g., lungs, liver)
- Skin biopsy:
  1. Biopsy of the most indurated area
  2. Immunophenotyping
  3. Evaluation for clonality
- Blood test:
  1. Complete blood count with differential, liver function tests, lactate dehydrogenase, chemistry
  2. T-cell receptor gene rearrangement

TABLE E1 TNMB Classification and Staging for Patients with Mycosis Fungoides/Sézary Syndrome

T (Skin)	
T_1	Limited patch or plaque (<10% of BSA)
T_2	Generalized patch or plaque (>10% of BSA) T_{2a} = patch only
T_3	One or more tumors (>1 cm)
T_4	Generalized erythroderma (>80% of BSA)
N (Nodes)	
N_0	No clinically abnormal peripheral lymph nodes
N_1	Clinically abnormal peripheral lymph nodes Dutch grade 1, NCI grade LN_0-LN_2
N_{1a}	Clone negative
N_{1b}	Clone positive
N_2	Clinically abnormal peripheral lymph nodes Dutch grade 2, NCI grade LN_3
N_{2a}	Clone negative
N_{2b}	Clone positive
N_3	Clinically abnormal peripheral lymph nodes Dutch grade 3, NCI grade LN_4, clone positive or negative
N_x	Clinically abnormal peripheral lymph nodes No histologic confirmation
M (Viscera)	
M_0	No visceral organ involvement
M_1	Visceral organ involvement (pathology confirmation required)
B (Blood)	
B_0	Atypical circulating cells not present (<5%)
B_{0a}	Clone negative
B_{0b}	Clone positive
B_1	Atypical circulating cells present (>5%)
B_{1a}	Clone negative
B_{1b}	Clone positive
B_2	≥1000/μL Sézary cells, clone positive

Stage	T	N	M	B
I_A	1	0	0	0, 1
I_B	2	0	0	0, 1
II_A	1, 2	1, 2	0	0, 1
II_B	3	0-2	0	0, 1
III_A	4	0-2	0	0
III_B	4	0-2	0	1
IV_{A1}	1-4	0-2	0	2
IV_{A2}	1-4	3	0	0-2
IV_B	1-4	0-3	1	0-2

BSA, Body surface area; *NCI,* National Cancer Institute; *TNMB,* tumor, node, metastasis, blood.
From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

3. Determination of Sézary cell count and/or flow cytometry
- Radiologic tests: Depending on the stage of the disease, chest radiograph; ultrasound; and CT scan of the chest, abdomen, and pelvis alone, with or without fluorodeoxyglucose positron emission tomography scan
- Lymph node biopsy:
  1. Excisional biopsy
  2. Biopsy of the largest lymph node
  3. If multiple nodes enlarged, order of preference is cervical, axillary, and inguinal areas
  4. Histopathology, flow cytometry, T-cell receptor gene rearrangement

Rx TREATMENT

Treatment is guided according to the stage of disease (Box E1) and involves a multidisciplinary team consisting of dermatopathologists, dermatologists, radiation oncologists, and medical oncologists. Therapeutic options are summarized in Table E2, and a treatment algorithm is described in Fig. E4.

NONPHARMACOLOGIC THERAPY

- For dry, cracking skin, emollients (e.g., lanolin and petrolatum) are applied bid.
- Moisturizing lotion (e.g., ammonium lactate) applied bid.
- Topical antibiotics (e.g., bacitracin) are used on ulcerative tumors.

ACUTE GENERAL Rx

- Treatment of patients with stage I_A limited patch or plaque phase includes skin-directed therapies: Topical corticosteroids, topical chemotherapy (nitrogen mustard or carmustine), topical retinoid, phototherapy, and local radiation. There are no well-designed prospective randomized controlled trials comparing the efficacy of these treatment modalities. Most of the patients respond to one or another modality of therapy.
- Treatment of patients with stage I_B to II_A disease is similar to stage I_A. Skin-directed therapies alone or in combination are used with good results:
  1. Topical chemotherapy (nitrogen mustard, carmustine)
  2. Topical retinoids
  3. Phototherapy includes ultraviolet A light with oral methoxypsoralen (PUVA)
  4. Total skin electron beam therapy
  5. Combination of PUVA phototherapy with systemic interferon has been studied in patients with stage I_B to II_A and complete response rates of about 80% have been reported. Similarly, a randomized trial comparing PUVA with systemic interferon and systemic interferon with retinoids has shown superior response rate and less time to response with PUVA phototherapy and systemic interferon compared to interferon with retinoids
- Treatment of patients with stage II_B disease with generalized tumor and plaque disease:
  1. Total skin electron beam therapy has shown effectiveness in patients with II_B disease. The 5-yr disease-free survival is about 50%. Patients with <10% BSA involvement do better than patients with extensive involvement. Phototherapy in combination with interferon have shown a response rate of about 50%.
  2. Patients who do not respond to local therapies need treatment with systemic therapy.
- Topical therapies can be considered in stage III disease but the response and duration of response are less. Hence systemic therapies (biologic therapy or systemic chemotherapy) are considered in stage III and stage IV disease.

Biologic therapies used in these advanced diseases are interferon alfa, photopheresis, systemic retinoid, histone deacetylase inhibitors (vorinostat, romidepsin, belinostat, and panobinostat), denileukin diftitox (recombinant DNA derived cytotoxic protein), and monoclonal antibodies (alemtuzumab, brentuximab, mogamulizumab). The combination of biological agents has shown improved response rate.

FIG. E1 Mycosis fungoides. A, Plaques of mycosis fungoides often have a polycyclic appearance. **B,** Tumors are more elevated above the skin surface. By the time tumors supervene, sun-exposed skin, such as the face, is often involved. (From Jaffe ES et al: *Hematopathology,* Philadelphia, 2011, WB Saunders.)

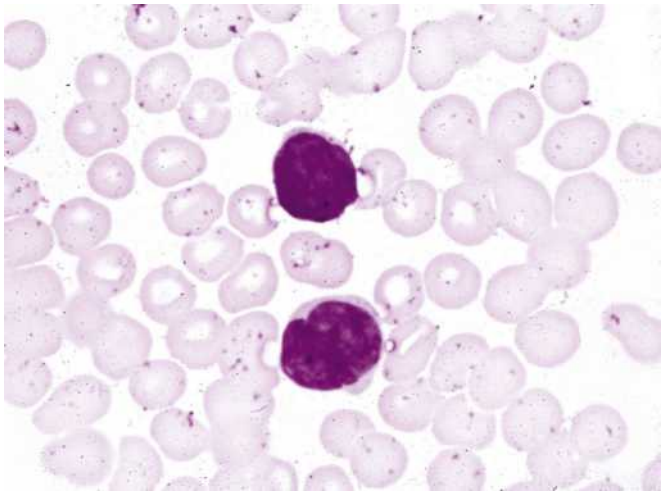

FIG. E2 Sézary cells in a peripheral blood smear. Recognition of these cells is no longer critical for the diagnosis since the advent of clonality studies and flow cytometry. (From Jaffe ES et al: *Hematopathology,* ed 1, Philadelphia, 2011, WB Saunders.)

FIG. E3 Sézary syndrome presents with erythroderma-diffuse red skin. The term *erythroderma* is overused by clinicians; it should refer to confluent erythema, not just widespread erythematous lesions. (From Jaffe ES et al: *Hematopathology,* Philadelphia, 2011, WB Saunders.)

BOX E1 Summary of Treatment Approaches for Patients with Mycosis Fungoides and Sézary Syndrome

Early-Stage Mycosis Fungoides
Topical
- Corticosteroids
- Phototherapy
- Nitrogen mustard
- Bexarotene
- Radiation or TSEBT

Refractory Early-Stage Mycosis Fungoides
Combined therapy
- PUVA or NB-UVB and INF-α
- PUVA or NB-UVB and bexarotene (low dose)

Advanced Mycosis Fungoides/Sézary Syndrome
Biologic therapy
- Interferons (INF-α, IFN-γ)
- Retinoid or rexinoid (bexarotene)
- Extracorporeal photopheresis
- Alemtuzumab
- HDACIs (romidepsin, vorinostat)
- Bortezomib
- Antifolates (methotrexate, pralatrexate)
- Mogamulizumab (anti-CCR4)
- Denileukin diftitox (Ontak)
- Brentuximab vedotin

Combined therapy
- INF-α and phototherapy
- INF-α and retinoid or rexinoid
- Retinoid and phototherapy
- ECP and INF-α
- ECP and retinoid or rexinoid

Systemic chemotherapy
Single agent
- Pegylated doxorubicin
- Purine or pyrimidine analogues
  - Pentostatin
  - Gemcitabine
- Temozolomide

Multiagent
- CHOP and CHOP-like, CMED, CHOEP

Stem cell transplant
- Autologous
- Allogeneic
- Nonmyeloablative allogeneic

Investigational therapy
- Lenalidomide

CHOP, Cyclophosphamide, doxorubicin, vincristine, and prednisone; *CHOEP,* cyclophosphamide, doxorubicin, etoposide, vincristine, prednisone; *CMED,* cyclophosphamide, methotrexate, etoposide, dexamethasone; *ECP,* extracorporeal photopheresis; *HDACI,* histone deacetylase inhibitor; *INF,* interferon; *NB-UVB,* narrow-band ultraviolet-B light therapy; *PUVA,* psoralens and ultraviolet-A light therapy; *TSEBT,* total-skin electron-beam therapy.
From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

TABLE E2 Therapeutic Options for Mycosis Fungoides

Topical Therapy

Ultraviolet A with psoralen
Ultraviolet B
External beam radiation therapy
Total-skin electron beam radiation
Topical chemotherapy
Topical retinoids

Systemic Therapy

Photophoresis
Interferon-α
Oral retinoids
Targeted therapies
Single-agent chemotherapy
Combination chemotherapy
Stem cell transplantation
Investigational agents

From Hoffman R et al: *Hematology: basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

Unfortunately, most of these patients relapse and develop disease that is refractory to treatment.

Cytotoxic combination chemotherapy regimens have demonstrated activity in advanced-stage cutaneous T-cell lymphoma. Even though they produce higher responses, these are not durable and there are significant toxicities. Hence, single-agent systemic chemotherapy is preferred over combination chemotherapy unless patients are refractory or immediate palliation is needed for extensive tumor burden. Allogenic stem cell transplant has been shown to induce complete and durable remissions in a small number but carries a risk of transplant-related mortality. Hence, reduced intensity allogenic stem cell transplantation is currently being investigated.

DISPOSITION

The 10-yr rates of overall survival are as follows:

- Stage I disease: 65% to 90%
- Stage II disease: 35% to 50%
- Stage III disease: 25% to 35%
- Stage IV disease: 15% to 20%

REFERRAL

Any patient with suspected mycosis fungoides should be referred to a dermatologist with expertise in this entity for definitive diagnosis and initiating therapy. Oncology consultation is indicated in patients with more advanced disease.

PEARLS & CONSIDERATIONS

- The International Society for Cutaneous Lymphomas (ISCL) and the Cutaneous Lymphoma Task Force of the European Organization of Research and Treatment of Cancer (EORTC) recommended revisions to the TNM classification and staging system

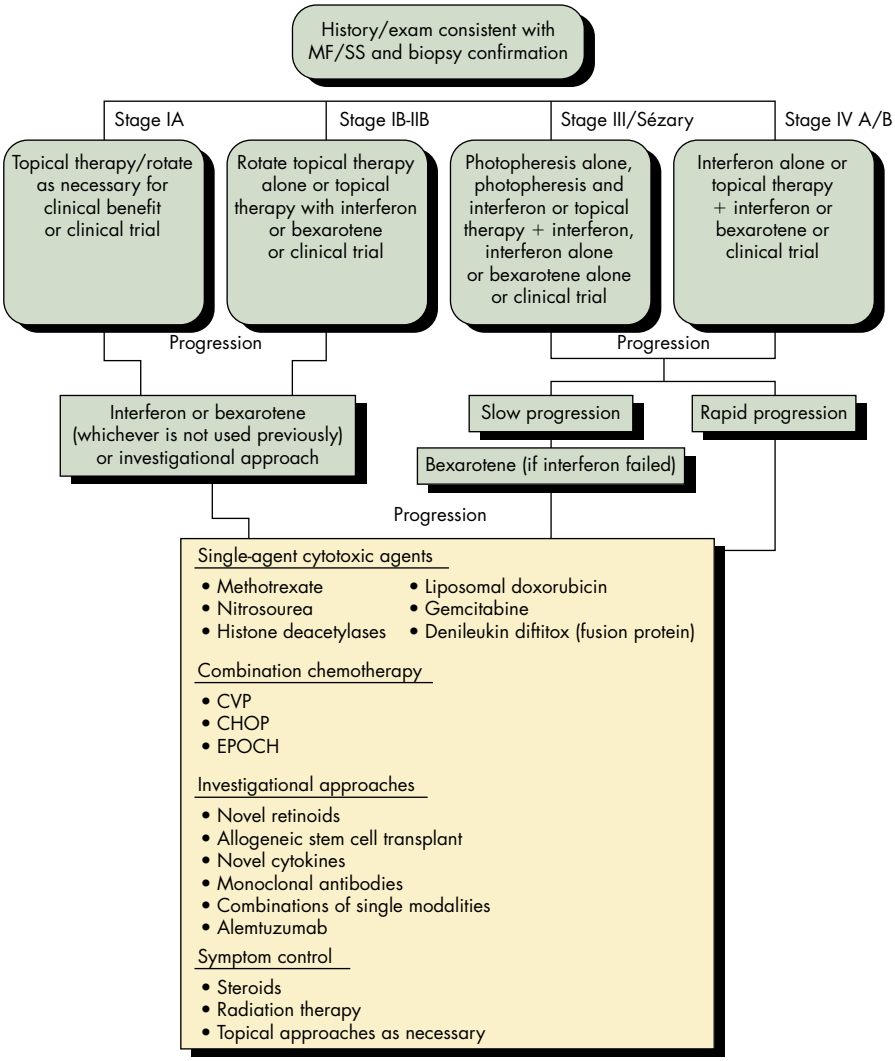

FIG. E4 Algorithm for the care of patients with mycosis fungoides or Sézary syndrome. *CHOP,* Cyclophosphamide, doxorubicin (hydroxorubicin), Oncovin (vincristine), prednisone; *CVP,* central venous pressure; *EPOCH,* etoposide-prednisone-Oncovin-cyclophosphamide-hydroxydaunorubicin; *MF,* mycosis fungoides; *SS,* Sézary syndrome. of cutaneous T-cell lymphoma in 2007. Table E3 compares EORTC and WHO classifications of primary cutaneous lymphoma. The ISCL/EORTC revision to the classification of MF and SS (adaptation) is described in Table E4.

- Diagnostic workup always includes assessment of skin, blood, nodes, and the viscera.
- The prognosis of mycosis fungoides in most patients with limited patch/plaque disease is favorable and similar to that of an age-, sex-, and race-matched control population.
- Important quality-of-life considerations include pruritus, xerosis, and the prevention of skin infections.

AUTHOR: **Bharti Rathore, MD**

TABLE E4 ISCL/EORTC Revision to the Classification of MF and SS (Adaptation)

TNMB Stages	
Skin	
T_1	Limited patches, papules, and/or plaques covering <10% of the skin surface. May stratify into T_{1a} (patch only) vs T_{1b} (plaque ± patch).
T_2	Patches, papules or plaques covering ≥10% of skin surface. May stratify into T_{2a} (patch only) vs T_{2b} (plaque ± patch).
T_3	One or more tumors (≥1-cm diameter)
T_4	Confluence of erythema covering ≥80% body surface area
Node	
N_0	No clinically abnormal peripheral lymph nodes; biopsy not required
N_1	Abnormal peripheral lymph nodes; histopathology Dutch grade 1 or NCI LN_{0-2}
N_2	Abnormal peripheral lymph nodes; histopathology Dutch grade 2 or NCI LN_3
N_3	Abnormal peripheral lymph nodes; histopathology Dutch grades 3-4 or NCI LN_4
N_x	Abnormal peripheral lymph nodes; no histologic confirmation
Visceral	
M_0	No visceral organ involvement
M_1	Visceral involvement (must have pathology confirmation and involved organ should be specified)
Blood	
B_0	Absence of significant blood involvement: ≤5% of peripheral blood lymphocytes are atypical (Sézary) cells
B_1	Low blood tumor burden: >5% of peripheral blood lymphocytes are atypical (Sézary) but does not meet the criteria for B_2
B_2	High blood tumor burden: ≥1000/μL Sézary cells with positive clones
Clinical Staging	
I_A	T_1, N_0, M_0, $B_{0,1}$
I_B	T_2, N_0, M_0, $B_{0,1}$
II_A	$T_{1,2}$, $N_{1,2}$, M_0, $B_{0,1}$
II_B	T_3, N_{0-2}, M_0, B0,1
III_A	T_4, N_{0-2}, M_0, B_0
III_B	T_4, N_{0-2}, M_0, B_1
IV_{A1}	T_{1-4}, N_{0-2}, M_0, B_2
IV_{A2}	T_{1-4}, N_3, M_0, B_{0-2}
IV_B	T_{1-4}, N_{0-3}, M_1, B_{0-2}

BASIC INFORMATION

DEFINITION

Myelodysplastic syndromes (MDS) are a group of acquired clonal disorders affecting hematopoietic stem cells and are characterized by altered differentiation and proliferation. Patients present with peripheral blood cytopenias and morphologic abnormalities but have a hypercellular bone marrow upon examination. The increased marrow cellularity reflects ineffective hematopoiesis with inadequate maturation resulting in cytopenias.

CLASSIFICATION

- In 1982, the French-American-British (FAB) classification included refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess blasts (RAEB), chronic myelomonocytic leukemia (CMML), and refractory anemia with excess blasts in transformation (RAEB-T).
- In 1999, the World Health Organization (WHO) modified the FAB by incorporating newer morphologic insights and cytogenetic findings. It reduced the blast percentage for the diagnosis of acute myeloid leukemia (AML) to 20%, added refractory cytopenia with multilineage dysplasia (RCMD), refined refractory anemia with excessive blasts into types 1 and 2 (RAEB-1, RAEB-2), and added unclassified MDS, and MDS associated with isolated del(5q).
- In 2008, the WHO further modified the classification by subcategorizing MDS into six different categories (Table 1).

SYNONYMS

MDS
Preleukemia

ICD-10CM CODES

D46.9	Myelodysplastic syndrome, unspecified
D46.C	Myelodysplastic syndrome with isolated del(5q) chromosomal abnormality
D46.Z	Other myelodysplastic syndromes

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Approximately five new cases/100,000 persons per yr. An estimated 30,000 new cases are diagnosed annually in the U.S.

PREDOMINANT AGE: More common in elderly patients; median age >65 yr

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients often present with fatigue due to anemia and also with thrombocytopenia and leukopenia.
- Skin pallor, mucosal bleeding, and ecchymosis may be present.
- Fever, infection, and dyspnea are common.

ETIOLOGY

Exposure to radiation, chemotherapeutic agents, benzene, or other organic compounds is associated with myelodysplasia. Table 2 describes predisposing factors and epidemiologic associations of patients with MDS. Up to 40 genes that affect specific functional pathways are mutated in MDS, with 90% of patients having at least one mutation and a median of two to three mutations detected per patient. The most common mutations occur in genes involved in RNA splicing *(SF3B1, SRSF2, U2AF1,* and *ZRSR2),* epigenetic modification *(TET2, ASXL1,* and *DNMT3A),* regulators of signal transduction *(NRAS* and *JAK2),* and transcription factors *(RUNX1* and *TP53).*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hereditary dysplasias (e.g., Fanconi anemia, Diamond-Blackfan syndrome)

TABLE 1 2008 World Health Organization Classification of the Adult Myelodysplastic Syndromes

Refractory Cytopenia with Unilineage Dysplasia	
Dysplasia	≥10% of cells from a single lineage
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	Includes refractory anemia (RA), refractory neutropenia, refractory thrombocytopenia; RA is by far the most common subtype
Refractory Anemia with Ring Sideroblasts	
Dysplasia	Isolated erythroid dysplasia
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	≥15% of erythroid precursors are ring sideroblasts Frequently associated with SF3B1 mutations
MDS with Isolated del(5q)	
Dysplasia	Normal or increased megakaryocytes with hypolobated nuclei
Blasts	<20% (though usually much less)
Notes	del(5q31) must be sole chromosomal abnormality
Refractory Cytopenia with Multilineage Dysplasia	
Dysplasia	≥10% of cells from two or more myeloid lineages
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	Peripheral monocyte count must be $<1 \times 10^9$/L; ring sideroblasts may be present
Refractory Anemia with Excess Blasts	
Dysplasia	No specific requirement
Blasts	RAEB-1: 5%-9% in marrow, <5% in peripheral blood, AND no Auer rods RAEB-2: 10%-19% in marrow, 5%-19% in peripheral blood, OR Auer rods
Notes	Old designation of RAEB-t (20%-30% blasts) now considered AML
Unclassifiable MDS	
Dysplasia	Minimal, or not meeting criteria for another subtype
Blasts	<5% in marrow; <1% in peripheral blood; no Auer rods
Notes	In presence of *clonal cytogenetic finding* considered diagnostic of MDS

Excludes refractory cytopenias of childhood. MDS/myeloproliferative neoplasms such as chronic myelomonocytic leukemia and RARS with thrombocytosis are classified separately.
AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome; *RAEB,* refractory anemia with excess blast.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE 2 Predisposing Factors and Epidemiologic Associations of Patients with Myelodysplastic Syndrome

Heritable

Constitutional Genetic Disorders

Trisomy 8 mosaicism
Familial monosomy 7
Down syndrome (trisomy 21)
Neurofibromatosis 1
Germ cell tumors [embryonal dysgenesis del(12p)]

Congenital Neutropenia

Kostmann syndrome
Shwachman-Diamond syndrome

DNA Repair Deficiencies

Fanconi anemia
Ataxia-telangiectasia
Bloom syndrome
Xeroderma pigmentosum
Pharmacogenomic polymorphisms (GSTq1-null)

Acquired

Senescence

Mutagen Exposure

Alkylator therapy (chlorambucil, cyclophosphamide, melphalan, N-mustards)
Topoisomerase II inhibitors (anthracyclines)
β Emitters (32p)
Autologous stem cell transplantation
Environmental/occupational (benzene)
Tobacco
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Churchill Livingstone.

- Vitamin B_{12}/folate deficiency
- Exposure to toxins (drugs, alcohol, chemotherapy)
- Renal failure
- Irradiation
- Autoimmune disease
- Paroxysmal nocturnal hemoglobinuria

WORKUP

Diagnostic workup includes laboratory evaluation and bone marrow examination (Fig. E1). Cytogenetic analysis (Box E1) by conventional metaphase karyotyping or by MDS FISH assessment should be performed in patients with MDS. Genes recurrently mutated in myelodysplastic syndrome are summarized in Table 3. Physical examination, medical history, and laboratory tests aiding in diagnosis of MDS are described in Table 4. Key features of the major myelodysplastic syndromes are summarized in Table 5.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Packed red blood cell transfusions in patients with severe symptomatic anemia
- Platelet transfusions in patients with severe thrombocytopenia or those with bleeding episodes

ACUTE GENERAL Rx

- The initial focus of MDS therapy involves stratification of patients into low-, intermediate-, and high-risk states using well-defined and validated risk stratification systems. The original International Prognostic Scoring System (IPSS), which incorporated cytopenias, cytogenetics, and blast percentage, is still clinically used. The revised IPSS (IPSS-R) has been created from an evaluation of more than 7000 patients and utilizes a five-tier risk grouping that accounts for the degree of cytopenias and bone marrow blast percentage and has 15 cytogenetic subtypes.
- Fig. 2 and Table 6 summarize a treatment approach for MDS.
- Low-risk patients are treated with supportive care or growth factors.
- Intermediate- and high-risk patients are offered treatment with hypomethylating agents along with supportive care.
- Appropriate patients are offered allogeneic donor stem cell transplantation as a potentially curative option, with high-volume centers treating patients <80 yr old.
- Erythropoietin (10,000 to 40,000 units/week) or pegylated erythropoietin (200-500 mg every 1 to 3 wk) is used in patients

TABLE 3 Genes Recurrently Mutated in Myelodysplastic Syndrome

Gene	Frequency (%)	Notes
Splicing Factors		
SF3B1	20-30	Strong association with RARS
SRSF2	10-15 (MDS) 40 (CMML)	Enriched in CMML
U2AF1	5-12	Association with del(20q)
Epigenetic Modifiers		
TET2	20-30 (MDS) 40-50 (CMML)	Enriched in CMML Mutually exclusive with IDH
DNMT3A	8-13	
ASXL1	10-20 (MDS) 30-40 (CMML)	Enriched in CMML
EZH2	5-10 (MDS) 20-30 (CMML)	Enriched in CMML May be functionally involved in 7q–
IDH1/2	<5	More frequent in AML
ATRX	Rare	Associated with acquired thalassemia
Transcription Factors		
RUNX1	10-15	Can be somatic or germline
GATA2	Rare	Mostly germline
ETV6	<5	Can be somatic or germline
TP53	10-12	Association with complex karyotype, therapy-related disease
Kinases and Receptors		
JAK2	<5	Enriched in RARS-T
NRAS	5-10	Seen in progression to AML
CBL	<5	Enriched in JMML
PTPN11	<5	More common in JMML
BRAF	Rare	Also seen in hairy cell leukemia
Cohesin Complex		
STAG2	5-10	Cohesin class mutations enriched in high-risk MDS and secondary AML.
RAD21	<5	
SMC3	<2	
SMC1A	<2	
GCPR Complex		
GNAS	Rare	Mutations recently described in wide range of hematologic malignancies, including MDS.
GNB1	Rare	

AML, Acute myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *GCPR,* G-coupled protein receptor; *IDH,* isocitrate dehydrogenase; *JMML,* juvenile myelomonocytic leukemia; *MDS,* myelodysplastic syndrome; *RARS,* refractory anemia with ring sideroblasts; *RARS-T,* RARS with thrombocytosis.

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE 4 Physical Examination, Medical History, and Laboratory Tests Aiding in Diagnosis of Myelodysplastic Syndrome

Medical History

- Duration of symptoms
- History of blood disease
- History of exposure to occupational toxins or cytotoxic agents
- Medication history
- Alcohol intake
- Comorbid conditions

Physical Examination

- Pallor
- Petechiae
- Purpura
- Bruising
- Tachypnea
- Signs of infection
- Splenomegaly

Laboratory Testing

- Complete blood count with a manual differential
- Reticulocyte count
- Vitamin B_{12} and folate levels
- Consider methylmalonic acid and red blood cell folate levels
- Iron, total iron-binding capacity, and ferritin level
- Thyroid-stimulating hormone level
- Lactate dehydrogenase
- Antinuclear antibody
- Coombs test and haptoglobin
- Serum erythropoietin level
- Human leukocyte antigen (histocompatibility antigens) typing in appropriate patients
- Paroxysmal nocturnal hemoglobinuria screen

Bone Marrow Testing

- Hematopathology
- Percentage of blasts on 200 cell aspirate differential
- Presence or absence of Auer rods
- Percentage of cellularity of bone marrow biopsy
- Iron stain on aspirate (ringed sideroblasts)
- Iron stain on biopsy (storage)
- Dysplastic features (% and number of dysplastic lineages)
- Cytogenetics (karyotype of 20 metaphase cells)
- Fluorescent in situ hybridization
- Flow cytometry (not useful for quantitation)

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Churchill Livingstone.

TABLE 5 Diagnostic Criteria for Myelodysplastic Syndrome

A. Presence of at Least One Unexplained Cytopenia for at Least 6 Mo[a]

Hemoglobin <11 g/dl, *or*

Absolute neutrophil count $<1.5 \times 10^9$/L, *or*

Platelet count $<100 \times 10^9$/L

***plus* B. Presence of One or More MDS-Qualifying Criteria:**

>10% dysplasia in one or more hematopoietic lineage, *or*

5%–19% blasts in bone marrow, *or*

MDS-defining cytogenetic abnormality, such as:

t(1;3)(p36.3;q21.1)	t(2;11)(p21;q23)	inv(3)(q21;q26.2)
t(3;21)(q26.2;q22.1)	–5 or del(5q)	t(6;9)(p23;q34)
–7 or del(7q)		del(9q)
del(11q)	t(11;16)(q23;p13.3)	del(12p) or t(12p)
–13 or del(13q)	i(17q) or del(17p)	idic(X)(q13)

***plus* C. Exclusion of Alternative Diagnoses**

AML (i.e., <20% blasts, and no t(8;21), inv(16), t(16;16), t(15;17), or erythroleukemia) or *ALL*

Other hematologic diseases (aplastic anemia, PNH, LGL, lymphoma, myelofibrosis and other MPN)

Viral infections (HIV, EBV, parvovirus)

Nutritional deficiencies (iron, copper, B_{12}, folate)

Medications (methotrexate, azathioprine, isoniazid, cytotoxic chemotherapy)

Alcohol or other toxins

Autoimmune diseases (SLE, Felty syndrome, ITP, autoimmune hemolytic anemia)

Congenital disorders (Diamond-Blackfan anemia, Shwachman-Diamond syndrome, Fanconi anemia, and others)

[a]Diagnosis can be made earlier than 6 mo if no other cause is apparent for cytopenias, or there are excess blasts or an MDS-defining cytogenetic abnormality.

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *EBV,* Epstein-Barr virus; *ITP,* immune thrombocytopenic purpura; *LGL,* large granular lymphocyte leukemia; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *PNH,* paroxysmal nocturnal hemoglobinuria; *SLE,* systemic lupus erythematosus.

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

with symptomatic anemia. Responses with increase in hemoglobin and decreased transfusion requirements are achieved typically in patients who have serum erythropoietin levels <500 U/L and adequate iron stores.

- DNA methyltransferase inhibitors: Azacitidine, a pyrimidine nucleoside analogue of cytidine, has been shown to improve the quality of life for patients and to prolong overall survival. Decitabine, another nucleoside analogue, has also been FDA approved for patients with MDS. These agents may also be useful in preventing the transition of MDS to AML.
- Immunomodulators: Lenalidomide, a novel analogue of thalidomide, has demonstrated hematologic activity in patients with low-risk MDS who have no response to erythropoietin or who are unlikely to benefit from conventional therapy. Lenalidomide can also reduce transfusion requirements and reverse cytologic and cytogenetic abnormalities in patients who have MDS with the 5q31 deletion.
- Glasdegib, a Hedgehog pathway inhibitor, has shown promising initial activity and a favorable benefit-risk profile when used in combination with low-dose chemotherapy in high-risk MDS patients who are unsuitable for intensive chemotherapy.
- Results of chemotherapy are generally disappointing. Combination chemotherapy regimens (e.g., cytarabine plus doxorubicin) that are used to treat AMLs generally induce a complete response in only a minority of patients, and the average duration of response is <1 yr.
- The use of myeloid growth factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF]) is reserved for patients with severe neutropenias and high infection risk. Additionally, these provide a synergistic effect when used in combination with erythropoietin in terms of improvement in the hemoglobin levels.

CHRONIC Rx

Monitor for infections, bleeding, and complications of anemia. Supportive measures include packed red blood cell (PRBC) transfusions and erythropoietin for anemia and antimicrobials to treat opportunistic infections. Iron overload from frequent transfusions (>100 PRBC units) requires iron chelation therapy.

DISPOSITION

- The 5-yr overall survival is approximately 30%. Median overall survival rates are best for patients with refractory anemia (56 mo), refractory anemia with ring sideroblasts (48 mo), and deletion 5q subtype (32 mo). The International Prognostic Scoring System (IPSS) for MDS is summarized in Tables 7 and 8. Table 9 describes survival based on IPSS.
- Long-term remission rates in young patients with allogeneic stem cell transplantation approach 40% to 50%.
- The risk of transformation to AML varies with the percentage of blasts in the bone marrow.

REFERRAL

- Hematology referral for all patients
- Bone marrow transplant evaluation for stem cell transplant eligibility as a potentially curative modality

PEARLS & CONSIDERATIONS

COMMENTS

- Somatic point mutations in *TP53, EZH2, ETV6, RUNX1,* and *ASXL1* are predictors of poor overall survival in patients with MDS independent of established risk factors. Patients with cytogenetic abnormalities associated with poor prognosis should be considered for upfront allogeneic stem cell transplantation.
- Many younger patients who respond to immunosuppressive therapy with drugs such as antithymocyte globulin and cyclosporine have clonal expansions of cytotoxic $CD8^+$ T cells that suppress normal hematopoiesis, as well as expansion of $CD4^+$ helper T cell subsets that promote and sustain autoimmunity.
- Nearly 50% of the deaths that result from MDS are the result of cytopenias associated with bone marrow failure.

Myelodysplastic Syndrome (Patient Information)

AUTHOR: **Ritesh Rathore, MD**

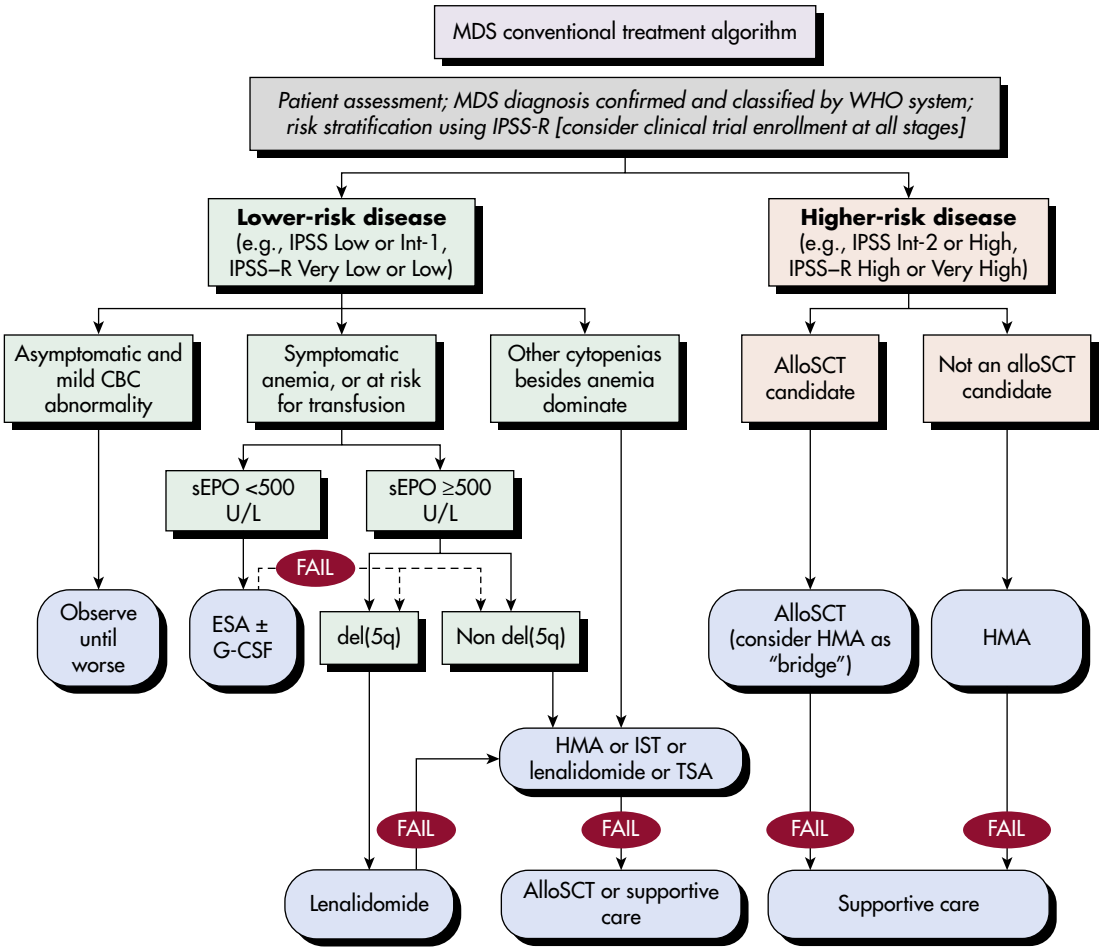

FIG. 2 A suggested treatment algorithm for myelodysplastic syndrome (MDS), described further in the text and in Table 6. Risk assessment has traditionally been based on the International Prognostic Scoring System *(IPSS)* (and more recently the IPSS-R), but that is likely to change with the advent of new prognostic scoring systems and molecular markers. IPSS-R intermediate-risk disease may follow the track for lower- or higher-risk disease. Disease classification should use the 2016 World Health Organization *(WHO)* system. Clinical trial enrollment should be considered at each step. Some clinicians would proceed to lenalidomide without a trial of an ESA if del(5q) is present, even if the serum erythropoietin level is less than 500 U/L. *CBC,* Complete blood count; ESA, erythropoiesis-stimulating agent (epoetin or darbepoetin—off-label uses); *G-CSF,* granulocyte colony-stimulating factor (e.g., filgrastim or tbo-filgrastim); *HMA,* hypomethylating agent (azacitidine or decitabine); *IPSS-R,* revised International Prognostic Scoring System; *IST,* immunosuppressive therapy (antithymocyte globulin with cyclosporine A or tacrolimus—off-label uses); *SCT,* stem cell transplantation; *sEPO,* serum erythropoietin level; *TSA,* thrombopoiesis-stimulating agent (e.g., eltrombopag, romiplostim—off-label uses). (From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.)

TABLE 6 Available Therapies for Myelodysplastic Syndromes in the United States and Preferred Dosage Regimen[a]

1. Erythropoiesis-stimulating agents (should hold if hemoglobin ≫10 g/dl)
   a. Epoetin alfa 20-60,000 mIU/wk subcutaneously; dose can be adjusted every 1-2 mo depending on response; or
   b. Darbepoetin alfa 200–300 μg subcutaneously every 1-2 wk or 500 μg subcutaneously every 3 wk; or
   c. Epoetin alfa as per (a) plus G-CSF (filgrastim) 0.5 μg /kg subcutaneously 1-3 times per wk (pegfilgrastim is commonly substituted in the United States, but data are absent, and splenic rupture and leukemoid reactions are risks); epoetin beta and other ESAs (e.g., Mircera) are available outside the United States
2. Iron chelation therapy
   a. Deferoxamine (starting dose ~20 mg/kg/day; a typical effective dose for an adult is 6 g/day subcutaneously or intravenously, administered by infusion pump over 8-16 h daily); or
   b. Deferasirox, tablet for oral suspension 20–30 mg/kg/day orally once daily oral tablet, 14-28 mg/kg/day, adjust as tolerated and according to efficacy.
   c. Deferiprone (L1) is available outside the United States, but is only approved for thalassemia in the United States and is a weaker chelator than the other two and cytopenias can be problematic
3. Lenalidomide: 10 mg orally once daily for 21-28 days per 28-day cycle (dose reduction due to cytopenias is commonly required)
4. Azacitidine: 75 mg/m^2/day subcutaneously or intravenously for 7 days, repeat every 28 days; "weekend-sparing" schedules may also be effective
5. Decitabine: 15 mg/m^2/dose over 3-4 h intravenously every 8 h × 9 doses (=3 days); or 20 mg/m^2/day intravenously over 1-2 h daily × 5 consecutive days; repeat every 4-6 wk
6. Immunosuppression: equine ATG per aplastic anemia regimens (e.g., 40 mg/kg/day × 4 days intravenously, after test dose), with corticosteroids to prevent serum sickness, with or without cyclosporine A or tacrolimus
7. Miscellaneous therapies such as antifibrinolytics (aminocaproic acid, tranexamic acid), androgens (danazol), or romiplostim can be useful in some cases.

[a]Consult the package insert in each case. Only azacitidine, lenalidomide, and decitabine are approved by the U.S. Food and Drug Administration for myelodysplastic syndrome–related indications in the United States.

ATG, Antithymocyte globulin; *ESA,* erythropoiesis-stimulating agent; *G-CSF,* granulocyte colony-stimulating factor.

BASIC INFORMATION

DEFINITION

Myocardial infarction (MI) is a clinical syndrome characterized by symptoms of myocardial ischemia, persistent electrocardiographic (ECG) changes, and release of biomarkers of myocardial necrosis resulting from an insufficient supply of oxygenated blood to an area of the heart. MI may be classified as ST-segment elevation MI (STEMI) and non–ST-segment elevation MI (NSTEMI) depending on the ECG findings on MI presentation. Acute coronary syndrome (ACS) refers to acute myocardial ischemia without myocardial necrosis (unstable angina) or myocardial infarction (NSTEMI or STEMI). According to the European Society of Cardiology/American College of Cardiology guidelines, the following criteria for acute evolving or recent MI (NSTEMI and STEMI) satisfies the diagnosis:

- Detection of the rise and/or fall of cardiac biomarker values (preferably cardiac troponin [cTn]) with at least one value above the 99th percentile upper reference limit and with at least one of the following:
  1. Symptoms of ischemia
  2. Development of pathologic Q waves in the ECG
  3. Imaging evidence of new loss of viable myocardium or a new regional wall motion abnormality
  4. Identification of an intracoronary thrombus by angiography or autopsy pathologic findings of acute MI
  5. Electrocardiogram criteria:
     a. STEMI:
        (1) New, or presumed new, significant ST-T changes or new left bundle branch block (LBBB)
        (2) New ST elevation at the J-point in at least 2 contiguous leads of ≥2 mm (0.2 mV) in men or ≥1.5 mm (0.15 mV) in women in leads V2 to V3 and/or of ≥1 mm (0.1 mV) in another contiguous chest leads or the upper limb leads
     b. NSTEMI:
        (1) New ST-segment depression ≥0.5 mV (0.5 mm) and T-wave abnormalities

New generation troponin assays are extremely sensitive to small changes in serum troponin levels at the cost of diagnostic specificity for MI related to plaque rupture or erosion.

Universal classification of acute MI:

- Type 1: Spontaneous MI related to ischemia due to a primary coronary event such as plaque erosion and/or rupture, fissuring, or dissection.
- Type 2: MI secondary to ischemia, other than coronary artery disease, due to either increased oxygen demand or decreased supply (e.g., coronary endothelial dysfunction, coronary artery spasm, coronary embolism, anemia, arrhythmias, respiratory failure, hypertension with/without left ventricular hypertrophy (LVH), or hypotension). Also in critically ill patients or in patients undergoing major noncardiac surgery, elevated values of cardiac biomarkers may appear due to the direct toxic effects of endogenous or exogenous high circulating catecholamine levels.
- Type 3: Sudden unexpected cardiac death, including cardiac arrest, often with symptoms suggestive of myocardial ischemia, accompanied by presumed new ST elevation, new left bundle branch block, or evidence of fresh thrombus in a coronary artery by angiography and/or at autopsy, or death occurring before blood samples could be obtained or at a time before the appearance of cardiac biomarkers in the blood.
- Type 4a: MI associated with percutaneous coronary intervention. Elevation of cTn >5× percentile of upper reference limit (URL) in patients with normal baseline value, or a rise of cTn >20% if the baseline values are stable and are stable or falling. In addition to either symptoms of ischemia, new ischemic ECG changes or new LBBB, or angiographic loss of a patent coronary artery, persistent slow or no-flow, or embolization, or imaging of new wall motion abnormality.
- Type 4b: MI associated with stent thrombosis as documented by angiography or at autopsy in the setting of myocardial ischemia and with a rise/fall of cardiac biomarker values.
- Type 5: MI associated with coronary artery bypass grafting. Elevation of cardiac biomarker values >10× 99% URL in patients with normal baseline cTn values, in addition to either new pathological Q waves or new LBBB, or new native coronary artery occlusion or imaging of new abnormal wall motion abnormality.
- Myocardial Infarction with Nonobstructive Coronary Arteries (MINOCA): It is defined as acute myocardial infarction in the absence of obstructive coronary artery disease. Conditions like takotsubo cardiomyopathy, spontaneous coronary artery dissection, coronary artery spasm, microvascular dysfunction, and pulmonary embolism come under this novel category.

ICD-10CM CODES

I21.01	ST elevation (STEMI) myocardial infarction involving left main coronary artery
I21.02	ST elevation (STEMI) myocardial infarction involving left anterior descending coronary artery
I21.09	ST elevation (STEMI) myocardial infarction involving other coronary artery of anterior wall
I21.11	ST elevation (STEMI) myocardial infarction involving right coronary artery
I21.19	ST elevation (STEMI) myocardial infarction involving another coronary artery of inferior wall
I21.21	ST elevation (STEMI) myocardial infarction involving left circumflex coronary artery
I21.29	ST elevation (STEMI) myocardial infarction involving other sites
I21.3	ST elevation (STEMI) myocardial infarction of unspecified site
I21.4	Non-ST elevation (NSTEMI) myocardial infarction
I22.0	Subsequent ST elevation (STEMI) myocardial infarction of anterior wall
I22.1	Subsequent ST elevation (STEMI) myocardial infarction of inferior wall
I22.2	Subsequent non-ST elevation (NSTEMI) myocardial infarction
I22.8	Subsequent ST elevation (STEMI) myocardial infarction of other sites
I22.9	Subsequent ST elevation (STEMI) myocardial infarction of unspecified site

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE/PREVALENCE (IN U.S.):

- According to data from National Health and Nutrition Examination Survey (NHANES) 2009 to 2012 (National Heart, Lung, and Blood Institute [NHLBI] tabulation), the overall prevalence for MI is 2.8% in U.S. adults ≥20 years of age. MI prevalence is 4.0% for men and 1.8% for women.
- In 2013 in the U.S., coronary heart disease alone caused ≈1 of every 7 deaths. In 2013, 370,213 Americans died of coronary heart disease. Each year, an estimated 660,000 Americans have a new coronary attack (defined as first hospitalized myocardial infarction or coronary heart disease death), and 305,000 have a recurrent attack. It is estimated that an additional 160,000 silent myocardial infarctions occur each year. Approximately every 34 seconds, one American has a coronary event, and approximately every 1 minute 24 seconds, an American will die of one.
- Community incidence rates as well as mortality rates from STEMI have declined over the past decade, whereas those for NSTEMI have increased. At present, STEMI comprises approximately 30% to 40% of MI presentations. In-hospital mortality (approximately 5% to 6%) and 1-yr mortality (approximately 7% to 18%). The most common cause of death in adults over the age of 40 is myocardial infarction. A heart attack takes the life of >1,500,000 people each yr in the U.S.
- Modifiable risk factors such as hypertension, diabetes, and cigarette smoking have recently declined, although hyperlipidemia has shown no significant change, and obesity has steadily increased.
- Tobacco use remains the second-leading cause of total deaths and disability. The percentage of adults who reported current cigarette use declined from 24.1% in 1998 to 15.5% in 2016. Still, almost one third of coronary heart disease deaths are attributable to smoking and exposure to secondhand smoke. Patients with first acute MI were

found to have an almost threefold increase in cigarette smoking from 2002 to 2009. Cigarette smoking is associated with endothelial dysfunction, prothrombotic defects, and increased oxidative stress.
- It is more prevalent in males between the ages of 45 and 65 yr old; there is no predominant sex differential after the age of 65.
- Women comprised 30% of STEMI patients. They experience more lethal and severe first acute MIs than men regardless of comorbidity, previous angina, or age. Studies have suggested that women are less likely to receive reperfusion therapy, have longer reperfusion times, are often given the standard of care treatment within 24 hours of presentation, and have higher risk of bleeding with antithrombotic therapy.
- At least one fourth of all MIs are clinically unrecognized. Approximately 23% of patients with STEMI in the U.S. have diabetes mellitus, and three quarters of all deaths among patients with diabetes mellitus are related to coronary artery disease. Diabetes mellitus is associated with higher short- and long-term mortality after STEMI. In the CRUSADE (Can Rapid risk stratification of Unstable angina patients Suppress ADverse outcomes with Early implementation of the ACC/AHA guidelines) trial, 7% of eligible patients did not receive reperfusion therapy. The most important factor for not providing reperfusion therapy in eligible patients was increasing age.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The clinical presentation of myocardial infarction is usually based on a history of substernal pressure type chest pain radiated to the neck, lower jaw, left arm, or mid-back lasting 20 min or more that is not completely relieved by sublingual nitroglycerin. The pain may not be severe. Some patients may present with atypical symptoms such as nausea/vomiting, shortness of breath, fatigue, palpitations, and diaphoresis. The elderly in particular may present with dizziness, or syncope. The patients who tend to present with atypical symptoms are more likely to be women, diabetic patients, or elderly patients and less frequently receive reperfusion therapy and other evidence-based therapies than patients with a typical chest pain presentation. Records show that up to 30% of patients with STEMI present with atypical symptoms.

Physical findings:
- Skin may be diaphoretic and exhibit pallor (because of decreased oxygen).
- Rales may be present at the bases of lungs (indicative of heart failure [HF]).
- Cardiac auscultation may reveal an apical systolic murmur caused by mitral regurgitation from papillary muscle dysfunction; S_3 or S_4 may also be present.
- Up to 10% of patients may present with acute pulmonary edema and/or cardiogenic shock.
- Physical examination may be completely normal.

ETIOLOGY

- Coronary atherosclerosis and plaque rupture
- Coronary artery spasm
- Coronary embolism (caused by infective endocarditis, rheumatic heart disease, intracavitary thrombus, atrial fibrillation)
- Periarteritis and other coronary artery inflammatory diseases
- Dissection into coronary arteries (aneurysmal or iatrogenic or spontaneous)
- Anomalous origin of coronary artery, especially interarterial (aorta and pulmonary artery) course of coronary artery
- MI with normal coronaries: More frequent in younger patients and cocaine addicts. The risk of acute MI is increased by a factor of 24 during the 60 min after the use of cocaine in persons who are otherwise at relatively low risk. Most patients with cocaine-related MI are young, nonwhite, male cigarette smokers without other risk factors for coronary heart disease and who have a history of repeated cocaine use. Blood and urine toxicology screen for cocaine is recommended in all young patients who present with acute MI.
- Hypercoagulable states, increased blood viscosity (polycythemia vera and autoimmune diseases such as systemic lupus, antiphospholipid syndrome)

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The various causes of myocardial ischemia are described along with the differential diagnosis of chest pain.

LABORATORY TESTS

- Electrocardiogram (Fig. 1): A 12-lead ECG should be performed and shown to an experienced emergency physician within 10 min of emergency department (ED) arrival for all patients with chest discomfort (or anginal equivalent) or other symptoms suggestive of MI. Table 1 and Table E2 describe ECG findings in myocardial infarction. If the initial ECG is not diagnostic for MI but the patient remains symptomatic and

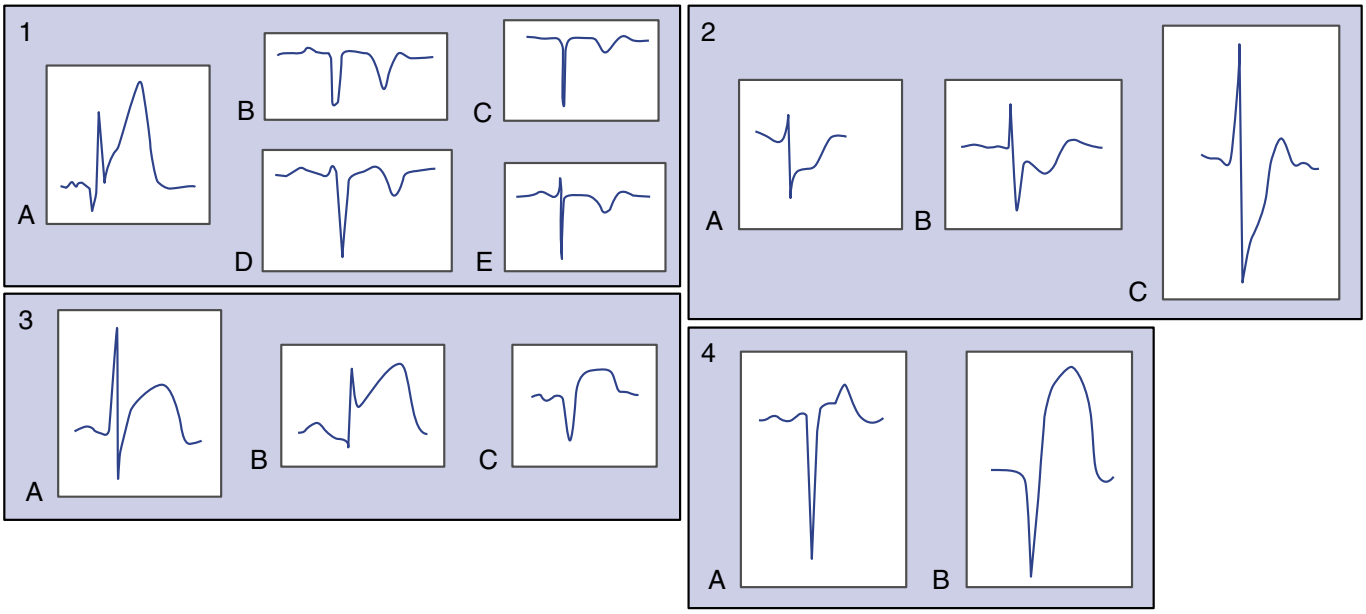

FIG. 1 Electrocardiographic findings of acute myocardial infarction (AMI). 1, T-wave abnormalities of AMI. *A,* Prominent "hyperacute" T wave. *B* through *E,* T-wave inversions of non–ST-segment elevation MI (NSTEMI). **2,** ST-segment depression. *A,* Flat. *B,* Downsloping. *C,* Upsloping. **3,** ST-segment elevation. *A,* Convex ST-segment elevation. *B,* Obliquely straight ST-segment elevation. *C,* Convex ST-segment elevation. **4,** Pathologic Q waves. *A,* Pathologic Q wave of completed myocardial infarction. *B,* Simultaneous ST-segment elevation with pathologic Q wave 2 hours into the course of ST-segment elevation MI (STEMI). (From Vincent JL et al: *Textbook of critical care,* ed 6, Philadelphia, 2011, WB Saunders.)

there is a high clinical suspicion for MI, serial ECGs at 5- to 10-min intervals or continuous 12-lead ST-segment monitoring should be performed to detect the potential development of ST deviation. In patients with inferior STEMI, right-sided ECG leads should be obtained to look for ST elevation suggestive of right ventricular (RV) infarction. The joint ESC/ACCF/AHA committee for the definition of MI established the definition for the diagnosis of ST-elevation MI, which is considered to be present when there is an ST-segment elevation in two contiguous leads, ≥2 mm for men and ≥1.5 mm for women in precordial leads and/or ≥1 mm in limb leads. ST-segment elevation is measured at 0.08 sec after the J point (the junction between the end of the QRS and the beginning of the ST segment). In addition, ST depression in >2 precordial leads (V1 to V4) may indicate transmural posterior injury; multilead ST depression with coexistent ST elevation in lead aVR has been described in patients with left main or proximal left anterior descending artery involvement.

- New or presumably new LBBB at presentation occurs infrequently, may interfere with ST-elevation analysis, and should not be considered diagnostic of acute myocardial infarction (MI) in isolation.
- Diagnosing new STEMI in patients with old left bundle branch block could be challenging. Sgarbossa and colleagues emphasized that concordant 1 mm ST-segment elevation in any lead with a positive QRS deflection or discordant ST-segment elevation >5 mm in any lead with negative QRS deflection suggest STEMI.
- New ST-segment depression ≥0.5 mV (0.5 mm) and T-wave abnormalities suggest NSTEMI. ECG findings alone, without laboratory results, are sufficient to diagnose STEMI; therefore, treatment should not be delayed until biomarkers are available.
- Cardiac troponin levels: Cardiac-specific troponin T (cTnT) and cardiac-specific troponin I (cTnI) are generally indicative of myocardial injury with increases in serum levels of >99th percentile of a normal reference population. Detection of a rise and fall pattern of the measurements is essential to the diagnosis of AMI. The rise may occur relatively early after muscle damage (3 to 6 hours), peak at 12 to 16 hours, and may be present for several days after MI (up to 7 days for cTnI and more than 14 days for cTnT). Earlier peaking and rapid decline of cardiac enzymes may present in light of successful revascularization (Fig. 2). cTnT or cTnI tests can be falsely positive for myocardial infarction in patients with renal failure, heart failure, myocarditis, aortic dissection, and pulmonary embolism. Recently, highly sensitive troponin assays (hs-cTnI, hs-cTnT) have also been developed to facilitate an early diagnosis of AMI. Most patients can be diagnosed with AMI within the first 2 to 3 hours of presentation. However, an initial negative high-sensitivity troponin at the time of presentation is not sensitive enough to completely rule out AMI. MI can be excluded in most patients by 6 hours of presentation, and guidelines suggest serial samples be obtained every 3 to 6 hours after an initial sample if there is a high degree of suspicion for AMI.
- Troponin is the preferred marker for the diagnosis of myocardial necrosis. A single high-sensitivity assay for cardiac troponin (hs-cTnT) concentration below the limit of detection in combination with a nonischemic ECG may successfully rule out an MI in patients presenting to EDs with possible emergency acute coronary syndrome.[1] Because troponins need 7 to 14 days to be cleared by the kidneys, they are not sensitive enough to detect a recurrent MI within days from the initial MI. CK-MB isoenzyme can be useful in such circumstances (Fig. 2).

TABLE 1 Leads Showing Abnormal Electrocardiographic Findings in Myocardial Infarction

	Limb Leads	Precordial Leads
Lateral	I, aVL	V5, V6
Anterior		V1, V2, V3
Anterolateral	I, aVL	V2-V6
Diaphragmatic	II, III, aVF	
Posterior		V1-V3*

*None of the leads is oriented toward the posterior surface of the heart. Therefore, in posterior infarction, changes that would have been present in the posterior surface leads will be seen in the anterior leads as a mirror image (e.g., tall and slightly wide R waves in V1 and V2, comparable to abnormal Q waves, and tall and wide, symmetric T waves in V1 and V2).

aVF, Augmented vector foot; *aVL,* augmented vector left.

Used with permission of Mayo Foundation for Medical Education and Research.)

- CK-MB isoenzyme is also a useful marker for MI if troponin levels are not available. It is released in the circulation in amounts that correlate with the size of the infarct. An increased CK-MB value for the diagnosis of MI is defined as a measurement above the 99th percentile of the upper reference limit. CK-MB can be detected within 3 to 8 hours of the onset of chest pain, peak at 12 to 24 hours, and return to baseline levels within 24 to 48 hours.

IMAGING STUDIES

Imaging studies such as a high-quality portable chest x-ray, transthoracic echocardiography, and a contrast chest CT scan should be used to differentiate MI from aortic dissection, pulmonary embolism, and other intrathoracic causes of chest pain (i.e., pneumonia and pneumothorax) in patients for whom this distinction is initially unclear, or to assess for complications of AMI such as pulmonary edema. Transthoracic echocardiography may provide evidence of focal wall motion abnormalities and facilitate triage in patients with ECG findings that are difficult to interpret.

RISK ASSESSMENT

For STEMI patients, TIMI (Thrombolysis in Myocardial Infarction) risk index, TIMI risk score (30-day outcomes), and GRACE (Global Registry of Acute Coronary Events) risk score (6-mo outcomes) are commonly available risk assessment models. In the TIMI risk score for STEMI, the mean 30-day mortality was 6.7%. It is composed of eight baseline variables. The risk score showed a >40-fold graded increase in mortality, with scores ranging from 0 to >8 ($P < 0.0001$); 30-day mortality was 0.1% among patients with a score of 0, 2.25 with a score of 5, and >8.8% among patients with a score of 8 or greater. The higher the score, the higher the 30-day mortality rate. The variables are divided between historic, exam, and presentation:

Historic:
- Age 65 to 74 (2 points), >75 (3 points)
- Diabetes/HTN or angina (1 point)

Exam:
- SBP <100 mm Hg (3 points)
- Heart rate >100 bpm (2 points)
- Killip 2 to 4 (2 points)
- Weight <67 kg (1 point)

Presentation:
- Anterior ST elevation or LBBB (1 point)
- Time to reperfusion >4 hours (1 point)

For NSTEMI patients, TIMI risk score (14-day outcomes) and GRACE (Global Registry of Acute Coronary Events) risk score (in hospital outcomes) are available.
- Age ≥65 yr
- Presence of ≥3 risk factors for CAD
- Known CAD (coronary artery stenosis ≥50%)
- Aspirin use in the past 7 days
- ≥2 episodes of angina within 24 hours
- ST changes ≥0.05 mV
- Positive cardiac enzymes

In TIMI score for the NSTEMI patients, each variable scores one point. The risk score of 6 to 7 carries estimated major acute coronary event (MACE) rate of 41% during 14 days of post-MI. Risk assessment is a continuous process that should be repeated throughout hospitalization and at time of discharge.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Limit patient's activity: Bed rest with bedside commode for the initial 12 to 24 hours. If the patient remains stable, gradually increase.1
- Diet: Nothing by mouth until stable, then clear liquids as tolerated to advance gradually to a diet tailored to the patient's comorbidities (i.e., diabetes, hypertension, heart failure, hyperlipidemia, renal failure, chronic obstructive pulmonary disease [COPD], etc.).
- Patient education to decrease the risk of subsequent cardiac events, counseling on smoking cessation, dietary restrictions, regular exercise, and medication compliance should be initiated when the patient is medically stable.

ACUTE GENERAL Rx

- Fig. 3 shows a treatment algorithm for STEMI. Assessment and treatment algorithm for non–ST-segment MI is described in Fig. 4. Rationale of the treatment of a patient with STEMI is based on "time is muscle." Therefore, all communities should create and maintain a regional system of STEMI care that includes assessment and continuous quality improvement of EMS and hospital-based activities. A 12-lead ECG must be done by EMS personnel at the site of first medical contact (FMC).
- Reperfusion therapy should be administered to all eligible patients with STEMI with symptom onset within 12 hours. Indications for primary angioplasty and comparison with fibrinolytic therapy are described in Table 3. Primary PCI (Fig. E5) is the recommended method of reperfusion when it can be performed in a timely fashion by experienced operators with an ideal FMC-to-device time system goal of 90 min or less.
- In the absence of contraindications, fibrinolytic therapy (Table 4) should be administered to patients with STEMI at non–PCI-capable hospitals when the anticipated FMC-to-device time at a PCI-capable hospital exceeds 120 min because of unavoidable delays. Door-in door-out time (DIDO) for fibrinolytic therapy should be less than 30 min. If more than 30 min delay, transfer the patient to a PCI-capable hospital.
- Among STEMI patients who were treated with fibrinolytics, patients with >50% ST-segment resolution on EKG were at much lower risk for cardiac-related mortality compared with those with <50% resolution at 30 days.
- PCI is superior to thrombolytic therapy and is the standard of care. It is effective and generally results in more favorable outcomes than thrombolytic therapy.
- Primary PCI should be performed in patients with STEMI and persistent ischemic symptoms and who have contraindications to fibrinolytic therapy, irrespective of the time delay from FMC, or in patients with cardiogenic shock or acute severe HF irrespective of time delay from myocardial infarction (MI) onset, first medical contact to balloon time is <90 minutes or door to balloon/door to needle time is <1 hour, symptoms onset was >3 hours ago and when diagnosis of STEMI in doubt. Coronary stents (drug-eluting or bare-metal) are useful in patients with STEMI.
- The question of culprit vessel vs. complete revascularization during PCI has been brought up since the stent technology was applied to the management of STEMI. The most recent clinical trials (CuLPRIT, PRAMI and DANAMI3-PRIMULTI [FFR-driven revascularization]) appear to favor complete revascularization in the setting of STEMI. However, CULPRIT-SHOCK trial showed culprit vessel only PCI associated with 9.5% absolute reduction in the rate of death or renal replacement therapy at 30 days compared to multivessel PCI in acute MI patients with cardiogenic shock. One-yr outcomes did not show significant difference in mortality between two groups. Korea Acute Myocardial Infarction-National Institutes of Health (KAMIR-NIH) Registry data showed better outcomes with multivessel PCI in cardiogenic shock patients compared to culprit vessel-only PCI. Thus, multivessel PCI should be reserved for few selective patients.
- For patients presenting to a non–PCI-capable hospital, rapid assessment should be done of (1) the time from onset of symptoms, (2) the risk of complications related to STEMI, (3) the risk of bleeding with fibrinolysis, (4) the presence of shock or severe HF, and (5) the time required for transfer to a PCI-capable hospital and a decision about administration of fibrinolytic therapy reached. Because the effectiveness of thrombolytics is time dependent, these agents should ideally be administered either in the field or within 30 min of the patient's arrival to the emergency department (door-to-needle time).
- Fibrinolytic therapy: If tissue plasminogen activator (t PA) or reteplase is used, anticoagulants, such as heparin, are given to increase the likelihood of patency in the infarct-related artery for 48 hr and preferably for the duration of the index hospitalization, up to 8 days. In patients receiving fibrinolysis for STEMI, treatment with enoxaparin is superior to treatment with unfractionated heparin for 48 hr but is associated with an increase in major bleeding episodes. In patients receiving streptokinase or APSAC, heparin after thrombolysis is not indicated because it does not offer any additional benefit and can result in increased bleeding complications. Tenecteplase and reteplase are comparable with accelerated infusion recombinant t-PA in terms of efficacy and safety but are more convenient because they are administered by bolus injection. Lanoplase and heparin bolus plus infusion are as effective as tPA with regard to mortality rate, but the rate of intracranial hemorrhage is significantly higher.

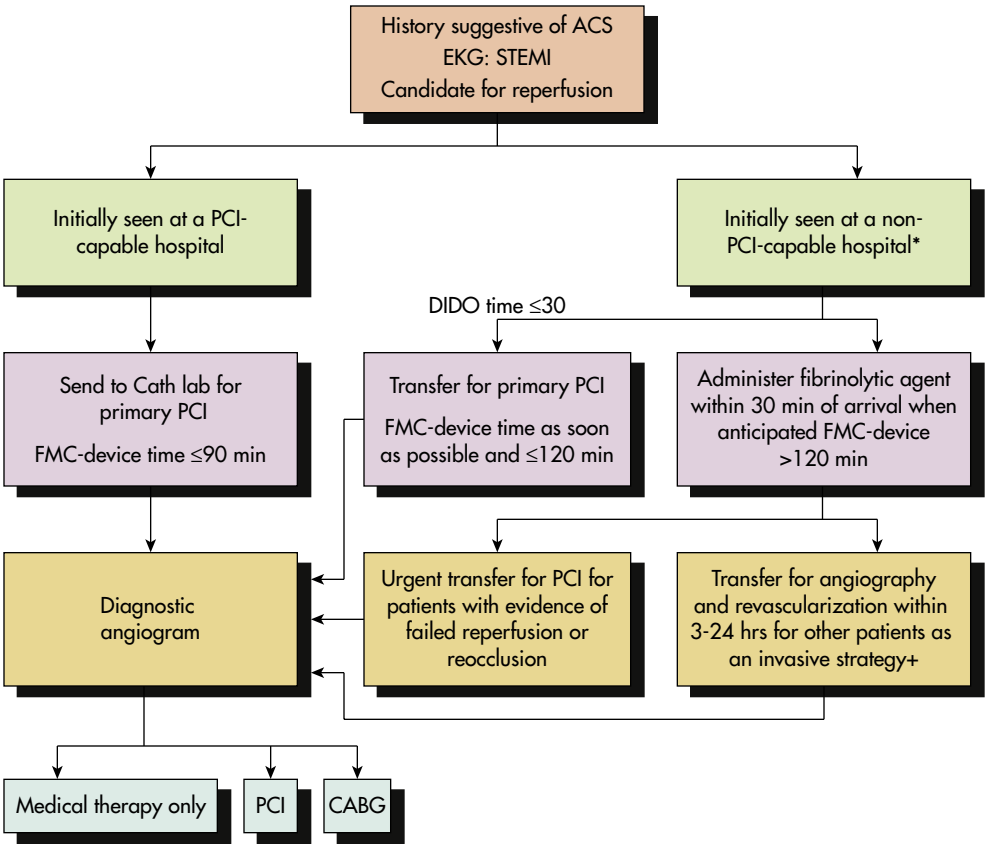

FIG. 3 Reperfusion therapy for patients with STEMI. *Patients with cardiogenic shock or severe heart failure initially seen at a non–PCI-capable hospital should be transferred for cardiac catheterization and revascularization as soon as possible, irrespective of time delay from MI onset. +Angiography and revascularization should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy. *ACS,* Acute coronary syndrome; *CABG,* coronary artery bypass graft; *Cath,* catheterization; *DIDO,* door-in to door-out; *EKG,* electrocardiogram; *FMC,* first medical contact; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention; *STEMI,* ST-elevation myocardial infarction. (Modified from O'Gara PT et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction, *JACC* 61(4): e78-e140, 2013.)

- Absolute contraindications to thrombolytic therapy (Table 5) include history of intracranial hemorrhage, known intracranial malignant neoplasm or arteriovenous malformation, ischemic stroke within 3 mo (except acute ischemic stroke within 4.5 hours), suspected aortic dissection, active bleeding or bleeding diathesis (except menses), significant closed head or facial trauma within 3 mo, intracranial or intraspinal surgery within 2 mo, or severe uncontrolled hypertension (unresponsive to therapy). For streptokinase, this applies to prior treatment within 6 mo.
- Relative contraindications: History of chronic severe, poorly controlled hypertension, SBP >180 mm Hg, DBP >110 mm Hg, history of prior ischemic stroke more than 3 mo, dementia, known intracranial pathology, traumatic or prolonged CPR (>10 min), major surgery <3 wk, recent internal bleeding within 2 to 4 wk, noncompressible vascular punctures, pregnancy, active peptic ulcer, oral anticoagulant therapy. After the administration of thrombolytics, immediate transfer to a PCI-capable facility is advisable without waiting for lytic results.
- Transfer to a PCI-capable hospital: Immediate transfer for STEMI patients who develop cardiogenic shock or acute severe HF, irrespective of the time delay from MI onset. Urgent transfer if the patient demonstrates evidence of failed reperfusion or reocclusion after fibrinolytic therapy.
- Coronary angiography should not be performed within the first 2 to 3 hours after administration of fibrinolytic therapy.
- Coronary artery bypass graft (CABG): Urgent CABG is indicated in patients with STEMI and coronary anatomy not amenable to PCI who have ongoing or recurrent ischemia, cardiogenic shock, severe HF, or other high-risk features. CABG is recommended in patients with STEMI at time of operative repair of mechanical defects. Box 1 summarizes CABG in patients with MI.
- Therapeutic hypothermia should be started as soon as possible in comatose patients with STEMI and out-of-hospital cardiac arrest caused by ventricular fibrillation (VF) or pulseless ventricular tachycardia, including patients who undergo primary PCI.
- Immediate angiography and PCI when indicated should be performed in resuscitated out-of-hospital patients.
- The use of mechanical circulatory support is reasonable in patients with STEMI who are hemodynamically unstable and require urgent CABG.
- For NSTEMI patients, immediate invasive strategy (within 2 hours) recommended in patients with refractory angina, signs or symptoms of congestive heart failure or new or worsening ischemic mitral regurgitation, hemodynamic instability, recurrent angina or ischemia at rest or with low level activities despite intensive medical therapy and sustained ventricular tachycardia or ventricular fibrillation.
- Early invasive strategy (<24 hours) for NSTEMI patients recommended if GRACE risk for more than 140, dynamic ST changes on EKG and temporal change in troponin levels.
- NSTEMI patient with low-risk TIMI score (0 or 1) and/or low GRACE score (<109) and/or troponin-negative female patients can benefit from ischemia-guided strategy. Fibrinolytic therapy is contraindicated in NSTEMI patients.

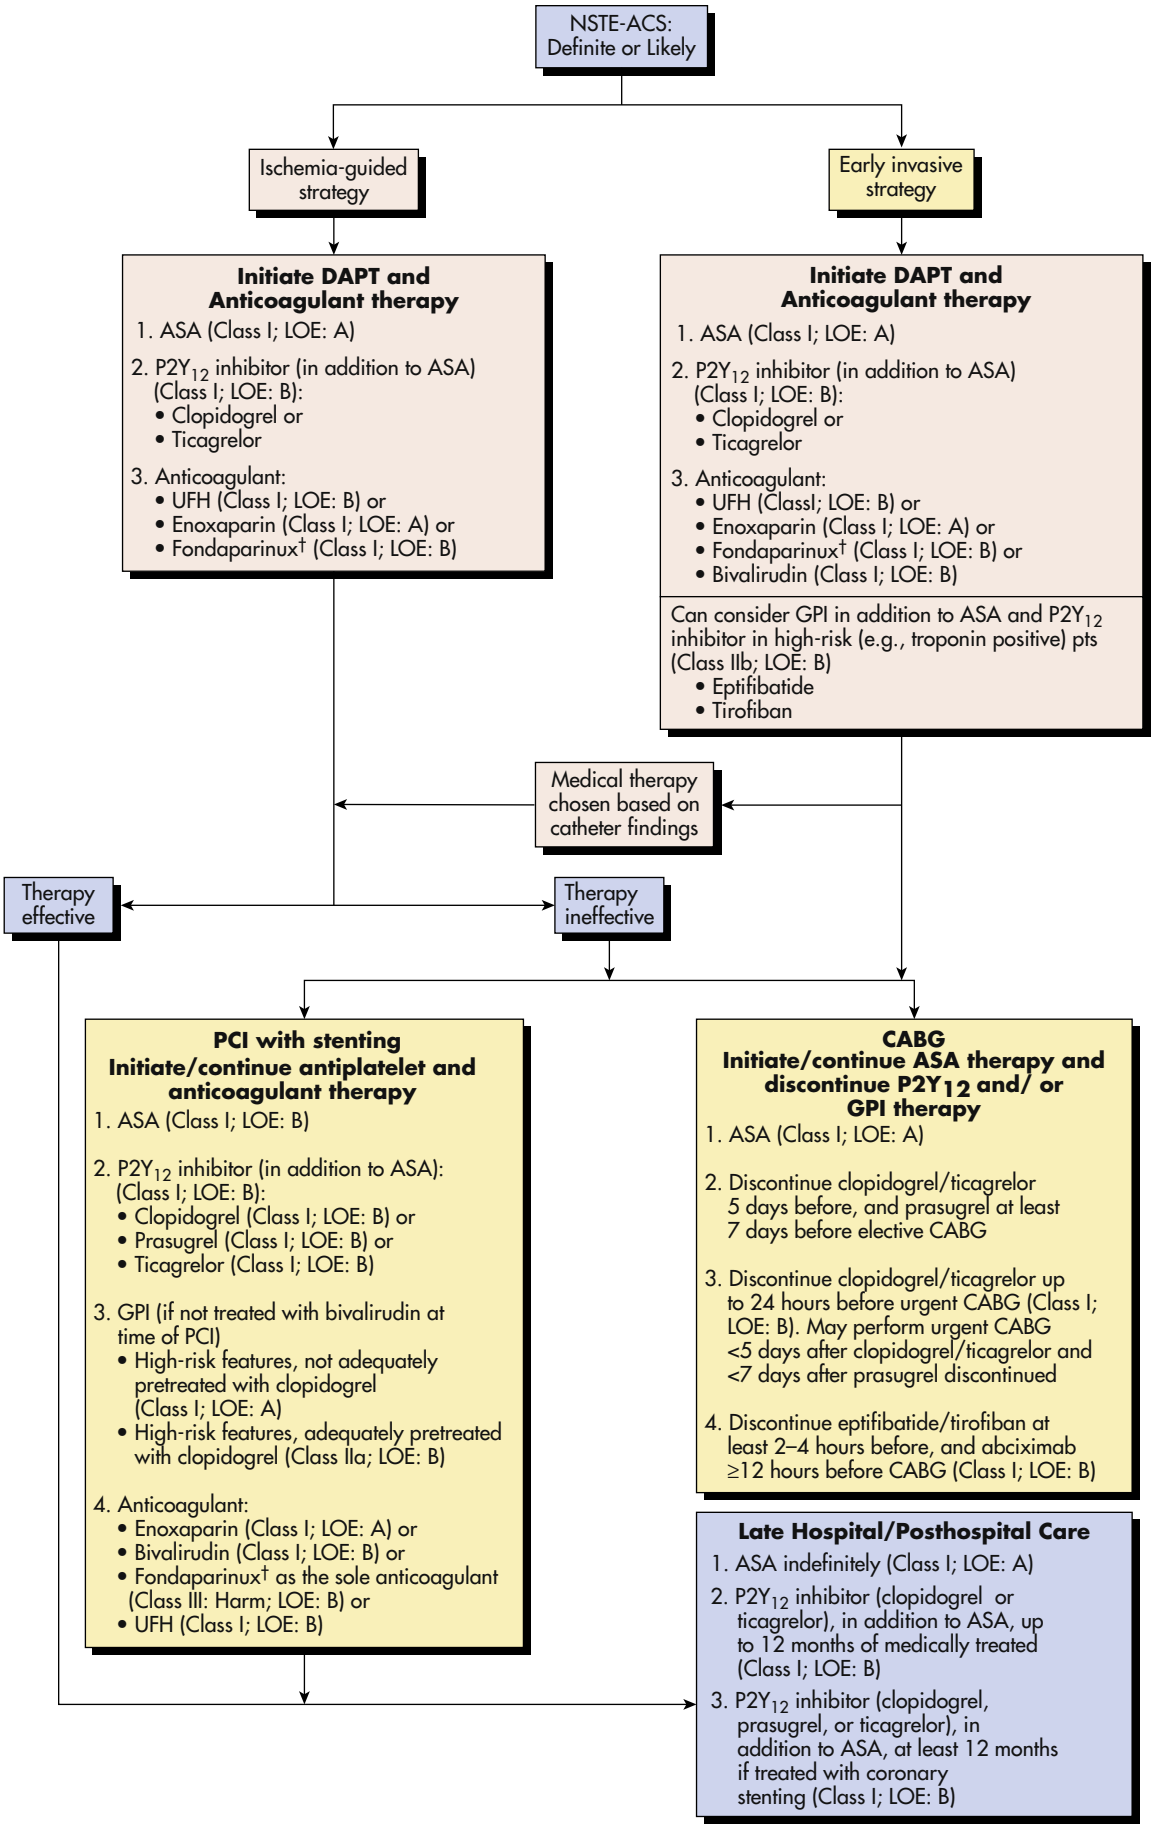

FIG. 4 Algorithm for management of patients with definite of likely non–ST-elevation acute coronary syndromes *(NSTE-ACS).* †In patients who have been treated with fondaparinux (as upfront therapy) who undergo percutaneous coronary intervention (PCI), an additional anticoagulant with anti-IIa activity should be administered at the time of PCI because of the risk of catheter thrombosis. *ASA,* Acetylsalicylic acid (aspirin); *CABG,* coronary artery bypass grafting; *DAPT,* dual-antiplatelet therapy; *GPI,* glycoprotein inhibitor; *LOE,* level of evidence; *UFH,* unfractionated heparin. (From Amsterdam EA et al: 2014 AHA/ACC guideline for the management of patients with non-ST-elevation acute coronary syndromes: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2014;64:e139-228. In Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

TABLE 3 Indications for Primary Angioplasty and Comparison with Fibrinolytic Therapy

Indications
Alternative recanalization strategy for ST segment elevation or LBBB acute MI within 12 hours of symptom onset (or >12 hours if symptoms persist)
Cardiogenic shock developing within 36 hours of ST segment elevation/Q wave acute MI or LBBB acute MI in patients >75 yr old who can be revascularized within 18 hours of shock onset
Recommended only at centers performing >200 PCI/yr with backup cardiac surgery and for operators performing <75 PCI/yr
Advantages of Primary PCI
Higher initial recanalization rates
Reduced risk of intracerebral hemorrhage
Less residual stenosis; less recurrent ischemia or infarction
Usefulness when fibrinolysis contraindicated
Improvement in outcomes with cardiogenic shock
Disadvantages of Primary PCI (Compared with Fibrinolytic Therapy)
Access, advantages restricted to high-volume centers, operators
Longer average time to treatment
Greater dependence on operators for results
Higher system complexity, costs

LBBB, Left bundle branch block; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention (includes balloon angioplasty, stenting).
From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.

TABLE 4 Dosing Regimens of Commonly Used Thrombolytic Agents

Thrombolytic Agents	Dosing Regimen
t-PA (alteplase)	15 mg bolus IV, followed by 0.75 mg/kg body weight (not to exceed 50 mg) over 30 min, followed by 0.5 mg/kg (not to exceed 35 mg) over 60 min
r-PA (reteplase)	Two 10-U IV boluses, given 30 min apart
TNK–t-PA (tenecteplase)	Single bolus IV 0.5 mg/kg (dose rounded to the nearest 5 mg, ranging from 30 to 50 mg)
Streptokinase	1.5 million U IV over 60 min

IV, Intravenous; *PA,* plasminogen activator; *r-PA,* recombinant plasminogen activator; *TNK–t-PA,* tenecteplase tissue plasminogen activator; *t-PA,* tissue plasminogen activator; *U,* units.
From Andreoli TE et al: *Andreoli and Carpenter's Cecil essentials of medicine,* ed 8, Philadelphia, 2010, WB Saunders.

- Medical therapy should be initiated immediately in the emergency department for all MI patients. This includes:
  1. Routine measures
     a. Oxygen: Supplemental oxygen should be administered to patients with arterial oxygen desaturation (SaO_2 less than 90%). No benefit has been demonstrated to supplemental oxygen in patients with normal SaO_2.
     b. Nitroglycerin: Increase oxygen supply by reducing coronary vasospasm and decrease oxygen consumption by reducing ventricular preload. Patients with ongoing ischemic discomfort should receive sublingual nitroglycerin every 5 min for a total of three doses, after which an assessment should be made about the need for intravenous nitroglycerin. Intravenous nitroglycerin is indicated for relief of ongoing ischemic discomfort, control of hypertension, or management of pulmonary congestion. Nitrates should not be administered to patients whose systolic blood pressure is <90 mm Hg or ≥30 mm Hg below baseline or severe bradycardia (<50 beats/min), tachycardia (>100 beats/min), or suspected RV infarction. Nitrates should not be administered to patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the last 24 hours (48 hours for tadalafil).
     c. Adequate analgesia: Morphine sulfate 2 to 4 mg IV initially with increments of 2 to 8 mg IV at 5- to 10-min intervals can be given for severe pain unrelieved by nitroglycerin. Morphine can reduce the catecholamine surge caused by anxiety and pain, particularly in patients with anterior myocardial infarctions, which in turn can reduce heart rate and pulmonary capillary wedge pressure (PCWP), the increased cardiac workload and oxygen demand, leading to decreased ischemia and pulmonary congestion. Hypotension from morphine can be treated with careful IV hydration with saline solution. If sinus bradycardia accompanies hypotension, use atropine (0.5 to 1.0 mg IV q5min prn to a total dose of 2.5 mg). Respiratory depression caused by morphine can be reversed with naloxone 0.8 mg. Morphine sulfate and nitroglycerine should be avoided in patients with RV involvement who usually present with bradycardia and hypotension. Pain management in these cases should be provided preferentially with meperidine 25 to 50 mg intravenously q 4h, in combination with Phenergan 12.5 mg to prevent nausea and/or vomiting. Blood pressure support with normal saline solution is of critical importance to maintain adequate hemodynamics until optimal revascularization is accomplished.
     d. Aspirin 162 to 325 mg PO should be crushed and chewed to enhance drug absorption and delivery. It should be given as soon as possible and continued indefinitely, at 81 mg daily. Depending on the clinical and ECG findings, if the patient is suspected to have a coronary anatomy that needs CABG rather than PCI, aspirin should be continued. P2Y12 receptor antagonists should be avoided (except Cangrelor) because they increase the perioperative bleeding risk; on-pump surgery should be deferred for at least 24 hours after clopidogrel and ticagrelor. Off-pump surgery might be considered within 24 hours of clopidogrel or ticagrelor if the benefits of revascularization outweigh the risk of bleeding. However, if the coronary artery disease is likely to benefit from PCI alone, then a loading dose of clopidogrel 600 or 300 mg or ticagrelor 180 mg PO or prasugrel 60 mg should be given as early as possible and no later than 1 hour after PCI. P2Y12 receptor antagonist should be continued for at least 1 yr after acute coronary syndrome or after primary PCI. Prasugrel showed significant net clinical benefit (MACE vs. bleeding complications) only in patients with MI who underwent revascularization. It shouldn't be given for nonrevascularized patients. Ticagrelor or Clopidogrel can be given in patients with MI with or without catheter-based revascularization. Cangrelor is the newest direct-acting P2Y12 platelet receptor inhibitor. It has a similar chemical structure to ATP, with a half-life of 3 to 6 min. It is given IV as a bolus plus 120 min of infusion at the time of primary PCI in patients who are naïve to P2Y12 receptor antagonists. It was approved by the FDA in 2015 after the CHAMPION PHOENIX trial. Clopidogrel and prasugrel should be started after its infusion is finished. The ticagrelor loading dose can be given during the infusion. Considering rapid onset action and

TABLE 5 Contraindications to and Cautions in the Use of Fibrinolytics for Treating ST-Elevation Myocardial Infarction*

Absolute Contraindications

Any previous intracranial hemorrhage
Known structural cerebral vascular lesion (e.g., arteriovenous malformation)
Known malignant intracranial neoplasm (primary or metastatic)
Ischemic stroke within 3 mo *except* acute ischemic stroke within 4.5 hours
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed-head or facial trauma within 3 mo
Intracranial or intraspinal surgery within 2 mo
Severe uncontrolled hypertension (unresponsive to emergency therapy)
For streptokinase, previous treatment within the previous 6 mo

Relative Contraindications

History of chronic, severe, poorly controlled hypertension
Significant hypertension at initial evaluation (SBP >180 mm Hg or DBP >110 mm Hg)†
History of previous ischemic stroke >3 mo
Dementia
Known intracranial pathology not covered in Absolute Contraindications
Traumatic or prolonged (>10 min) cardiopulmonary resuscitation
Major surgery (<3 wk)
Recent (within 2 to 4 wk) internal bleeding
Noncompressible vascular punctures
Pregnancy
Active peptic ulcer
Oral anticoagulant therapy

*Viewed as advisory for clinical decision making and may not be all-inclusive or definitive.
†Could be an absolute contraindication in low-risk patients with MI.
DBP, Diastolic blood pressure; *SBP,* systolic blood pressure.
From O'Gara PT et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2013;61:e78. In Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

BOX 1 CABG in Patients With Acute MI

Class I

1. Emergency CABG is recommended in patients with acute MI in whom (1) primary PCI has failed or cannot be performed, (2) coronary anatomy is suitable for CABG, and (3) persistent ischemia of a significant area of myocardium at rest or hemodynamic instability refractory to nonsurgical therapy is present.
2. Emergency CABG is recommended in patients undergoing surgical repair of a postinfarction mechanical complication of MI, such as ventricular septal rupture, mitral valve insufficiency because of papillary muscle infarction or rupture, or free wall rupture.
3. Emergency CABG is recommended in patients with cardiogenic shock and who are suitable for CABG irrespective of the time interval from MI to onset of shock and time from MI to CABG.
4. Emergency CABG is recommended in patients with life-threatening ventricular arrhythmias (believed ischemic in origin) in the presence of left main stenosis greater than or equal to 50% or three-vessel CAD.

Class IIa

1. The use of CABG is reasonable as a revascularization strategy in patients with multivessel CAD with recurrent angina or MI within the first 48 hours of STEMI presentation as an alternative to a more delayed strategy.
2. Early revascularization with PCI or CABG is reasonable for selected patients older than 75 yr of age with ST-segment elevation or left bundle branch block who are suitable for revascularization irrespective of the time interval from MI to onset of shock.

Class III

1. Emergency CABG should not be performed in patients with persistent angina and a small area of viable myocardium who are stable hemodynamically.
2. Emergency CABG should not be performed in patients with no reflow (successful epicardial reperfusion with unsuccessful microvascular reperfusion).

CABG, Coronary artery bypass graft; *CAD,* coronary artery disease; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention; *STEMI,* ST-segment elevation myocardial infarction.
From Hillis LD et al: 2011 ACCF/AHA guideline for coronary artery bypass graft surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol.* 2011;58:e123-e210. In Parrillo JE et al: *Critical care medicine, principles of diagnosis and management in the adult,* ed 5, Philadelphia, 2019, Elsevier.

clearance, Cangrelor can be started in the emergency room at the time of high-risk acute myocardial infarction diagnosis irrespective surgical or catheter-based revascularization.

2. In patients receiving fibrinolytics only or balloon angioplasty without stent, P2Y12 antagonists can be given for as little as 14 days. Clopidogrel is recommended for post-fibrinolytic patients.
3. Unfractionated heparin (UFH) is recommended in all patients with NSTEMI and STEMI (fibrinolysis or invasive revascularization). UFH infusion should not exceed more than 48 hours after PCI or fibrinolysis in the absence of an ongoing indication due to risk of heparin-induced thrombocytopenia. NSTEMI patients who underwent ischemia-guided therapy, low molecular weight heparin (LMWH) showed better MACE outcomes compared with UFH. The benefit was not significant in revascularized patients. Bivalirudin was associated with lower MACE and bleeding events in STEMI patients compared with UFH. However, it increased the risk of stent thrombosis. In NSTEMI patients who are undergoing PCI, LMWH, Bivalirudin, and UFH are acceptable.
4. Beta-adrenergic blocking agents should generally be given to all patients who do not exhibit evidence of shock. Table 6 summarizes recommendations for beta-blocker therapy for STEMI. Beta-blockers are useful to reduce myocardial oxygen consumption and prevent tachyarrhythmias. Early IV beta blockage (in the initial 24 hr) followed by institution of an oral maintenance regimen is also effective in reducing recurrent infarction and ischemia. Oral beta-blockers should be initiated in the first 24 hours in patients with MI who do not have any of the following: signs of HF, evidence of a low-output state, sinus tachycardia, increased risk for cardiogenic shock, or other contraindications for its use (bradycardia, PR interval more than 0.24 seconds, second- or third-degree heart block, active asthma, or reactive airways disease).
5. They should be continued during and after hospitalization for all patients with MI and with no contraindications to their use for at least 2 yr. Patients with initial contraindications to the use of beta-blockers in the first 24 hours after MI should be reevaluated to determine their subsequent eligibility. It is reasonable to administer intravenous beta-blockers at the time of presentation to patients with MI and no contraindications to their use who are hypertensive or have ongoing ischemia.
6. In patients with acute MI, treatment with drug-eluting stents is associated with decreased mortality rates and a reduction in the need for repeated revascularization

TABLE 6 Recommendations for Beta-Blocker Therapy for ST-Elevation Myocardial Infarction (STEMI)

Recommendation	COR	LOE
Oral beta blockers should be initiated in the first 24 hours in patients with STEMI who do not have any of the following: Signs of heart failure or evidence of a low-output state Increased risk for cardiogenic shock*: • Age >70 yr • Systolic blood pressure <120 mm Hg • Sinus tachycardia >110 beats/min or heart rate <60 beats/min • Increased time since the onset of symptoms of STEMI Other relative contraindications to use of oral beta blockers: • PR interval longer than 0.24 second • Second- or third-degree heart block • Active asthma or reactive airways disease	I	B
Beta blockers should be continued during and after hospitalization for all patients with STEMI and no contraindications to their use.	I	B
Patients with initial contraindications to the use of beta blockers in the first 24 hours after STEMI should be reevaluated to determine their subsequent eligibility.	I	C
It is reasonable to administer IV beta blockers at initial encounter to patients with STEMI and no contraindications to their use who are hypertensive or have ongoing ischemia.	IIa	B

*The greater the number of risk factors present, the higher the risk for development of cardiogenic shock.
COR, Class of recommendation; *IV,* intravenous; *LOE,* level of evidence.
Modified from O'Gara PT et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2013;61:e78. procedures compared with treatment including bare-metal stents.

7. Gp IIb/IIIa inhibitors in the era of DAPT therapy and primary PCI have failed to show benefit with "upstream" treatment. Abciximab might be useful in the presence of large thrombus burden during primary PCI. For patients receiving bivalirudin as the primary anticoagulant, routine adjunctive use of GP IIb/IIIa inhibitors is not recommended but may be considered as adjunctive or "bail-out" therapy in selected cases. In patients with acute coronary syndrome with high-risk features and not adequately pretreated with P2Y12 inhibitors, it is useful to administer GP IIb/IIIa inhibitors at the time of PCI.

CHRONIC Rx

- Discharge medications in all patients with MI (unless contraindicated) should include anti-ischemic medications (e.g., nitroglycerin, beta-blocker), lipid-lowering agents, and antiplatelet therapy (aspirin and/or P2Y12 antagonists).
- Aspirin, 81 mg PO daily, but should be continued indefinitely unless not tolerated (e.g., GI bleed). In MI patients, Clopidogrel 75 mg PO daily; ticagrelor, 90 mg bid, or prasugrel, 10 mg PO daily, can be combined with aspirin and should be continued without interruption for a minimum of 12 mo after drug-eluting stent placement; however, aspirin should be continued indefinitely. In cases of high bleeding risk or significant overt bleeding, consider discontinuation of P2Y12 inhibitor after 6 mo (Fig. 6). Combining P2Y12 antagonists with aspirin reduces risk for repeat myocardial infarction and stent thrombosis. If there is an elective surgical intervention pending, it is recommended to defer the surgery until completion of the full course of the P2Y12 antagonist treatment.
- Angiotensin-converting enzyme inhibitors (ACEIs) should be started within the first 24 hours of MI to all patients having MI with anterior infarction, pulmonary congestion, or LV EF <40%, in the absence of hypotension. They reduce LV dysfunction and dilation and slow the progression to HF during and after acute MI. Angiotensin receptor blockers (ARBs) should be given to patients who have indication but are intolerant of ACEIs. IV formulations of ACEIs should not be given within the first 24 hours of STEMI due to risk of hypotension. ARBs offer no advantage over ACEIs and should be considered only in patients who are intolerant to ACEIs.
  1. Commonly used ACEIs are ramipril 2.5 mg PO bid, captopril 12.5 mg PO bid, enalapril 2.5 mg PO bid, and lisinopril 2.5 to 5 mg PO qd initially, with subsequent titration as needed. Ramipril is associated with a lower mortality rate than most ACEIs.
  2. ACEIs may be stopped in patients without complications and no evidence of LV dysfunction after 6 to 8 wk.
  3. ACEIs should be continued indefinitely in patients with impaired LV function (EF <40%) or clinical HF.
- Long-term aldosterone antagonist therapy should be prescribed for post-MI patients without significant renal dysfunction (creatinine ≤2.5 mg/dl in men and ≤2.0 mg/dl in women) or hyperkalemia who are already taking an ACEI, a beta-blocker, and have LV EF <40% with symptomatic HF or diabetes.
- In late 2018, American College of Cardiology (ACC) recommended LDL goal of <70 mg/dL for secondary prevention of atherosclerotic cardiovascular disease. High-intensity statins (atorvastatin 40 to 80 mg or rosuvastatin 20 to 40 mg) should be started as early as possible in all patients with MI regardless of lipid panel, not only for their lipid-lowering effects, but also their antiinflammatory properties (JUPITER trial), which can stabilize the ruptured plaque. Atorvastatin 80 mg can be used (PROVE IT-TIMI 22 and MIRACL trials). IMPROVE-IT trial showed adding ezetimibe to statin treatment could decrease recurrent MI and ischemic stroke in MI patients. FDA also approved two PCSK9 (proprotein convertase subtilisin/kexin type 9) inhibitors (alirocumab and evolocumab) for heterozygous familial hypercholesterolemia patients who are receiving maximally tolerated statins or patients with clinical atherosclerotic cardiovascular disease who require lowering LDL levels. Newer 2018 lipid guidelines suggested starting PCSK9 inhibitor in very high risk atherosclerotic cardiovascular disease patients who did not meet the LDL goal on high intensity statin and ezetimibe. One should always consider adding ezetimibe to high intensity statin prior to initiation of PCSK9 inhibitor due to cost issues. A fasting lipid panel should be checked during the first 24 hours of hospital course, and the intensive therapy can be stepped down if appropriate.
- In diabetic patients, HbA1c goal should be aimed at below or around 7.0% to reduce micro- and macrovascular complications. Oral hypoglycemic agents GLP1 (glucagon like peptide) agonist (liraglutide) and SGLT2 (sodium-glucose cotransporter) inhibitor (empagliflozin) showed significant mortality benefit in type 2 diabetic patients with history of CAD.
- ACC/AHA 2017 hypertension guidelines recommend initiation of blood pressure (BP)-lowering medications in patients with clinical CVD and an average SBP ≥130 mm Hg or a DBP ≥80 mm Hg for goal BP of <130/80.

COMPLICATIONS OF MI

- Cardiogenic shock: Emergent revascularization with either PCI or CABG is the recommended treatment.
- Sustained ventricular tachycardia: Implantable cardioverter-defibrillator therapy (ICD) is indicated before discharge in patients who develop sustained ventricular tachycardia/ventricular fibrillation more than 48 hours after STEMI, provided the arrhythmia is not due to transient or reversible ischemia, reinfarction, or metabolic abnormalities.
- Pacing in MI: Temporary pacing is indicated for symptomatic bradyarrhythmias

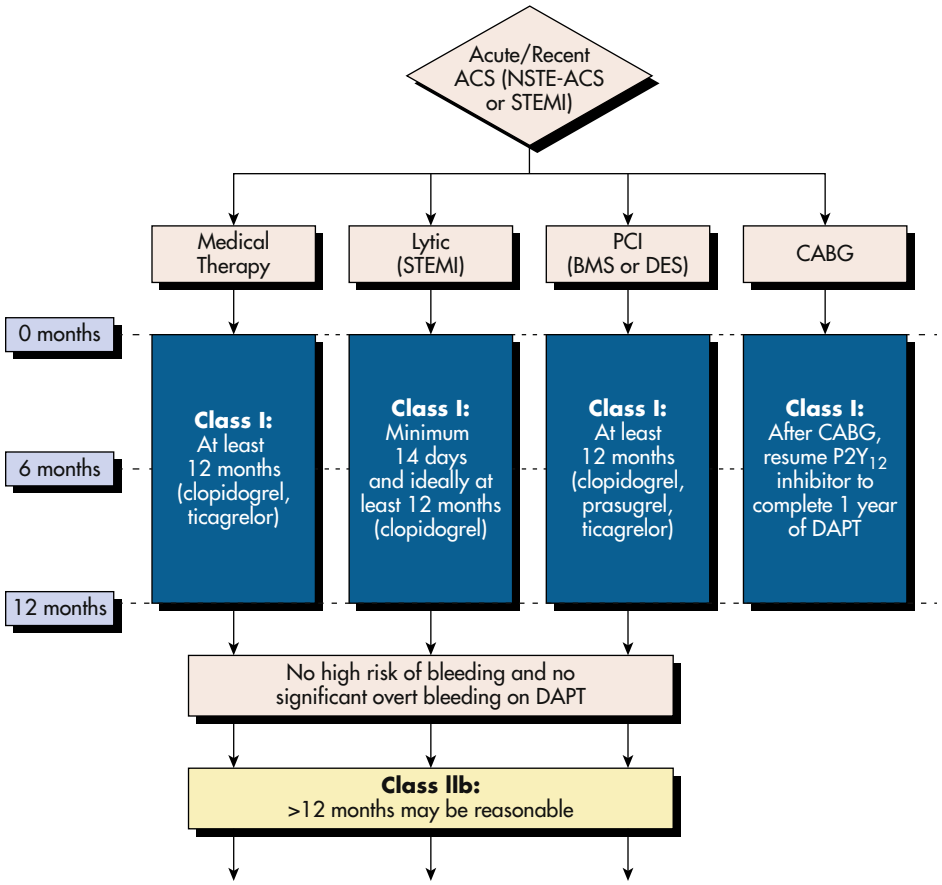

FIG. 6 ACC/AHA guideline recommendation for duration and choice of antiplatelet agent in patients with recent acute coronary syndrome (ACS), including STEMI. Aspirin therapy is generally continued indefinitely post-ACS. In patients treated with dual-antiplatelet therapy (DAPT) after DES implantation who have a high risk of bleeding (e.g. use of oral anticoagulant therapy, major intracranial surgery) or develop significant overt bleeding, discontinuation of P2Y12 inhibitor therapy after 6 mo for ACS may be reasonable. The optimal duration of prolonged DAPT is not established. *BMS,* Bare-metal stent; *CABG,* coronary artery bypass grafting; *CAD,* coronary artery disease; *DES,* drug-eluting stent; *Hx,* history; *lytic,* fibrinolytic therapy; *NSTE-ACS,* non–ST-elevation acute coronary syndrome; *PCI,* percutaneous coronary intervention; *STEMI,* ST-elevation myocardial infarction. (Modified from Levine GN et al: 2016 ACC/AHA guideline focused update on duration of dual antiplatelet therapy in patients with coronary artery disease, J Am Coll Cardiol 2016;68(10):1082-115. In Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

unresponsive to medical treatment and after revascularization. AV block and bradyarrhythmias in the setting of inferior wall MI are usually transient, will not require long-term pacing, and usually resolve within 2 to 4 wk of the event. On the contrary, AV block and bradyarrhythmias or new LBBB in the presence of an anterior wall MI is usually a sign of severe disruption of the bundle of His and often requires a permanent pacemaker.

- Pericarditis after MI: Post-MI pericarditis can occur early after MI. Dressler syndrome is an autoimmune inflammatory reaction to myocardial antigen after myocardial infarction. Symptoms of pericarditis usually occur 2 to 3 wk after myocardial infarction. Aspirin is recommended for treatment of pericarditis after MI. Glucocorticoids and nonsteroidal antiinflammatory drugs are potentially harmful for treatment of pericarditis after STEMI.
- Severe mitral regurgitation from papillary muscle rupture (1%), interventricular septum rupture (0.2%), and free wall rupture (1% to 3%) are the three major mechanical complications that can occur after acute myocardial infarction. Echocardiogram is helpful in diagnosing papillary muscle rupture, ventricular septal rupture, and free wall rupture. Right heart catheterization is needed to show "step-up" in oxygen saturation at the level of right ventricle. Emergent surgical repair is the treatment of choice for ventricular free wall rupture, intraventricular septum rupture, and papillary muscle rupture.

EVALUATION OF POST-MI PATIENTS

- Noninvasive testing for ischemia should be performed before discharge to assess the presence and extent of inducible ischemia in patients with STEMI who have not had coronary angiography and do not have high-risk clinical features for which coronary angiography would be warranted. It might be considered before discharge to evaluate the functional significance of a noninfarct artery stenosis previously identified at angiography and/or before discharge to guide the postdischarge exercise prescription.
- Assessment of LV function: LV ejection fraction should be measured in all patients with STEMI. Echocardiography to rule out presence of mural thrombi in patients suspected of having an extensive infarction (more common with anterior wall MI); contrast echocardiography is added if mural thrombus is suspected.
  1. Assessment of risk for sudden cardiac death: Patients with an initially reduced LV ejection fraction, <40%, who are possible candidates for implantable cardioverter-defibrillator therapy should undergo reevaluation of LV ejection fraction at 90 days (or 42 days if no revascularization was performed). ICD is recommended when LVEF remains <35% in the presence of NYHA class II or III heart failure, or in patients with LVEF <30% regardless of symptoms, if the life expectancy is >1 yr.

- Cardiac rehabilitation/secondary prevention programs are recommended for patients with STEMI.

DISPOSITION

The prognosis after MI depends on multiple factors:

- New bundle branch block, Mobitz II second-degree block, and third-degree heart block adversely affect outcome.
- Size of infarct: The larger it is, the higher the post-MI mortality rate. Significant myocardial stunning with subsequent improvement of ventricular function occurs in most patients after anterior MI. A lower level of creatine kinase, an estimate of the extent of necrosis, is independently predictive of recovery of function.
- Site of infarct: Inferior wall MI carries a better prognosis than anterior wall MI; however, patients with inferior wall MI and right ventricular involvement have a high risk for arrhythmic complications and cardiogenic shock.
- Ejection fraction after MI: The lower the LV ejection fraction, the higher the mortality rate after MI. The risk of death is higher in the first 30 days after MI among patients with LV dysfunction, HF, or both.
- Presence of post-MI angina indicates a high mortality rate.
- Performance on low-level exercise test: The presence of ST-segment changes during the test is a predictor of high mortality rate during the first yr.
- Presence of pericarditis during the acute phase of MI increases mortality rate at 1 yr.
- Type A behavior (competitive drive, ambitiousness, hostility) is associated with a lower mortality rate after symptomatic MI.
- The Killip classification is an independent predictor of all-cause 30-day mortality:
  1. Killip class I includes individuals with no clinical signs of HF. Mortality rate is 6%.
  2. Killip class II includes individuals with rales or crackles in the lungs, S_3 gallop, and elevated jugular venous pressure. Mortality rate is 17%.
  3. Killip class III describes individuals with frank acute pulmonary edema. Mortality rate is 38%.
  4. Killip class IV describes individuals in cardiogenic shock or hypotension (measured as systolic blood pressure <90 mm Hg) and evidence of peripheral vasoconstriction (oliguria, cyanosis, or sweating). Mortality rate is 67%.
- Self-reported moderate alcohol consumption in the yr before acute MI is associated with reduced 1-yr mortality rate.
- Discharge medication in patients with MI should include lipid-lowering agents. Statins may also lower vascular inflammation and damage by mechanisms other than reduction of low-density lipoprotein cholesterol. Early initiation of statin treatment in patients with acute MI is associated with reduced 1-yr mortality rate.
- Additional poor prognostic factors include cigarette smoking, history of hypertension or prior MI, presence of ST-segment depression in acute MI, older age, diabetes mellitus, and female sex (especially women >50 yr). Lammintausta and Fonarow reported that single men and women who live alone have a 60% to 70% greater risk of a heart attack. Furthermore, the study showed >160% increase in the risk of sudden death in these groups when compared to people who are married or live with family.
- Renal disease, even mild, as assessed by the estimated glomerular filtration rate, is a major risk factor for cardiovascular complications after MI.
- Although black patients with MI have worse outcomes than their white counterparts, these differences did not persist after adjustment for patient factors and site of care.

PEARLS & CONSIDERATIONS

COMMENTS

- Approximately 1.5 million patients undergo PCI in the U.S. each yr. Depending on local practices and the diagnostic criteria used, 5% to 30% of these patients have evidence of a periprocedural MI.
- The 12-lead ECG has low sensitivity for the detection of MI if the culprit lesion is in the left circumflex artery (LCX). If the initial 12-lead ECG is not diagnostic and high clinical suspicion for acute coronary syndrome exists, it is reasonable to obtain additional posterior chest leads (V_7 to V_9) to detect LCX occlusion.
- Triad of hypotension, elevated jugular venous pressure, and clear lungs are suggestive of RV infarction in patients with inferior AMI. Administration of nitroglycerin is contraindicated due to hypotension. IV fluids, inotropic support, and early reperfusion are the mainstays of treatment.

TABLE E2 Electrocardiographic Manifestations of Myocardial Infarction

Electrocardiographic Manifestations of Acute Myocardial Ischemia (In the Absence of Left Bundle Branch Block)

ST Elevation

New ST elevation at the J point in two contiguous leads with the following cut points:

- ≥0.1 mV in all leads (except V2-V3)
- In leads V2-V3 the following cut points apply:
  1. ≥0.2 mV in men ≥40 yr
  2. ≥0.25 mV in men <40 yr
  3. ≥0.15 mV in women

ST Depression and T Wave Changes

New horizontal or downsloping ST depression ≥0.05 mV in two contiguous leads

T-wave inversion ≥0.1 mV in two contiguous leads with a prominent R wave or R/S ratio >1

Electrocardiographic Manifestations of Ischemia In the Setting of Left Bundle Branch Block

Electrocardiographic Criterion	Points
ST-segment elevation ≥1 mm and concordant with the QRS complex	5
ST-segment depression ≥1 mm in lead V1, V2, or V3	3
ST-segment elevation ≥5 mm and discordant with the QRS complex	2

A score of ≥3 had a specificity of 98% for acute MI

Electrocardiographic Changes Associated with Previous Myocardial Infarction (In the Absence of Left Ventricular Hypertrophy and Left Bundle Block)

Any Q wave in leads V2-V3 ≥0.02 sec or a QS complex in leads V2 and V3

Q wave ≥0.03 sec and ≥0.1-mV deep or QS complex in leads I, II, aVL, aVF, or V4-V6 in any 2 leads of a contiguous lead grouping (I, aVL; V1-V6; II, III, aVF)

R wave ≥0.04 sec in V1-V2 and R/S ≥1 with a concordant positive T wave in absence of a conductions defect

aVF, Augmented vector foot; *aVL,* augmented vector left; *MI,* myocardial infarction.

Based on criteria from O'Gara PT et al: 2013 ACCF/AHA guideline for the management of ST-elevation myocardial infarction: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines, *J Am Coll Cardiol* 2013;61:e78. In Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,*, ed 11, Philadelphia, 2019, Elsevier.)

BASIC INFORMATION

DEFINITION

Myocarditis broadly refers to inflammation of the heart muscle (myocardium). Disease severity may range from benign and self-limiting illness to severe, acute decompensation requiring intensive care. Myocarditis may result from exposure to external antigens such as viruses, bacteria, parasites, and drugs, or from autoimmune conditions.

ICD-10CM CODES

I40.0	Infective myocarditis
I40.1	Isolated myocarditis
I40.8	Other acute myocarditis
I40.9	Acute myocarditis, unspecified
A39.52	Meningococcal myocarditis
B26.82	Mumps myocarditis
B33.22	Viral myocarditis
B58.81	Toxoplasma myocarditis
D86.85	Sarcoid myocarditis
I01.2	Acute rheumatic myocarditis
I09.0	Rheumatic myocarditis
I41	Myocarditis in diseases classified elsewhere
I51.4	Myocarditis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- Myocarditis is often underdiagnosed.
- The incidence of focal myocarditis reported at autopsy is 1% to 9% in asymptomatic patients and 50% in patients infected with HIV.
- Myocarditis is the third leading cause of sudden unexpected death (as high as 8% to 9%) in young adults <40 yr of age, especially in cases of idiopathic dilated cardiomyopathy, where myocarditis may account for 10% to 40% of the cases overall.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The most common presentations in patients are new onset heart failure (<6 months), chest pain, and arrhythmias, which include sinus tachycardia as well as atrial and ventricular premature contractions.
- Chest pain, especially pleuritic and positional, presents when the pericardium is involved.
- Persistent tachycardia out of proportion to fever.
- Bradyarrhythmia and new-onset unexplained heart block may also occur both in infectious (e.g., Lyme disease) and in immune-mediated forms of myocarditis.
- Faint S_1, S_3, and S_4 gallops on auscultation are important signs of impaired ventricular function.
- Murmur of functional mitral regurgitation and functional tricuspid regurgitation caused by severe left ventricular and right ventricular dilation.
- Pericardial friction rub if associated with pericarditis as in the clinical syndrome of myopericarditis.
- Patients may present with a history of a recent flulike syndrome or nonspecific viral prodrome (fever, arthralgias, malaise, fatigue); children often have a more fulminant presentation than adults. Difficulty breathing is the most common presentation of pediatric myocarditis.
- Congestive heart failure (CHF) symptoms that usually manifest with fatigue and decreased exercise capacity.
- If myocarditis is severe and diffuse and rapid in evolution, it can present with acute CHF symptoms leading to cardiogenic shock and death.
- Signs of biventricular failure (hypotension, hepatomegaly, peripheral edema, distention of neck veins, S_3 sounds, and pulmonary edema).
- Presyncope or syncope secondary to ventricular arrhythmias.
- Sudden cardiac death from ventricular tachycardia/ventricular fibrillation mediated by inflammation and/or a scar, which sets up a reentry-mediated pathway for ventricular arrhythmias.
- Acute coronary syndrome, which can occur due to local coronary spasm and inflammation and can present on ECG as acute injury pattern or ischemic changes.

ETIOLOGY

- Infection:
  1. Viral (adenovirus, parvovirus B19, hepatitis C virus [HCV], Coxsackie B virus, cytomegalovirus, enterovirus, poliovirus, mumps, HIV, and Epstein-Barr virus, etc.). Viruses are the most common cause of myocarditis in developed countries. In the 1980s and 1990s, enteroviruses were frequently associated with myocarditis and dilated cardiomyopathy. In the past 10 yr, however, other viruses such as adenovirus, HCV, parvovirus B19, and herpesvirus 6 (HH6) have emerged as the significant pathogens (Box E1)
  2. Bacterial (*Staphylococcus aureus, Clostridium perfringens,* diphtheria, mycoplasma, and any severe bacterial infection)
  3. Mycotic (*Candida, Mucor, Aspergillus, Blastomyces, Histoplasma*)
  4. Parasitic (*Trypanosoma cruzi*—most common worldwide, *Trichinella, Echinococcus, Amoeba*, *Toxoplasma*)
  5. *Rickettsia rickettsii*
  6. Spirochetal *(Borrelia burgdorferi*–Lyme carditis)
- Rheumatic fever
- Systemic lupus erythematosus
- Granulomatosis with polyangiitis (Wegener granulomatosis)
- Giant cell arteritis and Takayasu arteritis
- Drugs (e.g., cocaine, emetine, doxorubicin, sulfonamides, isoniazid, methyldopa, amphotericin B, tetracycline, phenylbutazone, lithium, 5-fluorouracil, phenothiazines, interferon-alfa, nivolumab, ipilimumab, tricyclic antidepressants, cyclophosphamides, smallpox vaccination)
- Toxins (carbon monoxide, ethanol, diphtheria toxin, lead, arsenicals)
- Systemic and collagen-vascular disease (scleroderma, sarcoidosis, celiac disease, Sjögren's syndrome, Kawasaki syndrome, etc.)
- Celiac disease: Two reports from Italy suggest that celiac disease, which is often clinically unsuspected, accounts for as many as 5% of patients with autoimmune myocarditis or idiopathic DCM
- Radiation
- Postpartum status
- Post–stem cell transplantation
- Hypersensitivity reactions from insect bites, such as bee and wasp bites; from snake bites; and from tetanus toxoid

DIAGNOSIS (TABLE 1)

DIFFERENTIAL DIAGNOSIS

- Ischemic cardiomyopathy and other, nonischemic cardiomyopathies
- Acute coronary syndromes
- Valvulopathies
- Infiltrative diseases of the myocardium, such as sarcoidosis, amyloidosis, hemochromatosis, and Chagas disease

The differential diagnosis of chest pain is described in Section II.

WORKUP

- Medical history: The clinical presentation of myocarditis is nonspecific and can consist of fatigue, palpitations, dyspnea, precordial discomfort, and myalgias.
- Diagnostic workup includes chest x-ray examination, ECG, laboratory evaluation, echocardiogram, cardiac catheterization, cardiac MRI with late gadolinium enhancement, and endomyocardial biopsy (in selected patients on the basis of the likelihood of finding specific treatable disorders such as giant cell myocarditis). Of note, endomyocardial biopsy has a sensitivity of only 10% to 35% using standard histologic criteria. This is due to variability in interpretation and sampling error.

LABORATORY TESTS

- Elevated cardiac troponin is suggestive of myocarditis in patients with clinically suspected myocarditis. Troponin I specificity is 89%; sensitivity is 34% to 53%. Elevated troponin aids in diagnosis but does not confer a prognostic value. A normal level does not rule out the diagnosis
- Increased creatine kinase (CK) (with elevated MB fraction, lactate dehydrogenase), and aspartate aminotransferase from myocardial necrosis
- Elevation of cardiac troponin I or T is more common than CK-MB elevation in patients with biopsy-proven myocarditis
- The elevations of cardiac troponin I were correlated with a short duration (typically less than 1 mo) of CHF symptoms, indicating that

TABLE 1 Expanded Criteria for Diagnosis of Myocarditis

Suggestive of myocarditis:	2 positive categories
Compatible with myocarditis:	3 positive categories
High probability of being myocarditis:	all 4 categories positive

(Any matching feature in category = positive for category)

Category I: Clinical Symptoms

- Clinical heart failure
- Fever
- Viral prodrome
- Fatigue
- Dyspnea on exertion
- Chest pain
- Palpitations
- Presyncope or syncope

Category II: Evidence of Cardiac Structural or Functional Perturbation *in the Absence* of Regional Coronary Ischemia

- Echocardiography evidence
- Regional wall motion abnormalities
- Cardiac dilation
- Regional cardiac hypertrophy
- Troponin release
- High sensitivity (>0.1 ng/ml)
- Positive indium In 111 antimyosin scintigraphy
- Normal coronary angiography *or*
- Absence of reversible ischemia by coronary distribution on perfusion scan

Category III: Cardiac Magnetic Resonance Imaging

- Increased myocardial T2 signal on inversion recovery sequence
- Delayed contrast enhancement after gadolinium-DTPA infusion

Category IV: Myocardial Biopsy—Pathologic or Molecular Analysis

- Pathology findings compatible with Dallas criteria
- Presence of viral genome by polymerase chain reaction or in situ hybridization

DTPA, Diethylenetriamine penta-acetic acid.
From Bonow RO et al: *Heart disease,* 9th ed, Philadelphia, 2012, Saunders.

the majority of myocardial necrosis occurs early in the disease course
- Persistent elevations of cardiac biomarkers are indicative of ongoing myocardial necrosis
- BNP or NT-proBNP is recommended if patient has heart failure symptoms
- Increased erythrocyte sedimentation rate (nonspecific but may be of value in following the progress of the disease and the response to therapy)
- Increased white blood cell count, again, nonspecific (increased eosinophils if parasitic infection)
- Viral titers (acute and convalescent)
- Cold agglutinin titer, antistreptolysin O titer, blood cultures
- Lyme disease antibody titer
- RPR, VDRL
- Histology on endomyocardial biopsy may reveal histiocytic and mononuclear cellular infiltrates, fulfilling the Dallas criteria, which were developed by a panel of cardiac pathologists as a working standard to define the disease; active myocarditis is defined as "an inflammatory infiltrate of the myocardium with necrosis and/or degeneration of adjacent myocytes not typical of the ischemic damage associated with coronary artery disease"
- Based on the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases, immunohistochemical criteria of myocarditis are abnormal inflammatory infiltrates defined as >14 leukocytes/mm^2 including up to 4 monocytes/mm^2 with the presence of >7 CD^3 positive T lymphocytes/mm^2

IMAGING STUDIES

- Chest x-ray: Enlargement of cardiac silhouette with or without pulmonary congestion may be present.
- ECG: May be normal or show nonspecific findings. Sinus tachycardia with nonspecific ST-T wave changes unless there is concomitant pericarditis in which the ECG changes are more specific; intraventricular conduction defects and bundle branch blocks are uncommon in typical viral myocarditis but are common manifestations in cardiac sarcoid and idiopathic giant cell myocarditis. The presence of Q waves or left bundle branch block was associated with higher rates of death or transplantation in some patients.
  1. Lyme disease and diphtheria can cause varying degrees of heart block.
  2. Changes mimicking acute myocardial infarction (regional ST elevations and Q waves) can occur with focal necrosis from myocarditis.
- Echocardiogram:
  1. The most useful test in detecting decreased ventricular function in suspected myocarditis even when subclinical.
  2. Acute severe myocarditis is associated with systolic dysfunction with decreased ejection fraction.
  3. Dilated and hypokinetic chambers.
  4. The systolic dysfunction is generally global but may be regional or segmental as in the case of focal myocarditis.
  5. Exercise-induced wall motion abnormalities may also be seen. This is usually due to microvascular dysfunction.
  6. Abnormal tissue Doppler signal can provide additional evidence for the presence of myocarditis.
  7. The echocardiogram can also be helpful with diagnosing coexisting pericardial involvement.
  8. The spheroid dysfunctional ventricle in acute myocarditis tends to remodel to the more normal elliptical shape over several months.
- Cardiac catheterization and angiography:
  1. To rule out coronary artery disease and valvular disease. Coronary angiography is most commonly normal with evidence of minimal or no coronary artery disease.
  2. A right ventricular endomyocardial biopsy can confirm the diagnosis, although a negative biopsy result does not exclude myocarditis owing to the low sensitivity of this test. Recent studies have shown that myocardial biopsy may be unnecessary because immunosuppression therapy based on biopsy results is generally ineffective. However, if idiopathic giant cell myocarditis is suspected, biopsy can confirm this diagnosis, and immunosuppression therapy is often helpful in this patient cohort.
- Cardiac MRI (Fig. E1):
  1. Can be used to detect myocardial edema and myocyte injury in myocarditis.
  2. Increased focal or global signal intensity can be used to calculate an edema ratio. Edema in the absence of necrosis or scar represents reversible injury and thus can predict functional recovery.
  3. Late gadolinium enhancement (LGE) and the presence of increased focal and global myocardial contrast enhancement relative to skeletal muscle.
  4. Any combination of two of the above has a sensitivity and specificity of 76% and 96%, with 85% diagnostic accuracy, and is probably the gold standard for diagnosis of myocarditis, as opposed to routine biopsy.
  5. Cardiac MRI has demonstrated that myocarditis tends to start as a focal process and becomes a more global process over time, with the extent of myocardial enhancement correlating with clinical status and left ventricular function.
  6. The pattern of LGE is different from that in ischemic cardiomyopathy. LGE in myocarditis tends to involve the epicardium with variable extension into the midmyocardium and sparing of the endocardium. This is in contrast to ischemic injury, which involves endocardium first with extension outward.
- Indium-111-labeled antimyosin antibody scintigraphy is positive in myocarditis with a sensitivity of up to 65%.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Supportive care is the first line of therapy for patients with myocarditis.
- Restrict physical activity (to decrease cardiac work). Bed rest is advisable during viremia.
- Avoid heavy use of alcohol.
- Nonsteroidal antiinflammatory drugs (NSAIDs) should be avoided in patients with HF generally, given the risk of HF exacerbation and possible risk of increased mortality. NSAIDs in the lowest required dose are reserved for patients with perimyocarditis in whom LV function is clearly normal and who have prominent chest pain from pericarditis.

ACUTE GENERAL Rx

- Treat underlying cause (e.g., use specific antibiotics for bacterial infection).
- Treat congestive heart failure (CHF) with diuretics, angiotensin-converting enzyme inhibitors (ACE inhibitors), and salt restriction. A beta-blocker may be added once clinical stability has been achieved. Digoxin should be used with caution and only at low doses.
- In patients with myocarditis associated with severe left ventricular dysfunction, major treatment decisions such as referral for heart transplant, left ventricular assist device, and with implantable cardioverter-defibrillator (ICD) implantation should be deferred for 3 to 6 months when feasible to allow for improvement with optimal medical therapy.
- Patients who are left with an LVEF ≤35% despite optimal medical therapy for 3 to 6 mo, and who have good functional status with prognosis >1 yr, will benefit from primary prevention therapy with ICD implantation as in patients with ischemic cardiomyopathy and other nonischemic cardiomyopathies.
- Antiarrhythmics if needed for ventricular arrhythmias. When antiarrhythmic therapy is necessary, options include amiodarone, dofetilide, and, in patients without class IV HF, cautious use of beta-blockers or calcium channel blockers. ICD implantation for secondary prevention in patients who have life-threatening ventricular arrhythmias and have good functional status with prognosis >1 yr.
- Complete heart block and/or symptomatic bradycardia are indications for pacing during the acute phase of myocarditis but are usually transient, so temporary pacing is sufficient.
- In patients with chronic CHF from myocarditis, only ACE inhibitors, beta-blockers, and possibly aldosterone receptor antagonists will decrease their mortality in the long term (as with all CHF etiologies).
- Anticoagulation is indicated in patients with evidence of systemic embolism or presence of acute left ventricular thrombus. Standard criteria for anticoagulation for atrial fibrillation should also be applied. Heart failure and/or low EF with normal sinus rhythm are generally not indications for anticoagulation.
- Inotropes or mechanical assist devices such as intraaortic balloon pumps, Impella device, and left ventricular assist device (LVAD) if severe heart failure or if cardiogenic shock persists despite medical therapy.
- Cardiac transplantation in patients with chronic or acute fulminant myocarditis with intractable cardiomyopathy and persistent CHF.
- Corticosteroid use is contraindicated in early infectious myocarditis; it may be justified in only selected patients with intractable CHF, severe systemic toxicity, and severe life-threatening arrhythmias.
- Immunosuppressive drugs (prednisone with cyclosporine/Cytoxan or azathioprine) do not have any significant effect on the prognosis of myocarditis and should not be used in the routine treatment of patients with myocarditis. Immunosuppression may have a role in the treatment of myocarditis from systemic autoimmune disease (e.g., lupus, scleroderma); in idiopathic giant cell myocarditis, sarcoidosis, or myocarditis caused by hypersensitivity reactions; or in severe hemodynamic compromise.
- Observational data suggest that patients with giant cell myocarditis treated with certain immunosuppressive regimes have improved survival compared with patients who do not receive immunosuppressive treatment.
- In patients with ongoing viral genomic expression, preliminary data suggest that treatment with interferons may improve both symptoms and left ventricular function when compared with standard heart failure therapy.
- IV immunoglobulins have been studied, but because of lack of efficacy data, at present there is no indication for their use except in some pediatric cases or those refractory to immunosuppressive therapy.
- Improved cardiac function and arrhythmias have been reported in patients with celiac disease and myocarditis or DCM following a gluten-free diet with or without immunosuppressive therapy, but controlled data are lacking.
- A treatment algorithm for patients with myocarditis is described in Fig. E2.

DISPOSITION

- Most patients with acute myocarditis and mild cardiac involvement have a partial or a full clinical recovery. In some cases, however, the process may continue subclinically with eventual progression to a cardiomyopathy. Therefore all patients with myocarditis should be followed up at least initially at intervals of 1 to 3 mo, depending on their initial severity of illness. Of those with advanced cardiac dysfunction, one third will have residual cardiac dysfunction, and 25% may progress to cardiac transplantation or death.
- Prognosis is best for patients with fulminant lymphocytic myocarditis (severe hemodynamic compromise, rapid onset of symptoms, or high fever). These patients tend to have complete recovery with total resolution of myocarditis on repeat biopsy.
- In contrast, patients with giant cell myocarditis have an extremely poor prognosis with a median survival of <6 mo, and most require cardiac transplantation.
- The American Heart Association recommends 3 to 6 mo abstinence from competitive sports after myocarditis.

REFERRAL

Consider heart transplant if intractable CHF develops.

BASIC INFORMATION

DEFINITION

Myoclonus is defined as a sudden, brief (<500 ms), involuntary movement of the extremities, face, or trunk. Positive myoclonus is caused by excessive muscle contraction, whereas negative myoclonus, asterixis, is due to a transient loss of postural tone. Myoclonus can be seen in a wide variety of neurologic and systemic disorders.

ICD-10CM CODE
G25.3 Myoclonus

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 1.3/100,000 persons
PREVALENCE: 8.6/100,000 persons
PREDOMINANT SEX & AGE: No gender preference; age at onset varies by the etiology of the myoclonus
GENETICS: Varies by etiology, can be hereditary or sporadic

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Clinically, myoclonus can be classified by its distribution: focal (only one body part involved), multifocal, segmental (spread to adjacent body parts), axial (muscles innervated by one or several spinal levels), or generalized. It can occur at rest, with maintenance of a posture, with action, or in response to an external stimulus (reflex myoclonus).
- Myoclonus can originate from the cerebral cortex, brain stem, spinal cord, or peripheral nerve. The causal location may not always influence the characteristics of the myoclonus.
- Negative myoclonus is typically seen in postural muscles of the limbs, causing a bobbing appearance. Asterixis is a form of negative myoclonus.

ETIOLOGY

- The causes of myoclonus are numerous and can be grouped into the categories of physiologic, essential, epileptic, and symptomatic.
- Physiologic myoclonus is a normal phenomenon and includes sleep (hypnic) jerks, hiccups (singultus), and exercise-induced myoclonus.
- Essential myoclonus occurs in the absence of other neurologic symptoms and is usually autosomal dominant. When dystonia is present, it is called myoclonus-dystonia. The myoclonus is often responsive to alcohol in this condition.
- In epileptic myoclonus, seizures dominate the clinical picture. Syndromes include infantile spasms and juvenile myoclonic epilepsy. Progressive myoclonic epilepsies are symptomatic myoclonus associated with some combination of seizures, ataxia, and dementia.
- Symptomatic or secondary myoclonus comprises myoclonus in the setting of an underlying neurologic or systemic disorder. The number of secondary causes prevents giving a full list, but common etiologies include neurodegenerative diseases (Alzheimer, atypical forms of parkinsonism), CNS infections (Creutzfeldt-Jakob disease, viral encephalitis), metabolic derangements (uremia, hepatic failure), as well as drug-induced (selective serotonin reuptake inhibitors [SSRIs], tricyclic antidepressants [TCAs], lithium, stimulants, opioids, gabapentin), autoimmune, paraneoplastic, and post-hypoxic etiologies (myoclonic status epilepticus, Lance-Adams syndrome).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Tremor: A rhythmic oscillation around a point; slower than myoclonus
- Tic: A rapid, patterned movement that, unlike myoclonus, may be briefly suppressed voluntarily or may be accompanied by a premonitory urge
- Dystonia: Patterned contractions of agonist/antagonist muscles causing twisting or pulling; slower than myoclonus
- Chorea: Typically slower, more complex writhing, patterned movements
- Psychogenic myoclonus: Variable in duration and location, distractible, or entrainable

LABORATORY TESTS

- Evaluate for metabolic precipitants (renal and hepatic function, Mg, Ca, thyroid studies, ammonia)
- Toxicology screen (amphetamines, cocaine, opiates/opioids)
- Lumbar puncture if an infectious, inflammatory (including autoimmune), or paraneoplastic CNS process is suspected. Paraneoplastic antibody testing if clinically indicated (i.e., opsoclonus-myoclonus syndrome, limbic encephalitis)
- Electroencephalogram to evaluate for epileptic/cortical myoclonus
- Electromyography (EMG) may be useful in patients with psychogenic or mixed movement disorders, particularly to characterize subtle myoclonus from a coexistent tremor if there is clinical uncertainty

IMAGING STUDIES

MRI of the brain with and without gadolinium can evaluate for a structural lesion if the myoclonus is cortical. Creutzfeldt-Jakob disease can show diffusion weighted abnormalities in the striatum and/or cortical gray matter.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Treatment should be directed toward correcting the underlying cause if it is reversible (e.g., hepatic or renal failure).
- Carefully remove or decrease potentially causative medications.

ACUTE Rx

Following evaluation for systemic infections and metabolic derangements, myoclonus that is epileptic; interferes with respiration, swallowing, or walking; or causes other severe distress to the patient may be managed acutely with IV formulation antiepileptic drugs such as valproic acid, levetiracetam, or benzodiazepines (lorazepam or midazolam).

CHRONIC Rx

- Clonazepam (preferred over other benzodiazepines for its long half-life), valproic acid, and levetiracetam are typically used for all forms of myoclonus, and often combinations of these medications are more effective.
- If dystonia is present (myoclonus-dystonia), a trial of levodopa is worthwhile although only rarely effective. Anticholinergics may also help dystonia. Botulinum toxin is used for focal dystonia.
- Peripheral focal myoclonus (e.g., hemifacial spasm) can also be helped by botulinum toxin.

DISPOSITION

The ultimate prognosis depends on the etiology of the myoclonus.

REFERRAL

Referral to a general neurologist or movement disorders center is appropriate.

PEARLS & CONSIDERATIONS

COMMENTS

- When myoclonus is seen with parkinsonism, atypical forms of parkinsonism should be high on the differential, such as dementia with Lewy bodies, corticobasal syndrome, and multiple system atrophy. Myoclonus is only rarely seen in idiopathic Parkinson disease.
- Symptomatic palatal myoclonus is a specific syndrome that is often associated with a focal brain-stem lesion. In essential palatal myoclonus (no lesion), ear "clicking" is an additional symptom that is not seen in the symptomatic form.

AUTHORS: **Jennifer E. Vaughan, MD,** and **Andrew P. Duker, MD**

Myofascial Pain Syndrome

BASIC INFORMATION

DEFINITION

- Myofascial pain syndrome is myalgia characterized by trigger point.
- Trigger point: Trigger points are discrete, focal, hyperirritable spots located in a taut band of skeletal muscle. They produce pain locally and in a referred pattern. Muscle involvement is asymmetric and focal.

SYNONYMS

Chronic myofascial pain
CMP

ICD-10CM CODE
M79.1 Myalgia, myofascial pain syndrome

EPIDEMIOLOGY & DEMOGRAPHICS

Myofascial pain syndrome is a common painful muscle disorder which can affect any sex at any age. About 85% of the general population at some point suffers from it during their lifetime. It also coexists with other chronic pain conditions.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Regional body pain and stiffness; often muscles responsible for body posture are affected. Neck, upper back, and lower back muscles are commonly involved. The most commonly affected muscles are trapezius, scalene, infraspinatus, subscapularis, levator scapulae, piriformis, tensor fasciae latae, iliopsoas, gluteus, and quadratus lumborum. Pain is present at rest and with muscle movement
- Table E1 lists some distinguishing features of myofascial pain and fibromyalgia
- Limited range of motion and pain-related weakness of affected muscle
- Twitch response: Brisk contraction of a taut band of skeletal muscle fibers elicited by snapping palpation of a trigger point in that band producing a taut band
- One or more trigger points asymmetrical location
- Referred pain from a trigger point to a zone of reference, but not following dermatomal distribution
- Resolution of the symptoms with lidocaine injection of the trigger point

ETIOLOGY

- Etiology is unknown. There are several proposed histopathologic mechanisms to account for the development of trigger points, but they are lacking scientific evidence. Most researchers agree that acute trauma or repetitive microtrauma may lead to the development of a trigger point.
- Fig. E1 lists causes of myofascial pain and dysfunction.
- Lack of exercise, prolonged poor posture, vitamin deficiencies, sleep disturbances, and joint problems may all predispose to the development of microtrauma.

TABLE E1 Distinguishing Features of Myofascial Pain and Fibromyalgia

	Myofascial Pain	Fibromyalgia
Age distribution	20-40 yr	20-50 yr
Gender distribution	Mainly women	Mainly women
Distribution of pain	Localized; usually unilateral	Generalized; bilaterally symmetric
Tender points	Few	Multiple
Trigger points	Uncommon	Common
Fatigue	Localized muscle fatigue	Generalized fatigue
Sleep disturbance	Common	Common

From Firestein GS et al: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2013, WB Saunders.

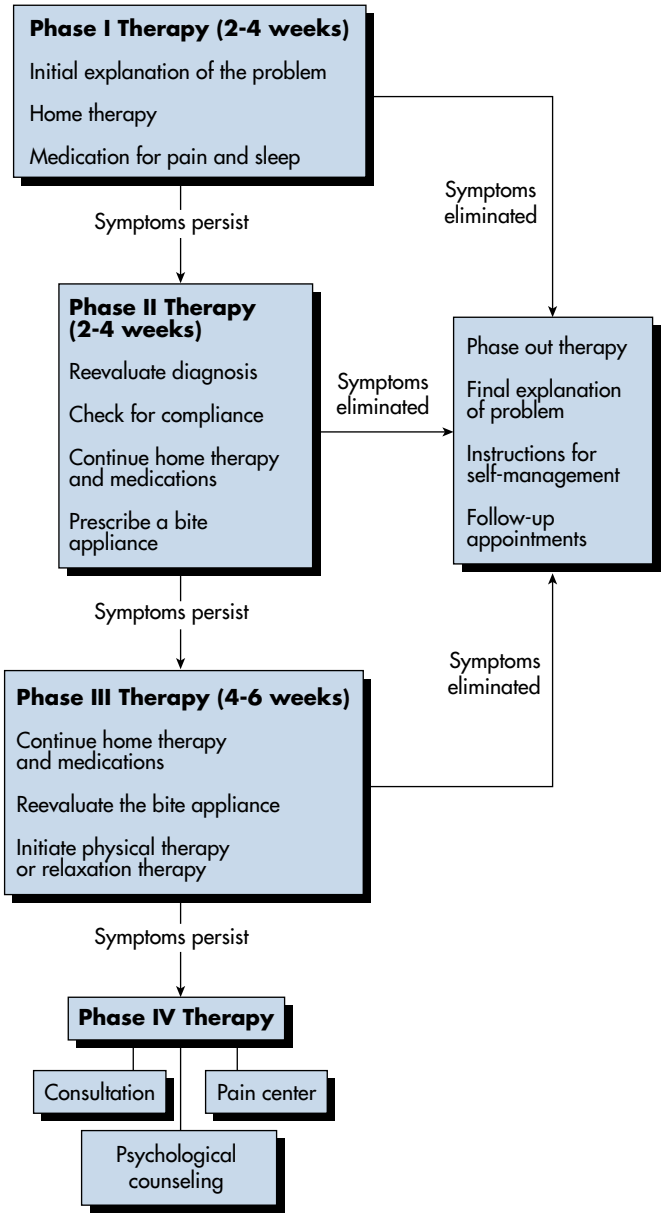

FIG. E1 Management of myofascial pain and dysfunction. Treatments are divided into four phases. If the symptoms are eliminated in any of the first three phases, the ongoing therapy is gradually phased out, and the patient is instructed in continued self-management of the condition. (Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain-dysfunction [MPD] syndrome, *J Prosthet Dent* 56:75-84, 1986.)

DIAGNOSIS

A detailed physical examination and clinical presentation usually make the diagnosis of myofascial pain syndrome.

DIFFERENTIAL DIAGNOSIS

- Fibromyalgia
- Polymyositis
- Migraine
- Tension headache
- Muscle strain
- Bursitis and tendinitis
- Radiculopathies

WORKUP

Not indicated usually, treatment can be started on clinical grounds alone.

LABORATORY TESTS

Generally not indicated, except to exclude other causes of myalgia.

IMAGING STUDIES

Generally not indicated in clear-cut cases of myofascial pain syndrome. Indicated only to exclude other causes of pain (e.g., referred pain).

TREATMENT

- Spray and stretch therapy: Involves passive stretching of the affected muscle. Position patient for maximum decrease in muscle tension, identify trigger points, and mark them. Apply vapocoolant spray over entire length of the affected muscle. Passively stretch muscle by applying gentle pressure.
- Physical therapy: TENS unit, ultrasound, massage therapy, myofascial release technique.
- Invasive technique: Trigger point injection with 1% lidocaine is the most commonly used technique.
- NSAIDs and muscle relaxants: Short-term use.
- Fig. E2 shows the management of myofascial pain and dysfunction.

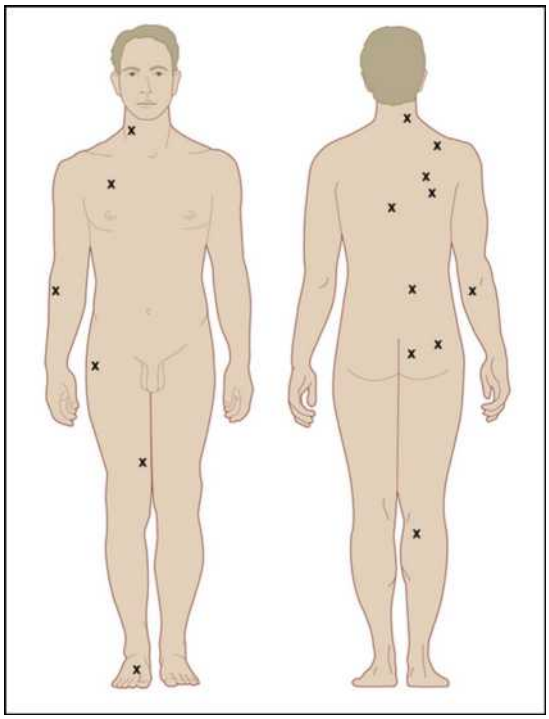

FIG. E2 Most frequent locations of myofascial trigger points. (Adapted from Rachlin E, Rachlin I: *Myofascial pain and fibromyalgia: trigger point management,* ed 2, St Louis, 2002, Mosby.)

REFERRAL

An interventional pain management referral is made if trigger point injection is indicated. To physical therapist for increasing range of motion and massage therapy.

PEARLS & CONSIDERATIONS

- Trigger point is commonly misdiagnosed as tender point, which is characteristic finding of fibromyalgia.
- Tender point: Characterized as non-palpable nodule with symmetric and multiple locations. Tender points are located close to muscle attachment, usually not associated with specific muscle activity. Lacking twitch response and relief of symptoms with localized lidocaine injection.

Myotonia

BASIC INFORMATION

DEFINITION

Myotonia is a type of muscular dystrophy in which relaxation of a muscle after contraction is delayed or prolonged. The most common type of muscular dystrophy with myotonia is myotonic dystrophy. The nondystrophic myotonias (NDMs) are rare disorders (prevalence 1:100,000) caused by mutations in skeletal muscle chloride and sodium channels with the common clinical feature of myotonia without muscle wasting.

SYNONYM

Myotonic dystrophy

ICD-10CM CODES	
G71.1	Myotonic disorders
M62.89	Other specified disorders of muscle
M62.40	Contracture of muscle, unspecified site
G71.12	Myotonia congenita
G71.14	Drug induced myotonia

EPIDEMIOLOGY & DEMOGRAPHICS

- Three to five cases/100,000 persons
- Genetic disorder inherited as an autosomal-dominant illness
- Symptoms usually manifest during adolescence or early adulthood. Cases of infantile myotonic dystrophy have been described

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Usual first symptom is distal extremity weakness sometimes associated with muscle stiffness, cramps, or difficulty relaxing grasp (Fig. E1).
- Weakness spreads to eventually involve all muscle groups. Flexor neck muscle weakness and masseter and temporal wasting are often prominent features, as is dysarthria.
- Percussion of a muscle produces a slow contraction followed by prolonged relaxation. The myotonic reflex is best tested by percussing the thenar muscles and observing a slow flexion followed by slow relaxation of the thumb.
- As the disease progresses, generalized weakness becomes more pronounced, and myotonia becomes less evident.
- Extramuscular involvement:
  1. Mental retardation of variable severity (may be absent)
  2. Frontal baldness (Fig. E2, Fig. E3)
  3. Cataracts
  4. Diabetes mellitus
  5. Hypogonadism
  6. Adrenal failure
  7. Cardiomyopathy
- Infantile myotonic dystrophy presents as neonatal extreme hypotonia with "shark mouth" deformity (upper lip forming an inverted V).

FIG. E1 Grip myotonia in myotonic dystrophy. The patient is unable to fully open the hand **(A)** after exerting a grip **(B).** (From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

FIG. E2 Myotonic muscular dystrophy (DM1). Findings in a patient with myotonic muscular dystrophy include wasting of the temporal muscles (shown) and male-pattern baldness that began at an early age. These patients may also have weakness of other facial muscles and micrognathia. (Courtesy Dr. Meir H. Kryger. From Kryger M et al: *Principles and practice of sleep medicine,* ed 6, Philadelphia, 2017, Elsevier.)

ETIOLOGY & PATHOGENESIS

Genetic disorder encoded on chromosome 19 leading to sustained firing of the muscle membrane, causing prolonged muscle contraction. Myotonic dystrophy 1 (the more common form) is caused by an expanded CTG repeat within the noncoding 3′ untranslated region of the myotonic dystrophy protein kinase *(DMPK)* gene. The less common form (myotonic dystrophy 2) is caused by an expanded CCTG repeat in the first intron of the zinc finger protein 9 *(ZNF9)* gene.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The disease is limited to muscles and causes hypertrophy and stiffness after rest. Muscle function normalizes with exercise. There is no weakness. Symptoms are exacerbated by exposure to cold.

- Myotonia congenita (Thomsen disease)
- May be autosomal dominant or recessive (two distinct varieties)
- Paramyotonia congenita (autosomal-dominant disease): Weakness and stiffness of facial muscles and distal upper extremities, especially or exclusively on cold exposure
- Muscular dystrophies
- Inflammatory myopathies (polymyositis)
- Metabolic muscle diseases
- Myasthenic syndromes
- Motor neuron disease

WORKUP

- History and physical examination usually sufficient

FIG. E3 The patient is a 54-year-old man with myotonic dystrophy type 1. Typical characteristics of balding, thin face, and distal muscle atrophy are evident. (From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

- Muscle enzymes usually abnormal (creatine phosphokinase, aldolase, aspartate aminotransferase)
- Electromyography: Typical myotonic "dive bomber" bursts
- Muscle biopsy: Type I fiber atrophy, ring fibers, increased central nucleation

Rx TREATMENT

- Phenytoin
- Quinine
- Quinidine
- Procainamide
- Acetazolamide
- Genetic counseling
- Assistive devices, orthotics
- The use of mexiletine resulted in improvement of patient-reported stiffness in patients with nondystrophic myotonias[1]

[1]Statland JM et al: Mexiletine for symptoms and signs of myotonia in nondystrophic myotonia, *JAMA* 308(13): 1357-1365, 2012.

DISPOSITION

- In myotonic dystrophy, death is usually caused by the wasting of skeletal muscle and defects in cardiac function.
- Among patients with myotonic dystrophy type 1, an invasive strategy based on systemic electrophysiological studies and prophylactic permanent pacing is associated with longer survival than a noninvasive strategy.[2]

REFERRAL

- To neurologist
- To physical therapy

AUTHOR: **Fred F. Ferri, MD**

[2]Wahbi K et al: Electrophysiological study with prophylactic pacing and survival in adults with myotonic dystrophy and conduction system disease, *JAMA* 307(12):1292-1301, 2012.

Myxedema Coma (PTG)

BASIC INFORMATION

DEFINITION

Myxedema coma is a rare life-threatening complication of hypothyroidism characterized by profound lethargy or coma and usually accompanied by hypothermia.

ICD-10CM CODES

E03.5 Myxedema coma
E03.8 Other specified hypothyroidism
E03.9 Hypothyroidism, unspecified

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Mental obtundation, profound lethargy or coma
- Hypothermia (rectal temperature <35° C [95° F]); often missed by using ordinary thermometers graduated only to 34.5° C (94.1° F) or because the mercury is not shaken below 36° C (96.8° F)
- Bradycardia, hypotension (attributable to circulatory collapse)
- Delayed relaxation phase of deep tendon reflexes, areflexia
- Myxedema facies (Fig. E1)
- Alopecia, macroglossia, ptosis, periorbital edema, nonpitting edema, doughy skin
- Bladder dystonia and distention
- Pleural, pericardial, and peritoneal effusions

ETIOLOGY

Decompensation of hypothyroidism from:

- Sepsis
- Exposure to cold weather
- Central nervous system depressants (sedatives, narcotics, antidepressants)
- Trauma, surgery
- Stroke, congestive heart failure, burns
- Intravascular volume contraction (GI blood loss, diuretic use)
- Myocardial infarction
- Metabolic derangements

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Severe depression, primary psychosis
- Drug overdose
- Cerebrovascular accident, liver failure, renal failure
- Hypoglycemia, CO_2 narcosis, encephalitis

WORKUP

Diagnosis of hypothyroidism and exclusion of contributing factors (e.g., sepsis, cerebrovascular accident) with laboratory and radiographic studies (see "Laboratory Tests")

LABORATORY TESTS

- Serum thyroid stimulating hormone and T_4 levels should be tested immediately. Results reveal markedly increased thyroid-stimulating hormone (if primary hypothyroidism), decreased serum free T_4
- Complete blood count with differential, urine and blood cultures to rule out infectious process
- Electrolytes, blood urea nitrogen, creatinine, liver function tests, calcium, glucose
- Arterial blood gases to rule out hypoxemia and carbon dioxide retention
- Stat cortisol level to rule out concomitant adrenal insufficiency prior to initiation of thyroid hormone replacement
- Elevated creatine phosphokinase may be present
- Hyperlipidemia is common

IMAGING STUDIES

- CT scan of head in suspected cerebrovascular accident
- Chest x-ray to rule out infectious process

TREATMENT

NONPHARMACOLOGIC THERAPY

- Prevent further heat loss; cover the patient but avoid external rewarming because it may produce vascular collapse. Consider warmed IV fluids.
- Support respiratory function; intubation and mechanical ventilation may be required.
- Monitor patient in the intensive care unit.

ACUTE GENERAL Rx

- Give levothyroxine 5 to 8 mcg/kg (200 to 500 mcg) IV infused over 15 min, then 50 to 100 mcg IV q24h until transition to an oral formulation is possible. Oral daily dose following IV administration is 1.6 mcg/kg. Lower doses may be indicated in patients with cardiac disease or advanced age.
- Glucocorticoids should also be empirically administered until coexistent adrenal insufficiency can be ruled out. Hydrocortisone hemisuccinate 100 mg IV bolus is initially given, followed by 100 mg IV q8h until initial plasma cortisol level is confirmed normal.
- IV hydration with D_5NS is used to correct hypotension and hypoglycemia (if present); avoid overhydration and possible water intoxication because clearance of free water is impaired in these patients.
- Rule out and treat precipitating factors (e.g., antibiotics in suspected sepsis).

CHRONIC Rx

Refer to "Hypothyroidism" in Section I.

DISPOSITION

Mortality rate in myxedema coma is high, up to 40% despite aggressive therapy.

REFERRAL

Endocrinology consultation

PEARLS & CONSIDERATIONS

COMMENTS

If the diagnosis is suspected, initiate treatment immediately without waiting for confirming laboratory results.

FIG. E1 Myxedema facies. Note dull, puffy, yellowed skin; coarse, sparse hair; temporal loss of eyebrows; periorbital edema; and prominent tongue. (Courtesy Paul W. Ladenson, MD, The Johns Hopkins University and Hospital, Baltimore, MD. In Seidel HM [ed]: *Mosby's guide to physical examination,* ed 5, St Louis, 2004, Mosby.)

BASIC INFORMATION

DEFINITION

Narcissistic personality disorder (NPD) is characterized by a pattern of grandiosity, need for admiration, and lack of empathy that begins by early adulthood and causes significant distress or impairment in multiple domains of functioning. The individual must meet five or more of the following criteria, each of which should be enduring and pervasive across contexts:

- Grandiose sense of self-importance. For example, the person may exaggerate achievements and talents or expect recognition as superior without commensurate achievements.
- Preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love.
- Views self as "special" and unique and should only associate with other special or highly regarded people and institutions.
- Requires excessive admiration.
- Sense of entitlement. For example, unreasonable expectations of especially favorable treatment or automatic compliance with his or her expectations.
- Interpersonally exploitative.
- Lacks empathy: Unwilling to recognize or identify with the feelings or needs of others.
- Often envious of others or believes others envious of him or her.
- Shows arrogant or haughty behaviors.

SYNONYM

NPD

ICD-10CM CODE
F60.81 Narcissistic personality disorder
DSM-5 CODE
301.81 Narcissistic personality disorder

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Less than 1% of the general population; estimates range from 2% to 6% in the clinical population
PREDOMINANT SEX: More commonly diagnosed in males (up to 3:1)
PREDOMINANT AGE: 20s and 30s

CLINICAL PRESENTATION

- Patients have an underlying sense of inferiority and inadequacy, despite outward behavior that suggests high self-regard.
- To avoid these beliefs and their associated painful effects, patients seek to convince self and others that they are special, the best, or unusually talented.
- They are astutely aware of status and "pecking order."
- Vulnerability in self-esteem makes these patients exquisitely sensitive to criticism, defeat, or perceived weakness, which in turn can lead to feeling humiliated, degraded, and empty.
- These patients react to perceived slights either with more intense grandiosity and admiration-seeking or with disdain and rage. Either approach seeks to bolster their sense of self, often by devaluing or criticizing the other person.
- Experiences of self-deflation can lead to social withdrawal, depressed mood, or feigned humility that can obscure the grandiosity.
- Interpersonal relationships are typically shallow and limited.
- Although ambition and confidence may lead to high achievement, vocational functioning may be disrupted by intolerance for criticism.

ETIOLOGY

- Twin studies suggest high heritability—up to 80%.
- Classic hypotheses focus on impaired development of self as "worthy" because of insufficient affirmation and warmth from parents.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Mania and hypomania
- Dysthymia and major depressive episode
- Substance-induced euphoria, especially cocaine abuse
- Histrionic, borderline, antisocial, and paranoid personality disorders share common features and are often comorbid
- Personality changes from a general medical condition, including central nervous system processes in the frontal-temporal regions of the brain

WORKUP

- History: Collateral information essential to establishing presence of long-standing interpersonal pattern in multiple domains of the patient's life
- Physical examination
- Mental status examination

LABORATORY TESTS

Tests necessary to rule out medical causes of personality changes

IMAGING STUDIES

Those necessary to rule out medical causes of personality changes

TREATMENT

NONPHARMACOLOGIC THERAPY

- Cognitive-behavioral therapy to help patients control rage, manage perceived criticism, and develop social skills
- Psychodynamic psychotherapy to help develop improved self-concept, affect tolerance, and interpersonal functioning
- Guidelines for general management of the patient with NPD:
  1. Be respectful and nonconfrontational.
  2. Help patient use self-perceived talents in the service of treatment.
  3. Do not take the patient's criticism personally, but understand it as the patient attempting to manage his or her own intense insecurity.
  4. Appeal to the patient's narcissism strategically. For example, agree with the patient that he or she is "entitled" to appropriate care and cite "top authorities" to support evidence-based care.

ACUTE GENERAL Rx

Benzodiazepines or low-dose antipsychotics for acute aggressive behavior, which is higher risk in NPD comorbid with impulsive disorders such as borderline or antisocial personality disorder

CHRONIC Rx

There is no evidence for specific pharmacologic treatment for NPD, so any medications used should target comorbid symptoms, such as selective serotonin reuptake inhibitors for depression.

COMPLEMENTARY & ALTERNATIVE MEDICINE

No evidence of efficacy in NPD

DISPOSITION

- Severity is variable, and course is chronic. The majority of patients obtain greater functioning in fifth decade and beyond when pessimism replaces grandiosity. Often lifelong difficulty maintaining intimate relationships.
- At increased risk for major depressive disorder and substance abuse or dependence (especially cocaine).

REFERRAL

If pharmacotherapy or psychotherapy is indicated

PEARLS & CONSIDERATIONS

COMMENTS

- Medical illness threatens these patients' image of superiority.
- To defend against this threat, patients may minimize symptoms or deny presence of illness.
- Patients will commonly demand special treatment from senior and well-known physicians.
- Patients may devalue, criticize, or question the behavior or credentials of the treating physician.

BASIC INFORMATION

DEFINITION

Narcolepsy is a chronic neurologic sleep disorder characterized by excessive daytime sleepiness and dysregulation of rapid eye movement (REM) sleep. It is the second most common cause of disabling daytime sleepiness after obstructive sleep apnea. Symptoms of REM sleep dysregulation include cataplexy, sleep paralysis, and hallucinations during transition between wake and sleep. Difficulty sleeping with either frequent awakenings or disrupted sleep may also occur. An international classification of sleep disorders is summarized in Table 1.

SYNONYMS

Hypersomnia of central origin
Narcolepsy with cataplexy
Narcolepsy-cataplexy syndrome
Narcolepsy with hypocretin deficiency
Gélineau syndrome

ICD-10CM CODES

G47.411 Narcolepsy with cataplexy
G47.419 Narcolepsy without cataplexy

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 0.74/100,000 persons/yr
PREVALENCE: 1 in 2000 people
PREDOMINANT SEX: Males and females equally affected
AGE OF ONSET: Peak 15 to 30 yr (range, 10 to 55 yr)
GENETICS:

- Associated with human leukocyte antigen (HLA) subtypes, specifically, *DQB1*0602,* which is present in 95% of patients with cataplexy and 96% of patients with hypocretin deficiency.
- Risk of narcolepsy increases 20 to 40 times if a family member is affected.
- Monozygotic twin concordance rate is 17% to 36%, thus indicating an incomplete penetrance and suggesting an environmental factor in the disease process.

RISK FACTORS: Anesthesia, head injury, history of meningitis or encephalitis, family history of narcolepsy, tumor, vascular malformations, stroke, and obesity.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Overwhelming urge to sleep with chronic hypersomnia may occur during the day.
- Cataplexy occurs in 60% to 100% of patients with narcolepsy and is reported as a partial or complete loss of voluntary muscle control with preserved consciousness that is precipitated by a strong emotion, more commonly with laughter. This is the most specific symptom and is considered pathognomonic for narcolepsy.
- Hypnagogic (wake to sleep) or hypnopompic (sleep to wake) hallucinations have been reported in 60% to 80% of patients with narcolepsy.
- Sleep paralysis, defined as loss of muscle tone during the transition between sleep and wakefulness, occurs in 60% to 80% of patients with narcolepsy. It may occur with hallucinations and can be interrupted by sensory stimuli.
- Only about one third of patients will have all four symptoms of narcolepsy: Chronic daytime sleepiness, cataplexy, hypnagogic hallucinations, and sleep paralysis.
- Fragmented sleep is seen in 60% to 80% of narcolepsy patients and can often be mistaken for insomnia or other intrinsic sleep disorder.
- Other symptoms that have been reported in narcolepsy include automatic behavior or semipurposeful movements in 40% of patients and memory disturbance in 50% of patients.

ETIOLOGY

The loss of hypocretin/orexin signaling, genetic factors, and brain lesions are presently identified factors in the development of narcolepsy. May be a manifestation of neuromyelitis optica spectrum disorder.

TABLE 1 International Classification of Sleep Disorders: Definitions and Pathophysiology

Condition	Diagnostic Criteria*	Pathophysiology
Type 1 narcolepsy	Presence of two or more of the following: Cataplexy, positive MSLT, and low CSF hypocretin-1	Hypocretin deficiency 98% HLA-DQB1*06:02
Type 2 narcolepsy	Positive MSLT; most often with no or unclear cataplexy	Unknown, heterogenous ~16% Hypocretin deficiency ~40% HLA-DQB1*0602
Secondary narcolepsy	As above, but due to neurologic conditions	With or without hypocretin deficiency, various disorders
Idiopathic hypersomnia	No cataplexy, no SOREMPs during the MSLT	Unknown, likely heterogeneous

*Abnormal Multiple Sleep Latency Test (MSLT): Sleep latency ≤8 min, ≥2 sleep-onset REM periods (SOREMPs), including a nocturnal SOREMP. For details, see *International Classification of Sleep Disorders*, third edition. (American Academy of Sleep Medicine: *International classification of sleep disorders*, ed 3, Darien, IL, 2014, American Academy of Sleep Medicine.)
CSF, Cerebrospinal fluid.
From Kryger M, Roth T, Dement WC et al: *Principles and practice of sleep medicine*, ed 6, Philadelphia, 2017, Elsevier.

HYPOCRETIN/OREXIN:

- Loss of hypocretin-1 and hypocretin-2 (also known as orexin-A and orexin-B) producing neurons in the lateral hypothalamus.
- Human cerebrospinal fluid (CSF) levels of hypocretin-1 are low to undetectable in narcoleptics with cataplexy.
- Narcolepsy without cataplexy may have a different cause because CSF hypocretin levels are usually normal in these patients, so there may be a completely separate mechanism in these patients, or it may result from less extensive loss of hypocretin neurons or impaired signaling.

SECONDARY ETIOLOGIES:

- Central nervous system lesions including tumors, vascular malformations, and strokes have all been reported to cause secondary narcolepsy.
- Direct injury to the hypocretin neurons or their projections is the most likely cause of secondary narcolepsy due to central nervous system lesions.
- Narcolepsy has been reported in genetic syndromes, including Prader-Willi syndrome and Niemann-Pick disease type C, as well as neuromyelitis optica spectrum disorder and paraneoplastic syndromes.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Excessive daytime somnolence:

- Autism
- Autosomal dominant cerebellar ataxia, deafness, and narcolepsy
- Behaviorally induced insufficient sleep syndrome
- Central or obstructive sleep apnea (sleep-disordered breathing)
- Circadian rhythm disorder
- Depression
- Diencephalic lesions
- Drug or alcohol abuse
- Hypothyroidism
- Idiopathic hypersomnia with long or short sleep time
- Inadequate sleep hygiene
- Insufficient sleep
- Increased intracranial pressure

Insomnia:

- Kleine-Levin syndrome
- Medication effect
- Menstrual-related hypersomnia
- Posttraumatic narcolepsy
- Seizures
- Sleep fragmentation (multiple causes)

Cataplexy:

- Seizures
- Periodic paralysis
- Cardiovascular insufficiency
- Psychogenic (multiple causes)
- Lesions of the hypothalamus or brain stem

WORKUP

- Because persistent sleepiness can occur with many conditions, it is important to rule out other sleep disorders.

- Narcolepsy is often diagnosed by clinical history. The Epworth Sleepiness Scale is very useful in determining the degree of excessive daytime sleepiness (Table 2).
- The diagnosis of narcolepsy can be made without the need for further testing if there is a clear history of cataplexy in the setting of excessive daytime somnolence. Sleep laboratory testing is otherwise necessary if cataplexy does not exist, if a diagnosis needs to be confirmed, or if concerns exist for another sleep disorder.
- The medical history should include questions regarding severity of daytime hypersomnia while also evaluating for sleep-disordered breathing, transient muscle weakness triggered by emotion, hallucinations while falling asleep or upon awakening, and inability to move after awakening. The clinical evaluation should also address symptoms of seizures and paraneoplastic disorders while also asking about previous stroke or genetic disorders. A detailed family history is imperative. Hypothalamic dysfunction such as unexplained weight gain, endocrine abnormalities, circadian dysrhythmias, and autonomic nervous system problems may provide useful insight.
- A thorough examination including a detailed neurologic examination should be performed.
- Nocturnal polysomnography followed by a multiple sleep latency test (MSLT) remains the gold standard for the diagnosis of narcolepsy. A drug screen should also be performed to rule out pharmacologic modulations of sleep.

LABORATORY TESTS

None

Rx TREATMENT

Narcolepsy can be treated with a combination of behavioral and pharmacologic approaches. Examples of initial treatment packages for adults are summarized in Table 3.

NONPHARMACOLOGIC THERAPY

Avoidance of over-the-counter drugs and illicit drugs, optimal sleep hygiene and scheduled daily naps, and psychosocial support can be used for symptoms of excessive daytime somnolence. However, nonpharmacologic therapy is typically not sufficient for treatment of narcolepsy alone but is often used as adjunct therapy with medications.

PHARMACOLOGIC THERAPY (TABLE 4)

For excessive daytime somnolence:

- Sodium oxybate: A central nervous system depressant that can be used for the treatment of cataplexy and REM-related symptoms
- Modafinil 200 to 600 mg PO every morning or divided bid
- Armodafinil 150 or 250 mg PO as a single dose in the morning
- Methylphenidate 5 to 15 mg PO bid to tid

TABLE 2 Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent time. Even if you have not done some of these things recently, try to work out how they would have affected you. Use the following scale to choose the most appropriate number for each situation.

0 = Would never doze
1 = Slight chance of dozing
2 = Moderate chance of dozing
3 = High chance of dozing

Situation	Chance of Dozing
Sitting and reading	
Watching TV	
Sitting and inactive in a public place (theater or meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after lunch (without alcohol)	
In a car, while stopped for a few minutes in traffic	
Total	

From Johns MW: A new method for measuring daytime sleepiness: the Epworth Sleepiness Scale, *Sleep* 14:540-545, 1991.

TABLE 3 Examples of Initial Treatment Packages for Adults

General Measures

Avoid shifts in sleep schedule
Avoid heavy meals and alcohol intake
Regular timing of nocturnal sleep: 10:30 P. M. to 7 A. M.
Naps: Strategically timed naps if possible (e.g., 15 min at lunchtime, 15 min at 5:30 P. M.)

Medications for Sleepiness

The effects of stimulant medications vary widely among patients. The dosing and timing of medications should be individualized to optimize performance. Additional doses, as needed, may be suggested for periods of anticipated sleepiness.

Modafinil* 100-200 mg (taken when waking up in the morning) and 100-200 mg at lunchtime *or*
Sodium oxybate† at bedtime: Dosage must start low at 2.25 g taken twice while in bed (at bedtime and 2.5-4 hr after bedtime); increase to total dosage of 5-6 g within 2-4 wk. This initial dose is usually ineffective, so increase to 3 g at bedtime and 3 g approximately 2.5-4 hr after bedtime if tolerated. Depending on response, dosage can be increased to as high as 9 g total nightly dose. Do not increase above 9 g because of risk of serious side effects during sleep. It may take more than 2 mo for daytime symptoms to improve, and cataplexy ma improve faster than excessive daytime sleepiness. If the patient is already taking a daytime stimulant, it may be possible to reduce the stimulant dose or to discontinue it once a therapeutic dosage of sodium oxybate has been reached.
Methylphenidate 5 mg (three or four tablets; 10 mg when waking up; 5 mg 30 min before lunch; 5 mg near 3 P. M.; better action is always obtained if the drug is taken on an empty stomach) or 20 mg SR in the morning (on an empty stomach)

If Persistent Difficulties

Modafinil 200 mg in the morning and 200 mg at lunch (total daily dosage, 400 mg) *or*
Add sodium oxybate (GHB) at bedtime: Dosage must start low as indicated above.
Methylphenidate (SR): 20 mg in the morning; 5 mg after noon nap; 5 mg at 4 P. M. *or*
Possibly (more in teenagers) atomoxetine: Start at 0.5 mg/kg within 1 wk to appropriate dosage of 1-1.2 mg/kg taken in the morning

If No Response

Dextroamphetamine sulfate: 15 mg on awakening; 5 mg after noon nap; 5 mg at 3:30 or 4 P. M. (or 15 mg at awakening and 15 mg after noon nap)

Medications for Cataplexy‡

Sodium oxybate (see above)
Venlafaxine 150-300 mg
Fluoxetine 20-60 mg
Duloxetine 60 mg

If No Response

Clomipramine 75-125 mg, *or*
Viloxazine 150-200 mg, *or*
Imipramine 75-125 mg

SR, Sustained-release tablet.
*Modafinil works best in naive subjects. It should be the drug of first choice in children and adults.
†Response to sodium oxybate is slow.
‡Medications may be taken in the evening near bedtime (sodium oxybate, clomipramine, imipramine), only in the morning (fluoxetine), or in the morning and at lunchtime (viloxazine, venlafaxine). The only medications specifically approved for use in narcolepsy by the Food and Drug Administration are modafinil and sodium oxybate.
From Kryger M et al: *Principles and practice of sleep medicine*, ed 6, Philadelphia, 2017, Elsevier.

TABLE 4 Narcolepsy Drugs Currently Available

Drug	Usual Dosage* (All Drugs Administered Orally)
Treatment of EDS	
Stimulants†	
Modafinil	100-400 mg/day
Sodium oxybate	6-9 g/day (divided in two doses)
Methylphenidate	10-60 mg/day
Atomoxetine	10-25 mg/day
Dextroamphetamine	5-60 mg/day
Methamphetamine	20-25 mg/day
Treatment of Auxiliary Effects (e.g., Cataplexy)	
Sodium oxybate (gamma-hydroxybutyrate)	6-9 g/day (divided in two doses)
Antidepressants	
Without Atropinic Side Effects	
Venlafaxine XR	75-300 mg/day
Fluoxetine	20-60 mg/day
Viloxazine	50-200 mg/day
Duloxetine	60 mg/day
With Atropinic Side Effects	
Protriptyline	2.5-20 mg/day
Imipramine	25-200 mg/day
Clomipramine	25-200 mg/day
Desipramine	25-200 mg/day

*On occasion, depending on clinical response, the dose may be outside the usual dosage range.

†Most stimulants should be administered in divided doses, commonly in the morning and at lunchtime. This is recommended for amphetamines and modafinil. Methylphenidate has a fast elimination rate, so the slow-release (SR) formula may be helpful in the morning (e.g., 20 mg SR). If it is administered by 5-mg increments, the usual timing of methylphenidate administration is every 3 to 4 hr until 3 p.m.

EDS, Excessive daytime somnolence. From Kryger M, Roth T, Dement WC: *Principles and practice of sleep medicine*, ed 6, Philadelphia, 2017, Elsevier.

- Methylphenidate SR 18 to 54 mg PO every morning or divided bid
- Dextroamphetamine 10 to 60 mg PO qd
- Eldepryl 5 mg PO bid

For cataplexy:

- Sodium oxybate: A central nervous system depressant that can be used for the treatment of cataplexy and rapid eye movement (REM) related symptoms
- Fluoxetine 20 mg PO qd initially
- Sertraline 25 mg PO qd initially
- Venlafaxine 25 mg PO qd initially
- Clomipramine 25 mg/day initially
- Protriptyline 5 mg tid initially
- Imipramine 25 to 50 mg/day initially
- Desipramine 10 mg bid initially

DISPOSITION

This is a chronic sleep disorder that may worsen for the first few years and then persist for life.

REFERRAL

Because of the complexity of this disorder and its ever-changing management and treatment, patients should be referred to centers or programs with highly trained sleep specialists with expertise caring for these patients, especially if sodium oxybate (Xyrem) therapy is needed.

PEARLS & CONSIDERATIONS

Many narcoleptics report the onset of symptoms beginning in childhood to early adulthood, with a long delay of actual diagnosis on the order of 10 to 15 yr. Typically, excessive daytime sleepiness is the initial symptom, followed by REM dysregulation (e.g., cataplexy, sleep paralysis, hypnagogic hallucinations). Patients with narcolepsy also have higher than expected incidence of other sleep disorders, including obstructive sleep apnea, periodic limb movements of sleep, and REM sleep behavior disorder.

COMMENTS

Narcolepsy is a rare disorder that is underdiagnosed. The average time from onset of symptoms to diagnosis is 5 to 15 yr. Cataplexy is specific for narcolepsy, but other symptoms of REM dysregulation, including sleep paralysis and hypnagogic or hypnopompic hallucinations, can occur even in normal patients. Sleep-onset REM or REM periods on an MSLT may occur as a result of sleep deprivation or withdrawal from REM-suppressing drugs.

Nasal Polyps

BASIC INFORMATION

DEFINITION

Nasal polyps are benign inflammatory masses arising from the mucosa of the nose and paranasal sinuses. They are a manifestation of chronic rhinosinusitis. Chronic inflammation of the lining of the nasal and sinus cavities results in reactive hyperplasia of the mucosal epithelium in the form of nasal polyps.

SYNONYMS

Nasal polyps
NP
Chronic rhinosinusitis with nasal polyps

ICD-10CM CODE
J33.0 Polyp of nasal cavity

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE:
- Affects 0.2% to 4.3% of the population.
- Approximately 10% of patients with nasal polyposis have asthma.

PREDOMINANT SEX & AGE:
- Greater than 2:1 male:female ratio.
- Childhood presentation (age <20) is rare and should prompt evaluation for cystic fibrosis or other pathology.

PEAK INCIDENCE: Mean age of onset is 42 yr

GENETICS: Some literature suggests there is a genetic component to the disease with an association between HLA-A74 and nasal polyposis.

RISK FACTORS:
- 10% of cases of nasal polyposis are associated with Samter Triad (asthma, aspirin sensitivity, nasal polyposis).
- Conditions associated with nasal polyps include asthma, bronchiectasis, cystic fibrosis, ciliary dyskinesia syndromes, Churg-Strauss syndrome, allergic fungal sinusitis, and bacterial rhinosinusitis.

CLASSIFICATION: Box E1 describes a classification of nasal polyps.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients usually present with nasal obstruction, anosmia/hyposmia, watery rhinorrhea, and/or post nasal drip.
- Physical exam:
  1. Smooth, round, mucosal-lined masses within the nasal cavity, often arising from the middle meatus
  2. Most often bilateral

ETIOLOGY

- The exact etiology is unclear but is thought to be multifactorial.
- Cytokine and cellular inflammatory markers found to be largely involved include T-helper 2 (Th-2) cells, eosinophils, IL-5 cytokines, and decreased T-regulatory function.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Possible alternative diagnoses include encephalocele, glioma, inverted papilloma, antrochoanal polyp, and neoplasm.

WORKUP

- Diagnosis can most often be made with history and physical exam.
- Anterior rhinoscopy.
- Nasal endoscopy (Figs. E1 and E2).

LABORATORY TESTS

Allergy testing may be considered based on symptoms and clinical presentation.

IMAGING STUDIES

CT sinus (Fig. E3): Not essential, but recommended for surgical planning if surgery is being considered. It is also important to help exclude other diagnoses in the case of unilateral polyps. Findings suggestive of nasal polyps include lobulated cysts or masses in the nasal cavity and partial or complete sinus or nasal cavity opacification.

TREATMENT

ACUTE GENERAL Rx

- Medical management is generally the first consideration in treatment. Goals of treatment are reduction in size of nasal polyps resulting in improvement of symptoms.
  1. Nasal corticosteroid sprays are a mainstay of treatment acutely and over the long term.
  2. Short courses of oral corticosteroids are reserved for advanced or refractory cases.
  3. Antihistamines may be helpful in controlling allergic symptoms but have little effect on nasal polyps.
- Surgical management may be considered for those who have failed medical therapy. Provides symptomatic relief but is rarely curative.
  1. High recurrence rate.
  2. Nasal polypectomy or more extensive functional endoscopy sinus surgery (FESS) performed by an otolaryngologist.
  3. Nasal saline irrigation is important postoperatively and can be continued by the patient as desired.

COMPLEMENTARY & ALTERNATIVE MEDICINE

There is some evidence that suggests topical intranasal capsaicin may be beneficial in treating nasal polyps.

DISPOSITION

Patients often require long-term intranasal corticosteroid therapy to reduce nasal inflammation. Recurrence after surgery is common, and the goals of treatment are to reduce symptoms.

BOX E1 Classification of Nasal Polyps

1. The antrochoanal polyp, mostly arising from the maxillary sinus and prolapsing into the choana; a commonly large, isolated, unilateral cyst-like noneosinophilic formation
2. Idiopathic unilateral or bilateral; mostly eosinophilic polyps without involvement of the lower airways
3. Bilateral eosinophilic polyposis with concomitant asthma and/or aspirin sensitivity
4. Polyposis with underlying systemic disease such as cystic fibrosis, primary ciliary dyskinesia, Churg-Strauss syndrome, or Kartagener syndrome

From Adkinson NF et al: *Middleton's allergy principles and practice,* ed 8, Philadelphia, 2014, WB Saunders.

FIG. E1 Nasal polyps. (From Swartz MH: *Textbook of physical diagnosis, history and examination*, ed 7, Philadelphia, 2014, Elsevier.)

REFERRAL

Referral to an otolaryngologist should be made in cases in which the diagnosis is unclear or the disease is not responsive to standard medical treatments.

PEARLS & CONSIDERATIONS

COMMENTS

- The inferior or middle turbinates are often mistaken for nasal polyps by inexperienced observers.
- When unilateral polyps are identified, histologic evaluation should be undertaken to exclude malignancy or other pathology as described previously.

PREVENTION

Avoidance of aspirin in sensitive patients

BASIC INFORMATION

DEFINITION

Nasopharyngeal carcinoma (NPC) is an epithelial carcinoma originating in the nasopharynx that is clinically distinct from other head and neck carcinomas.

SYNONYM

Nasopharynx cancer

ICD-10CM CODE

C11.9 Malignant neoplasm of nasopharynx, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- NPC is an uncommon cancer that is endemic to east and southeast Asia (70% of cases).
- Incidence rate of 3 per 100,000 population in China and 0.4 per 100,000 in Caucasian population.
- Incidence is higher in males (2.5 times than females).
- Incidence is decreasing steadily in the endemic regions in Asia.

GENETICS:

- HLA genes residing at the MHC region on chromosome 6p21 have been widely recognized as major risk loci conferring nasopharyngeal carcinoma risk.
- Genomic changes involved in the development of NPC include: multiple loss-of-function mutations in the NFkB–negative regulators, recurrent genetic lesions such as loss of the *CDKN2A/CDKN2B* locus, *CCND1* amplification, *TP53* mutation, and mutations in the PI3K/MAPK signaling pathways.

RISK FACTORS:

- Epstein-Barr virus (EBV) infection
- Tobacco smoking
- Alcohol consumption
- Family history
- Consumption of preserved foods
- Poor oral hygiene

ETIOLOGY

- Pathological subtypes of squamous NPC are: keratinising, non-keratinising, and basaloid type. The keratinising subtype accounts for less than 20% of cases worldwide and is seen in non-endemic areas. The non-keratinising subtype constitutes most cases in endemic areas (>95%) and is predominantly associated with Epstein-Barr virus (EBV) infection.
- Persistent EBV infection in genetically mutated epithelial cells and the proliferation of infected cells lead to tumorigenic transformation. Chronic exposure of the nasopharyngeal mucosa to environmental carcinogens increases DNA damage and leads to somatic genetic changes in the nasopharyngeal epithelial cells. EBV infection in turn facilitates inactivation of a variety of cancer-related genes. During tumor development, acquired mutations of regulatory factors in the NF-κB signaling pathway alter the activity of additional cancer-related genes. Mutations in the MHC class I genes, PI3K/MAPK pathways as well as somatic mutations of *TP53* and *RAS* genes may be at play in the development of tumor recurrence and metastasis.

CLINICAL PRESENTATION

- Chronically blocked or stuffy nose
- Recurrent epistaxis and bloody rhinorrhea
- Hearing impairment and tinnitus
- Headache
- Ear pain
- Palpable neck adenopathy
- Cranial nerve palsies

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Nasal polyps
- Nasopharyngeal lymphoma
- Nasopharyngeal sarcoma

WORKUP

- Direct nasopharyngoscopy by ENT physician followed by biopsy (Fig. E1) and imaging studies (Figs. E2 and E3)

LABORATORY TESTS

- Complete blood count
- Comprehensive chemistry panel
- Circulating cell-free EBV DNA is a biomarker for nasopharyngeal carcinoma. Pretreatment plasma EBV-DNA levels may add to the prognostic value of conventional TNM staging systems (Table 1)

IMAGING STUDIES

- CT or MRI of the head and neck; MRI is better than CT for soft-tissue extent assessment and retropharyngeal nodal detection
- PET/CT is used to assess for detection of distant metastasis and for detection of residual cancer after completion of therapy

TREATMENT

The mainstay of therapy is concurrent chemotherapy and radiation therapy. Both adjuvant chemotherapy and to a lesser extent neoadjuvant chemotherapy are routinely utilized after and before chemoradiotherapy in the clinical setting.

NONPHARMACOLOGIC THERAPY

- Surgery is utilized for diagnostic biopsies and for neck dissection in the setting of residual neck lymphadenopathy after completion of definitive chemoradiotherapy.
- Supportive care with gastrostomy tube nutrition is often required to maintain nutritional and hydration status during treatment.

ACUTE GENERAL Rx

- Intensity modulated radiotherapy (IMRT) with concurrent every 3-wk cycles of cisplatin and 5-fluorouracil chemotherapy over a period of 6 to 7 wk is the standard approach. Adjuvant chemotherapy with cisplatin and gemcitabine is routinely administered with benefits seen in reduction of distant metastases and improvement in overall survival. Neoadjuvant chemotherapy with the same regimen prior to definitive chemoradiotherapy was shown to improve survival in a recent report.
- Significant supportive care with nutrition, hydration, and mucositis management (especially pain control) is required.
- Post-therapy rehabilitation with swallowing therapy, dental care, endocrinology care, and lymphedema care are often required.

DISPOSITION

Patients with early stage disease typically have a good outcome (5-yr survival is 60% to 75%), whereas patients with stage IV disease have a poor outcome (5-yr survival is <40%).

REFERRAL

Diagnosis is usually confirmed by biopsy performed by otorhinolaryngology physician. Referrals include to medical oncology, radiation oncology, dietitian, and gastroenterology.

PEARLS & CONSIDERATIONS

- Analysis of EBV DNA in plasma samples has been found to be useful in screening for early asymptomatic cases. NPC was detected significantly earlier and outcomes were better in participants who were identified by screening compared to those in a historical cohort.
- Higher pre-treatment, mid-treatment, and post-treatment EBV DNA levels have been significantly correlated with poor outcomes for patients afflicted with NPC.

TABLE 1 Current TNM Staging Systems for Nasopharyngeal Carcinoma

Comparison of the seventh and eighth editions of the UICC/AJCC staging system for nasopharyngeal carcinoma.

Seventh edition		Eighth edition
Primary tumor (T)		
T_X	Primary tumor cannot be assessed	Primary tumor cannot be assessed
T_0		No tumor identified, but there is EBV-positive cervical node(s) involvement
T_1	Nasopharynx, oropharynx, or nasal cavity without parapharyngeal extension	Nasopharynx, oropharynx, or nasal cavity without parapharyngeal extension
T_2	Parapharyngeal extension	Parapharyngeal extension, adjacent soft tissue involvement (medial pterygoid, lateral pterygoid, prevertebral muscles)
T_3	Bony structures of skull base and/or paranasal sinuses	Bony structures (skull base, cervical vertebra) and/or paranasal sinuses
T_4	Intracranial, cranial nerves, hypopharynx, orbit, infratemporal fossa or masticator space	Intracranial extension, cranial nerve, hypopharynx, orbit, extensive soft tissue involvement (beyond the lateral surface of the lateral pterygoid muscle, parotid gland)
Regional lymph nodes (N)		
N_X	Regional lymph nodes cannot be assessed	Regional lymph nodes cannot be assessed
N_0	No regional lymph node metastasis	No regional lymph node metastasis
N_1	Unilateral cervical, unilateral, or bilateral retropharyngeal lymph nodes, above the supraclavicular fossa; ≤6 cm	Unilateral cervical, unilateral, or bilateral retropharyngeal lymph nodes, above the caudal border of cricoid cartilage; ≤6 cm
N_2	Bilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the supraclavicular fossa	Bilateral metastasis in lymph node(s), ≤6 cm in greatest dimension, above the caudal border of cricoid cartilage
N_{3a}	>6 cm in dimension	>6 cm and/or below caudal border of cricoid cartilage (regardless of laterality)
N_{3b}	Supraclavicular fossa	
Distant metastasis (M)		
M_0	No distant metastasis	No distant metastasis
M_1	Distant metastasis	Distant metastasis
Stage group		
I	T_1 N_0 M_0	T_1 N_0 M_0
II	T_2 N_0-$_1$ M_0, T_1 N_1 M_0,	T_2 N_0-$_1$ M_0, T_0-$_1$ N_1 M_0
III	T_1-$_3$ N_2 M_0, T3 N_0-$_1$ M_0	T_3 N_0-$_2$ M_0, T_0-$_2$ N_2 M_0
IVA	T_4 N_0-$_2$ M0	T_4 or N_3 M_0
IVB	Any T, N_3 M_0	Any T, any N, M_1
IVC	Any T, any N, M_1	

EBV, Epstein-Barr virus; *UICC/AJCC,* International Union Against Cancer/American Joint Committee on Cancer. T category: T_0 is added for EBV-positive cervical node(s) involvement despite unidentified primary tumor. Involvement of medial pterygoid, lateral pterygoid, and prevertebral muscles is now staged as T_2. In T_4, the original "infratemporal fossa or masticator space" has been replaced by specific description of soft tissue involvement to avoid potential ambiguity. N category: the previous N_{3b} criterion of "supraclavicular fossa" has been changed to "below caudal border of cricoid cartilage." N_{3a} and N_{3b} have been merged into a single N_3. Stage group: the previous stages IVA and IVB have been merged into IVA. The previous IVC has been upstaged to IVB.

BASIC INFORMATION

DEFINITION

Necrotizing autoimmune myopathy (NAM) is a subgroup of idiopathic inflammatory myopathies (IIM) that presents with myalgias, weakness, and markedly elevated CPK levels (up to 50 times upper limit of normal). Most cases of NAM are seen in patients who have a history of statin use, the average duration of which is about 3 yr. Unlike typical statin-induced myopathy, the symptoms of NAM may present long after statins are initiated and can persist long after statins have been discontinued. In contrast with IIM, there is necrosis but sparse inflammation seen on muscle biopsy. Two specific autoantibodies associated with NAM are anti–signal recognition particle (SRP) and anti–3-hydroxy-3-methylglutaryl-coenzyme-A reductase (HMGCR). Statins have been associated with developing anti-HMGCR in all populations; however, these autoantibodies can be present without statin exposure. Rarely, an individual with NAM can have both antibodies.

SYNONYMS

Immune-mediated necrotizing myopathy
NAM
Necrotizing autoimmune myositis

ICD-10CM CODE
G72.49 Other inflammatory and immune myopathies, not elsewhere classified

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Incidence of IIM in a homogenous population is 2.2 to 7.7 per million, and NAM, which is a rare disorder, accounts for 20% of IIM. Anti-SRP–associated NAM accounts for 3% to 6% of IIM, while anti-HMGCR accounts for 5% to 7% of IIM.

PREDOMINANT SEX & AGE: Primarily affects adults >18 yr, with mean age at onset around 50 to 60 yr, while younger ages of 47 to 49 have been reported in European studies. Also, statin- and cancer-related NAM patients are found to be older (60s). Anti-SRP–positive patients tend to be younger. There is a female predominance.

GENETICS: *HLADRB1*11:01* is associated with an increased risk of developing anti-HMGCR NAM in whites and African Americans when exposed to statins. *HLADRB1*08:03* may be associated with increased risk of anti-SRP NAM in Japanese. DQA1 and DQB6 may be protective against anti-HMGCR NAM.

RISK FACTORS:

- Statin exposure: Atorvastatin and simvastatin more than others (although this may reflect prescribing patterns)
- Cancer: GI origin most common as well as lung, thymoma, ovarian, etc.
- CTD: Scleroderma, Sjögren, and less with systemic lupus erythematosus
- Infections: Rarely HIV
- Can occur in association with the antisynthetase syndrome

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Acute (<4 wk) or subacute (<6 mo) onset of severe symmetrical proximal muscle weakness and atrophy that can involve both shoulder and pelvic girdle. Distal weakness may be present, along with myalgias and arthralgias. May be associated with interstitial lung disease, cardiac conduction abnormalities, mechanic hands, dysphagia or dyspnea, weight loss, and Raynaud. Case reports of isolated involvement of neck extensors have been reported.

ETIOLOGY

The exact pathogenesis of NAM is not clear, but studies suggest that statin exposure upregulates HMGCR in muscle in genetically susceptible individuals. Variable durations of statin exposure suggest environmental triggers may initiate autoimmunity. Increased TH1 responses and increased INF-gamma production by macrophages have been described. The presence of an autoantibody to HMGCR suggests that statins may be pathogenic, and that the aberrant immune response is sustained due to high levels of HMGCR expression by regenerating muscle fibers. However, elevated levels of HMGCR are often seen after full remission, suggesting that HMGCR antibodies may have a less direct role in pathogenesis.

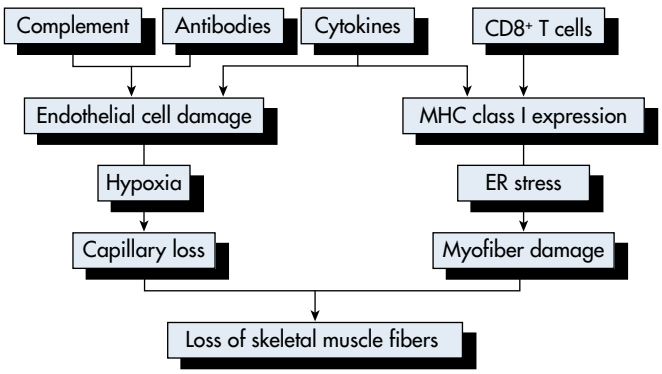

FIG. E1 Mechanisms of muscle fiber damage in myositis. *ER,* Endoplasmic reticulum; *MHC,* major histocompatibility complex. (From Firestein GS et al: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2013, WB Saunders.)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Other conditions that cause muscle weakness and/or elevated muscle enzymes, such as muscular dystrophy, polymyositis, dermatomyositis, inclusion body myopathy, drug-induced myopathy, and thyroid myopathy.

WORKUP

- MRI of affected muscle: Muscle and/or fascial edema, muscle atrophy, fatty replacement
- Electromyography: Commonly shows an irritable myopathy
- Muscle biopsy:Histopathologic findings on muscle biopsy include muscle fiber necrosis with prominent regeneration and minimal or no inflammatory infiltrate. Specific findings with immunofluorescence staining include upregulation of major histocompatibility complex class I and membrane attack complex C5b-9 on small blood vessels (Fig. E1).

LABORATORY TESTS

- Complete blood count
- Creatine kinase
- Aldolase
- Comprehensive metabolic panel (renal function, aspartate transaminase/alanine aminotransferase)
- Anti-HMGCR antibody (anti 200/100)
- Anti-signal recognition particle antibody
- Connective tissue disease antibody testing (antinuclear antibodies, extractable nuclear antigen antibodies, anti-Scl70, etc.)
- HIV, hepatitis testing
- Thyroid function tests

IMAGING STUDIES

- MRI of involved muscles
- CT chest/abdomen/pelvis and other age-appropriate cancer screening
- Echocardiogram, ECG
- Pulmonary function tests

TREATMENT

No guidelines yet exist, and therapy has to be individualized. Stop statins immediately if they are suspected to be the causative agent. Treatment of underlying malignancy can also ameliorate disease. Steroids are the mainstay of therapy; however, steroid monotherapy seldom is effective long term, so the addition of an immunosuppressant agent should be considered. Aggressive therapy from the beginning is preferred. Options include intravenous immunoglobulin, methotrexate, azathioprine, mycophenolate mofetil, rituximab, cyclosporine, cyclophosphamide, and plasmapheresis. Relapse can occur.

REFERRAL

- Rheumatology
- Neurology

PEARLS & CONSIDERATIONS

- NAM must be considered in patients who have persistent myalgias and weakness after discontinuation of statins.
- Not all cases of NAM have a history of statin use. Individuals with NAM without prior statin exposure can be more treatment resistant.
- Muscle biopsy is essential for diagnosis.

PREVENTION

Avoid statin rechallenge.

PATIENT & FAMILY EDUCATION

Report to your doctor immediately any symptoms of muscle pains and/or weakness at any time after starting statin therapy.

BASIC INFORMATION

DEFINITION

Necrotizing fasciitis (NF) is a rapidly spreading bacterial infection of the deep fascia, with associated inflammation, leading to necrosis of subcutaneous tissue planes. This infection can occur in wounds from trauma or surgical wounds or can be spontaneous or idiopathic. There are two clinical types, both of which carry a high rate of morbidity and mortality.

SYNONYMS

NF
Soft tissue gangrene
Flesh-eating bacteria
Fournier gangrene
Hemolytic streptococcal gangrene

ICD-10CM CODE
M72.6 Necrotizing fasciitis

EPIDEMIOLOGY & DEMOGRAPHICS

PREDOMINANT SEX: Male > female
PREDOMINANT AGE: 6 to 50 yr; less common in children
INCIDENCE: Invasive group A *Streptococcus* infection occurs at a rate of 3.5 cases per 100,000 persons, with a case fatality rate of around 24%.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

CLINICAL TYPES OF NECROTIZING FASCIITIS:

- Type I: Necrotizing fasciitis: At least one anaerobic species is isolated in conjunction with one or more facultative anaerobic species, such as streptococci (not group A), *and* members of the Enterobacteriaceae (gram-negative rods).
- Anaerobic bacteria, most commonly *Bacteroides* or *Peptostreptococcus* spp.
- Enterobacteriaceae: *Escherichia coli, Klebsiella* spp., *Proteus* spp., *Enterobacter* spp.
- Usually associated with diabetes or peripheral vascular disease.
- Example of type I: Fournier gangrene of the perineum.
- Type II: Necrotizing fasciitis: Group A *Streptococcus* is isolated alone or in combination with other bacteria, most likely *Staphylococcus aureus.* Also known as hemolytic streptococcal gangrene.
  1. Example of type II: Invasive group A *Streptococcus*, associated with virulence factors type 1 and type 3 M protein

EXAMPLES OF NECROTIZING FASCIITIS:

- Fournier gangrene: Aggressive type I infection of the perineum usually caused by penetration of the gastrointestinal or urethral mucosa by enteric organisms. It can rapidly spread to involve the scrotum, penis, and abdominal wall or gluteal muscles, causing gangrene. Use of sodium-glucose cotransporter-2 (SGLT2) inhibitors in diabetics has been associated with Fournier gangrene.
- Clostridial cellulitis: Caused by *Clostridium perfringens* associated with local trauma or surgery and crepitus caused by gas production; generally noted in the skin, with deeper tissues generally spared.

PHYSICAL FINDINGS

Minor skin trauma, toxic-appearing patient:

- Open skin wound
- Severe pain at injury or surgical site
- Fever, confusion, weakness, diarrhea
- Early skin erythema, quickly spreading in hours to days
- Skin redness changes to purple discoloration
- Gangrenous skin changes may develop
- Loosening of skin and subcutaneous skin in association with deep fascial necrosis (Fig. E1). "Woody" induration and crepitus of involved area are characteristics
- Muscle involvement, thrombosis of blood vessels, and myonecrosis may develop
- Bullae and gas formation at site

ETIOLOGY

- NF usually arises from skin damage or trauma. Risk is increased with presence of comorbidities (diabetes mellitus, cancer, liver disease, immunosuppression, use of SGLT2 inhibitors)
- Polymicrobial: Mixture of anaerobes and aerobic enteric gram-negative rods
- Group A streptococci *(S. pyogenes)*
- *S. aureus*
- *C. perfringens*
- *Bacteroides fragilis*
- *Vibrio vulnificus*
- Methicillin-resistant *S. aureus* (MRSA), especially community-acquired MRSA

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cellulitis
- Pyomyositis
- Gas gangrene
- A classification of necrotizing skin, soft-tissue, and muscle infections is described in Table 1

WORKUP

- Diagnosis of necrotizing fasciitis generally requires incision and probing. In patients with necrotizing fasciitis, there is no resistance to probing subcutaneously, and there is fascial plane involvement.
- Laboratory tests:
  1. The laboratory risk indicator for necrotizing fasciitis (LRINEC) consists of the following 6 variables. When present, the reported positive predictive value is 92%: Complete blood cell count (CBC) with differential (leukocytosis [white blood count >15,000], anemia [Hb <13.5]), elevated C-reactive protein (≥15 mg/dl), hyponatremia (sodium <135 mEq/L), elevated creatinine (>1.6 mg/dl), hyperglycemia (glucose >180 mg/dl).
  2. Cultures of skin, soft tissue, or debrided tissue, aerobically and anaerobically. Blood cultures are positive in 60% of patients with type II infections and 20% with type I infections.
- Imaging:
  1. Radiographs may show subcutaneous gas in fascial planes (Fig. 2).
  2. Computed tomography (CT) or magnetic resonance imaging (MRI) may be helpful because they can detect gas in the tissues. MRI with contrast is more sensitive than CT.

TREATMENT

- Aggressive surgical debridement of involved necrotic tissues is essential *as soon as possible* to reduce mortality.
- Fasciotomies of extremities may be necessary.
- Immediate start of empiric antibiotics:
  1. Type I: Vancomycin, daptomycin, or linezolid plus piperacillin/tazobactam; a carbapenem (such as imipenem, meropenem, or doripenem); and third-generation cephalosporin + metronidazole or a fluoroquinolone plus metronidazole (ceftriaxone) are reasonable choices pending cultures. Empiric clindamycin may also be added to suppress toxin production by staphylococci and streptococci. It is important to always have anaerobic coverage. Use the highest dosages possible for age and CrCl.
  2. Type II: For group A *Streptococcus*, give intravenous (IV) penicillin G, 4 million U q4h in patients who weigh >60 kg with clindamycin, 600 to 900 mg IV q8h.
     a. Clindamycin has the added effect of suppressing toxin production. If MRSA is suspected, add vancomycin, daptomycin, or linezolid.
- Intravenous gammaglobulin (IVIG): 1 g/kg on day 1 and 0.5 g/kg on days 2 and 3 neutralizes circulating streptococcal toxins and has been shown beneficial in severe forms of invasive group A streptococcal infections, although data are not definitive.
- For *Vibrio vulnificus* use doxycycline plus ceftazidime; for *Aeromonas hydrophila* use doxycycline plus ciprofloxacin.
- Hyperbaric oxygen evaluation as an adjunct to surgery and IV antibiotics.

TABLE 1 Classification of Necrotizing Skin, Soft-Tissue, and Muscle Infections

Disease	Bacteriology	Comments
Necrotizing Cellulitis		
Clostridial cellulitis	*Clostridium perfringens*	Local trauma, recent surgery; fascial/deep muscle spared
Nonclostridial cellulitis	Mixed: *Escherichia coli, Enterobacter, Peptostreptococcus* spp., *Bacteroides fragilis*	Diabetes mellitus predisposes; produces foul odor
Meleney synergistic gangrene	*Staphylococcus aureus,* microaerophilic streptococci	Rare infection; postoperative; slowly expanding, indolent, ulceration in superficial fascia
Synergistic necrotizing cellulitis	Mixed aerobic and anaerobic, including *B. fragilis, Peptostreptococcus* spp.	Diabetes mellitus predisposes; variant of necrotizing fasciitis type I; involves skin, muscle, fat, and fascia
Necrotizing Fasciitis		
Type I	Mixed aerobic and anaerobic; staphylococci, *B. fragilis, E. coli,* group A streptococci, *Peptostreptococcus* spp., *Prevotella, Porphyromonas* spp., *Clostridium* spp.	Usually requires a breach in the mucous membrane layer either through surgery or penetrating injuries or from chronic medical conditions such as diabetes, peripheral vascular disease, malignancy, and anal fissures
Type II	Group A streptococci	Increasing in frequency and severity since 1985; very high mortality; often begins at site of nonpenetrating minor trauma such as a bruise or muscle strain but often no identified precursor Predisposing factors: Blunt/penetrating trauma, varicella (chickenpox), intravenous drug abuse, surgical procedures, childbirth, nonsteroidal antiinflammatory drug use
Myonecrosis		
Clostridial myonecrosis	*Clostridium* spp.	Predisposing factors: Deep/penetrating injury, bowel and biliary tract surgery, improperly performed abortion and retained placenta, prolonged rupture of the membranes, and intrauterine fetal demise or missed abortion in postpartum patients. Recurrent gas gangrene occurs at sites of previous gas gangrene.
Streptococcal myonecrosis	Streptococci	
Special Type of Necrotizing Soft-Tissue Infection		
Fournier gangrene	Polymicrobial, with *E. coli* the predominant aerobe and *Bacteroides* the predominant anaerobe. Other microflora: *Proteus, Staphylococcus, Enterococcus,* aerobic and anaerobic *Streptococcus, Pseudomonas, Klebsiella,* and *Clostridium*	Necrosis of the scrotum or perineum that starts with scrotal pain and erythema and rapidly spreads onto anterior abdominal wall and gluteal muscle. It is more often seen in diabetics and can be associated with trauma.

From Vincent JL et al: *Textbook of critical care,* ed 6, Philadelphia, 2011, WB Saunders.

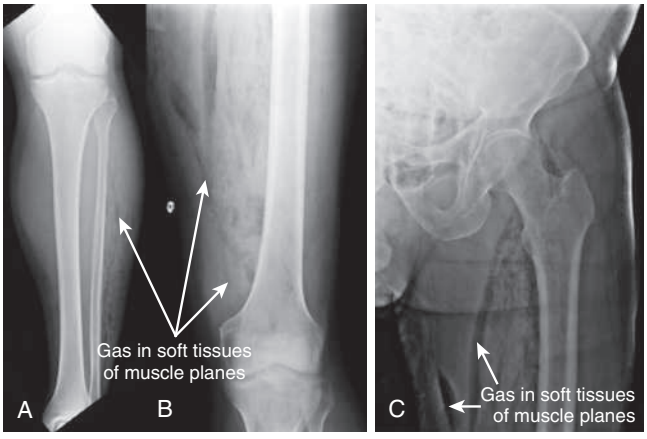

FIG. 2 Necrotizing fasciitis. This 71-yr-old man with aplastic anemia presented with fevers to 38.9° C (102.02° F), leg weakness, and extreme leg pain. Initially, the patient was thought to have neuropathic pain and weakness, possibly indicating spinal disease such as epidural abscess. He rapidly developed crepitus of his legs. Radiographs of the patient's legs were obtained, followed by noncontrast computed tomography. **A,** Anterior-posterior (AP) tibia and fibula. **B,** AP femur. **C,** AP hip. Air is seen dissecting in muscle planes of the legs. On radiograph, air appears black. Given the wide distribution of air, a focal abscess is unlikely, and necrotizing fasciitis with gas-producing organisms should be suspected. (From Broder JS: *Diagnostic imaging for the emergency physician,* Philadelphia, 2011, WB Saunders.)

FIG. E1 Necrotizing fasciitis. The so-called flesh-eating bacteria, group A β-hemolytic Streptococcus, can cause significant tissue destruction rapidly. This 32-yr-old woman had pain, erythema, and swelling of the foot followed by necrotic ulceration over a week. There was no history of trauma. (Courtesy Roger Bitar, MD. From White GM, Cox NH [eds]: *Diseases of the skin, a color atlas and text,* ed 2, St Louis, 2006, Mosby.)

Nephroblastoma

BASIC INFORMATION

DEFINITION

Nephroblastoma is an embryonal malignant renal tumor of childhood that accounts for 95% of childhood kidney tumors. Most tumors are unicentric, but some are multifocal in one or both kidneys.

SYNONYM

Wilms tumor

ICD-10CM CODE
C64 Malignant neoplasm of kidney

EPIDEMIOLOGY & DEMOGRAPHICS

- It represents 6% of all pediatric malignancies and 75% of all renal cancers in children
- Slightly more frequent in girls
- 75% of cases occur in patients at age <5 yr with most cases at age 2 to 3 yr
- Incidence is approximately 8 cases per yr per 1 million white children <15 yr (approximately 650 new cases annually in the U.S.); the incidence is double in black children
- Associated syndromes (Table E1):
  1. Cryptorchidism
  2. Hypospadias
  3. Hemihypertrophy with or without the Beckwith-Wiedemann syndrome, aniridia
  4. Denys-Drash syndrome (nephroblastoma, pseudohermaphroditism, glomerulonephritis)
  5. WAGR syndrome (***W***ilms tumor, ***a***niridia, ***g***enitourinary malformations, and mental ***r***etardation)
- Familial nephroblastoma occurs in 1.5% (with younger age at diagnosis and more frequent multifocal tumors)

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Nephroblastoma often is discovered when a parent notices a mass while bathing or dressing a child, most commonly a child who is approximately age 3 yr, or during a routine physical examination. The mass is unilateral, firm, and nontender and below the costal margin
- Abdominal swelling and/or pain
- Nausea
- Vomiting
- Constipation
- Loss of appetite
- Fever of unknown origin
- Night sweats
- Hematuria (less common than in adult renal malignancies)
- Malaise
- High blood pressure that is triggered when the tumor obstructs the renal artery
- Varicocele
- Signs of associated syndromes

ETIOLOGY & PATHOGENESIS

- Three cell types: Blastomal, stromal, and epithelial may be present. Structural diversity is characteristic.
- Anaplasia is evidenced by the presence of gigantic polyploid nuclei. The term *focal anaplasia* is used to describe such findings when it is confined within the primary tumor in the kidney.
- Abnormalities in the Wilms tumor gene *(WT1)* on locus 11p13 are present in the syndromes associated with this disease. These include deletions or point mutation in the WT1 locus. The *WT1* gene is a transcriptional regulator with a role in metanephric stem cell differentiation. Multiple studies in North America and Europe have suggested that LOH at 1p and/or 16q is associated with relapse and overall poor prognosis and is included in risk stratification of these patients.
- Gene mutations in Wilms tumors are summarized in Table E2.
- Staging: The staging system of the Children's Oncology Group is summarized in Table E3.

TABLE E1 Syndromes Associated with Development of Wilms Tumor

Syndrome	Genes	Locus	Wilms Tumor Risk
WAGR	*WT1*	11p13	50%
Denys-Drash	*WT1*	11p13	50%
Frasier	*WT1*	11p13	5%-10%
Beckwith-Wiedemann	*WT2*	IGF2, H19, p57, Klp2	5%-10%
Familial Wilms tumor	*FWT1*	17q21	30%
	FWT2	19q13	
Perlman	Unknown		>20%
Mosaic variegated aneuploidy	*BUB1B*	15q15	>20%
Fanconi anemia D1	*BRCA2*	13q12.3	>20%
Simpson-Golabi-Behmel	*GPC3*	Xq26	10% (in males)
Li-Fraumeni	*P53*	17p13	Low
Neurofibromatosis	*NF1*	17q11	Low
Sotos	*NSD1*	5q35	Low
Trisomy 18	Unknown	18	Low
Bloom	*BLM*	15q26	Low

WAGR, Wilms tumor, aniridia, genital anomalies, mental retardation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other renal malignancies:
  1. Hypernephroma
  2. Transitional cell carcinoma
  3. Lymphoma
  4. Clear cell sarcoma
  5. Rhabdoid tumor of the kidney
- Renal cyst
- Other intraabdominal or retroperitoneal tumors

LABORATORY TESTS

- Complete blood count
- Comprehensive chemistry panel
- Urinalysis

IMAGING STUDIES

- Renal ultrasound to confirm existence of a solid mass in a kidney
- Abdomen and pelvis MRI or CT scan with contrast (Fig. E1)
- Chest CT scan

TREATMENT

- Accurate staging and risk stratification are both required for appropriate treatment planning. Risk stratification is based upon age at diagnosis, local and overall stage, tumor weight, and loss of heterozygosity (LOH) of chromosomes 1p and 16q.
- Upfront surgical resection of unilateral nephroblastoma is recommended. This also provides the necessary biologic information for risk stratification and selection of appropriate therapy.
- Surgical resection and surgical staging: Radical nephroureterectomy with lymph node sampling is preferred, although some centers are performing nephron-sparing surgery after neoadjuvant chemotherapy use. The sequence of chemotherapy and surgery in localized disease is not definitively established; in Europe preoperative chemotherapy is preferred, whereas in the U.S. upfront surgery is standard.
  1. Stages I and II: Surgery followed by chemotherapy.
  2. Stages III and IV: Surgery followed by radiation and chemotherapy.
  3. Stage V: Preoperative chemotherapy for 6 to 12 wk followed by nephron-sparing surgery.
- Chemotherapeutic agents used in the treatment of nephroblastoma traditionally include vincristine, dactinomycin, and doxorubicin. Modern intensive regimens in high-risk disease can also include cyclophosphamide, etoposide, and carboplatin.

PROGNOSIS

- Stage I: 95% survival
- Stage II: 91% survival
- Stage III: 91% survival
- Stage IV: 81% survival
- Prognosis is better for patients <2 yr age

AUTHOR: **Bharti Rathore, MD**

TABLE E2 Gene Mutations in Wilms Tumors

Gene	Type of Mutation	Frequency (%)	Somatic or Germline
11p15	H19 epimutation Paternal uniparental disomy	74	Both
WTX	Deletion or insertion Nonsense	33	Somatic only
WT1	Deletion or insertion Missense and nonsense	21	Both
CTNNB1	In-frame deletions Missense	20	Somatic only
TP53	Missense	4	Both

From Wein AJ et al: *Campbell-Walsh urology,* ed 11, Philadelphia, 2016, Elsevier.

TABLE E3 Staging System of the Children's Oncology Group

Stage	
I	Tumor confined to the kidney and completely resected. The renal capsule is intact and the tumor was not ruptured before removal. No renal sinus extension. There is no residual tumor.
II	Extracapsular penetration, but tumor is completely resected. Renal sinus extension or extrarenal vessels may contain tumor thrombus or be infiltrated by tumor.
III	Residual nonhematogenous tumor confined to the abdomen: Lymph node involvement, any tumor spillage, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed.
IV	Hematogenous metastases to lung, liver, bone, brain, and so on.
V	Bilateral renal involvement at diagnosis.

From Wein AJ et al: *Campbell-Walsh urology,* ed 11, Philadelphia, 2016, Elsevier.

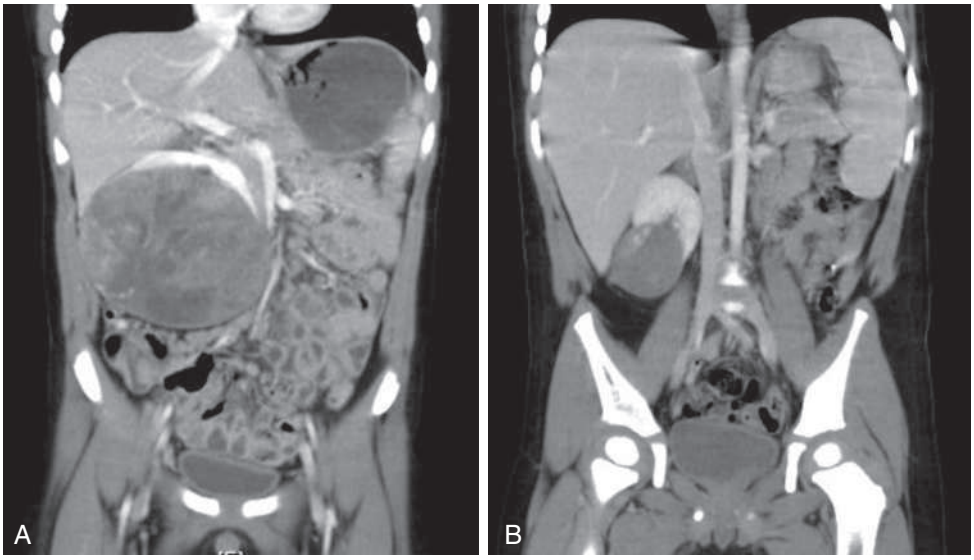

FIG. E1 A, Computed tomography scan of a Wilms tumor that was pretreated with chemotherapy. **B,** After 6 weeks of chemotherapy, the tumor is much smaller. (From Wein AJ et al: *Campbell-Walsh urology,* ed 11, Philadelphia, 2016, Elsevier.)

Nephrogenic Systemic Fibrosis

BASIC INFORMATION

DEFINITION

Nephrogenic systemic fibrosis (NSF) is a systemic sclerosis-like condition with induration of skin and contractures of joints seen in patients with acute or chronic kidney injury and end-stage renal disease. The adjective *nephrogenic* is a misnomer though, because gadolinium within gadolinium-based contrast agents (GBCAs) is considered the inciting factor. Patients may have a history of GBCA exposure; however, an exposure to nuclear magnetic resonance contrast is not required for diagnosis. Rarely, GBCA-induced systemic fibrosis has been reported with normal renal function. (Note that joint contractures, skin gadolinium deposition, and abnormal skin immunoreactivity have been described in a single patient with *normal renal function* and multiple exposures to gadolinium-based contrast.)

SYNONYMS

NSF
Nephrogenic fibrosing dermopathy
Nephrogenic systemic fibrosis
Gadolinium-associated systemic fibrosis

ICD-10CM CODES	
L90.8	Other atrophic disorders of skin
M34	Diseases of the musculoskeletal system and connective tissue
M34.0	Progressive systemic sclerosis
M34.2	Systemic sclerosis induced by drug and chemical
M34.9	Systemic sclerosis, unspecified
M35.5	Multifocal fibrosclerosis
T50.8X5	Adverse effect of diagnostic agents
T50.891A	Toxic effect of unspecified metal, accidental (unintentional)
T56.94XA	Toxic effect of unspecified metal, undetermined, initial encounter

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Annually, the incidence is 0.0043 cases per dialysis-dependent patient. In one retrospective study of patients referred to an academic nephrology subspecialty group, 18% were diagnosed with the disorder.

PREDOMINANT SEX AND AGE: The male:female ratio is 1:1. Ages have ranged from 8 to 87 yrs. Nationally, reported cases are U.S. > Europe > Asia, Australia, Canada, and South America.

RISK FACTORS:

- Renal insufficiency
- Exposure to gadolinium-based contrast
- Hepatorenal syndrome
- Infection
- Inflammatory condition
- Acidemia
- Erythropoietin-stimulating agents
- Hypercoagulability

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Onset of systemic fibrosis is variable, ranging from 24 hours to yrs after contrast exposure. Patients may complain of skin pain, paresthesia, or pruritus. The major clinicopathological criteria are patterned plaques, "cobblestoning," hardened/tethered/indurated skin, *peau d'orange* texturing, and joint contractures. Minor clinicopathologic criteria include puckered skin, linear banding, superficial plaques or patches, dermal papules, and scleral plaques. Patients have also presented with edema, hyperpigmentation, papules, and subcutaneous nodules. There can be fibrosis of several organs—skeletal muscle or visceral. *Gadolinium exposure is not requisite for the diagnosis.*

ETIOLOGY

- Gadolinium retention in the tissues may be the trigger; this element has been found in some skin lesions. Bone marrow–derived circulating fibrocytes constitute a large degree of cellularity in affected organs. Bone marrow retains a "memory" of prior gadolinium exposure that may explain why repeated exposures correlate with more severe forms of the disease.
- Brands with low reported numbers of contrast-induced fibrosis (e.g., "high thermodynamic stability" agent, gadoteridol) still demonstrate gadolinium deposition in the skin with a concomitant expression of profibrotic cytokines, such as transforming growth factor-β. Table E1 summarizes gadolinium agents and risk of NSF.
- The length of time on the market for any GBCA correlates with the respective number of NSF cases reported to the U.S. Food & Drug Administration Adverse Event Reporting System.
- Gadolinium tissue retention may lead to the liberation of substances that recruit circulating fibrocytes to affected areas. There is usually involvement of the limbs, with sparing of the upper trunk, neck, and face. In an experimental model, skin concentrations of monocyte chemoattractant protein-1 and C-C ligand 19 are elevated. Coadministration with an antagonist of monocyte chemoattractant protein-1 receptor reduced gross lesions, dermal cellularity, and extracellular matrix accumulation.
- See Fig. E1.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Amyloidosis
- β_2-microglobulin amyloidosis
- Borreliosis
- Calciphylaxis
- Carcinoid syndrome
- Chronic graft vs. host disease
- Dermatofibrosarcoma protuberans
- Environmental sclerotic disease (silica, polyvinyl chloride, toxic "Spanish" oil, eosinophilia-myalgia syndrome, bleomycin)
- Fibroblastic rheumatism
- Lipodermatosclerosis
- Melorheostosis
- Early cellulitis
- Early panniculitis
- Eosinophilic fasciitis
- Phenylketonuria
- Porphyria cutanea tarda
- Pretibial myxedema
- Progeria
- Scleroderma
- Systemic sclerosis/morphea

WORKUP

Skin biopsy

LABORATORY TESTS

Antibodies for nuclei, Scl 70, centromeres, phospholipids, and cardiolipin are negative. Skin biopsy demonstrates hypercellular fibrosis ± mucin, and immunostaining for CD34, procollagen type I, CD68, and Factor XIIIa may be positive. Important clinicopathologic findings on histologic examination are increased dermal cellularity, CD34-positive cells ("tram-tracked" around elastic fibers), thick and thin collagen bundles, preserved elastic fibers, septal involvement, and osseous metaplasia (Fig. E2).

TABLE E1 Gadolinium Agents and NSF

HIGHEST RISK OF NSF	Gadodiamide (Omniscan); Gadopentetate dimeglumine (Magnevist); Gadoversetamide (OptiMARK)
Contraindicated: CKD 4 and 5 (GFR <30 ml/min) – including if on dialysis; acute renal insufficiency; pregnancy; neonates	
Used with caution: CKD 3 (GFR = 30-60 ml/min) – at least 7 days between injections; children <1 yr	
Lactating women: Stop breastfeeding for 24 hrs and discard milk	
eGFR and clinical assessment mandatory before administration; never given in doses >0.1 mmol/kg	
INTERMEDIATE RISK OF NSF	Gadobenate dimeglumine (MultiHance); Gadofosveset trisodium (Vasovist); Gadoxetate disodium (Primovist)
LOWEST RISK OF NSF	Gadobutrol (Gadovist); Gadoterate meglumine (Dotarem); Gadoteridol (ProHance)
Used with caution: CKD 4 and 5 (GFR <30 ml/min) – at least 7 days between injections	
Pregnant women: Can be used to give essential information	
Lactating women: Discussion required whether to discard breast milk for 24 hours after injection	
eGFR testing not mandatory	

CKD, Chronic kidney disease; *eGFR,* estimated glomerular filtration rate; *GFR,* glomerular filtration rate. From Grant LA: *Grainger & Allison's diagnostic radiology essentials*, ed 2, Philadelphia, 2019, Elsevier.

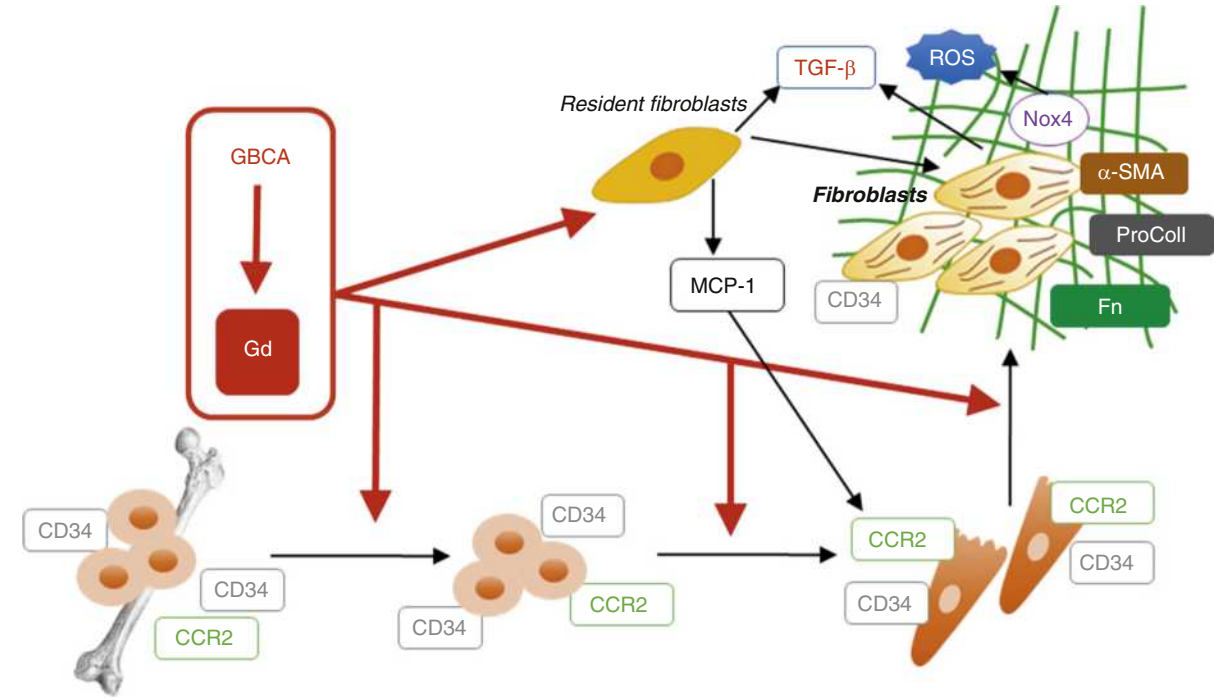

FIG. E1 The molecular mechanisms of gadolinium-based contrast agent-induced fibrosis. Gadolinium-based contrast agents (GBCA) may liberate gadolinium (Gd) as part of the initial disease process—this has yet to be experimentally confirmed. Bone marrow-derived cells are now known to infiltrate skin lesions. These myeloid cells express the C-C chemokine receptor 2 (CCR2) and migrate into affected areas in response to monocyte chemoattractant protein-1 (MCP-1). NADPH oxidase 4- (Nox4-) derived reactive oxygen species (ROS) generation is part of the disease process. Transforming growth factor-β (TGF-β) has been detected in patients and in preclinical models. Activated fibroblasts express α-smooth muscle actin (α-SMA). Other markers of myeloid-derived fibrocytes are procollagen I (ProColl) and CD34. The process culminates in the deposition of extracellular matrix. Fibronectin (Fn) is a marker of this scarring.

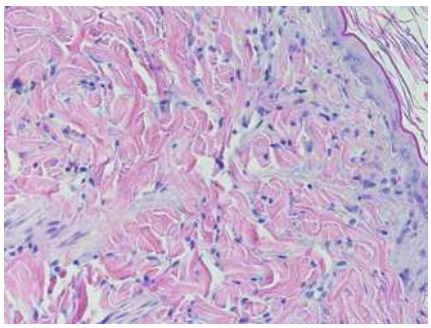

FIG. E2 Skin from a rodent model of gadolinium-induced systemic fibrosis. In addition to many of the protein markers of fibrosis, this model replicates the human condition in terms of increased cellularity of the dermis, thick and thin collagen bundles surrounded by clefts, and epidermal changes. Hematoxylin and eosin stain 20×.

IMAGING STUDIES

None

Rx TREATMENT

No single treatment has yet been found that is universally effective.

REFERRAL

Dermatology, physical therapy

PEARLS & CONSIDERATIONS

COMMENTS

In December 2013, Tomonori Kanda, MD, PhD, and colleagues reported that gadolinium-based contrast agent exposure correlated with high signal intensities in the dentate nucleus and globus pallidus even in the setting of normal renal function. Robert McDonald, MD, PhD, confirmed that these regions of the brain contained gadolinium (using mass spectroscopy with autopsy specimens). By July 2017, the European Medicines Agency restricted the use of a class of gadolinium-based contrast agents (i.e., those with a linear polyaminocarboxylate structure). Later, the U.S. Food & Drug Administration mandated a new class warning (i.e., *for all classes*) for all gadolinium-based contrast agents warning providers and consumers of long-term retention of the metal in various tissues. Provided the dire consequences of nephrogenic systemic fibrosis, and the lack of understanding of its pathophysiology, there is concern that adverse reactions reported in those with normal renal function may be a continuum with the well-established disease that occurs in renal impairment.

PREVENTION

Minimize patient exposure to GBCAs where feasible. Gadolinium contrast used in MRI must be avoided in patients with eGFRs <30 ml/min/1.73m^2. The severity of the disorder correlates with the total quantity of contrast an individual has been exposed to in a lifetime. Hence, the type and quantity of GBCAs should be clearly documented for all exposed individuals, particularly in the presence of liver and/or kidney disease. *There is no evidence that immediate hemodialysis can prevent contrast-induced systemic fibrosis.* Regular chronic dialysis three times weekly in end-stage renal disease has not been shown to prevent MRI contrast-induced systemic fibrosis. It has been well-documented that GBCAs rapidly disseminate into nondialyzable compartments, and the thresholds where disease is triggered remains unknown. Once in such a dialysis-protected space, the back diffusion of gadolinium is either absent or slow.

GBCAs are nephrotoxic. Acute kidney injury is a recognized adverse reaction listed in the respective prescribing information sheet of each GBCA. Preclinical models have shown that GBCAs are far from inert and may precipitate into gadolinium-rich nanostructures in kidney and skin.

BASIC INFORMATION

DEFINITION

Nephrotic syndrome is characterized by heavy proteinuria (usually defined as >3.5 g/24 hr), hypoalbuminemia, hyperlipidemia, lipiduria, and edema. Nephrotic-range proteinuria involves urine protein excretion of >3.5 g/24 hours without other features of the nephrotic syndrome. Proteinuria, primarily in the form of albuminuria, can have many causes that share a common mechanism of glomerular injury , the most common being diabetes, focal segmental glomerulosclerosis, membranous nephropathy, minimal change disease, and amyloidosis. Though less common, disorders that are classically categorized under the nephritic syndrome also may lead to nephrotic-range proteinuria.

ICD-10CM CODES

N04.9	Nephrotic syndrome with unspecified morphologic changes
N04.0	Nephrotic syndrome with minor glomerular abnormality
N04.1	Nephrotic syndrome with focal and segmental glomerular lesions
N04.2	Nephrotic syndrome with diffuse membranous glomerulonephritis
N04.3	Nephrotic syndrome with diffuse mesangial proliferative glomerulonephritis
N04.4	Nephrotic syndrome with diffuse endocapillary proliferative glomerulonephritis
N04.5	Nephrotic syndrome with diffuse mesangiocapillary glomerulonephritis
N04.6	Nephrotic syndrome with dense deposit disease
N04.7	Nephrotic syndrome with diffuse crescentic glomerulonephritis
N04.8	Nephrotic syndrome with other morphologic changes

EPIDEMIOLOGY & DEMOGRAPHICS

- Among children (especially <6 yr of age), the most common causes of nephrotic syndrome are:
  1. Minimal change disease (MCD) (75% of pediatric cases)
  2. Focal and segmental glomerulosclerosis (FSGS) (7% to 20% of cases)
- Among adults, diabetes is the most common cause of nephrotic syndrome. FSGS is the most common *primary* (nonsystemic) cause of nephrotic-range proteinuria. Membranous nephropathy is the second most common primary cause of nephrotic syndrome. FSGS is more common in persons of African ancestry, while membranous nephropathy is seen more commonly in Caucasians.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients usually present with severe lower extremity, periorbital edema, and weight gain.
- Ascites and anasarca may occur.
- Hypercoagulability is a potential clinical manifestation.
- Patients are at higher risk for infections due to urinary immunoglobulin loss.

ETIOLOGY

Glomerular diseases can be thought of as diseases affecting one of five elements that comprise the renal corpuscle: endothelium, basement membrane, podocyte, mesangium, or parietal epithelium. In general, disorders that involve the endothelium and/or mesangial compartment activate inflammatory mediators. Disorders that exclusively affect the basement membrane or podocyte generally have a noninflammatory pathology. Compromised structural integrity of the glomerulus leads to a breach of the normal mechanisms that prevent abnormal filtration, leading to proteinuria as primarily albuminuria, the hallmark of glomerular disease.

Traditionally, the clinical correlate to this pathological schema has been a subdivision of patients into those with a nephrotic versus nephritic presentation. Disorders that are considered "nephritic" have subnephrotic proteinuria and low glomerular filtration rates. "Nephrotic" disorders have greater proteinuria and more robust glomerular filtration rates. While generally true, this schema may cause diagnostic confusion because nephritic disease may present with nephrotic-range proteinuria, *especially earlier in the disease course before glomerular filtration is substantially reduced*. It is better to categorize these diseases with a noninflammatory urine sediment (proteinuria alone with no casts or cellular elements) versus an inflammatory sediment (i.e., RBC casts and/or dysmorphic RBCs in conjunction with proteinuria).

Fig. 1 details this breakdown. In this chapter, we focus on primary diseases that present with a noninflammatory sediment (namely, minimal change disease, focal segmental glomerulosclerosis, membranous nephropathy, and amyloidosis) and on primary disorders with inflammatory sediment often with nephrotic-range proteinuria, membranoproliferative glomerulonephritis (MPGN). The evaluation of "nephritic syndrome" is noted by worsening GFR in the setting of proteinuria and hematuria as detailed elsewhere. Important points regarding the most common etiologies of nephrotic syndrome are detailed in the following text (Table 1).

- MCD has a bland urine sediment with abrupt onset of disease and abrupt remission. Proteinuria may exceed 20 grams daily. Nonsteroidal antiinflammatory drug (NSAID) use, lithium use, viral infections, and lymphomas are associated with secondary forms of MCD.
- FSGS, primary or secondary: Primary FSGS denotes an idiopathic cause that typically manifests with heavy proteinuria and nephrotic syndrome and requires immunosuppressive therapy. FSGS is more prevalent

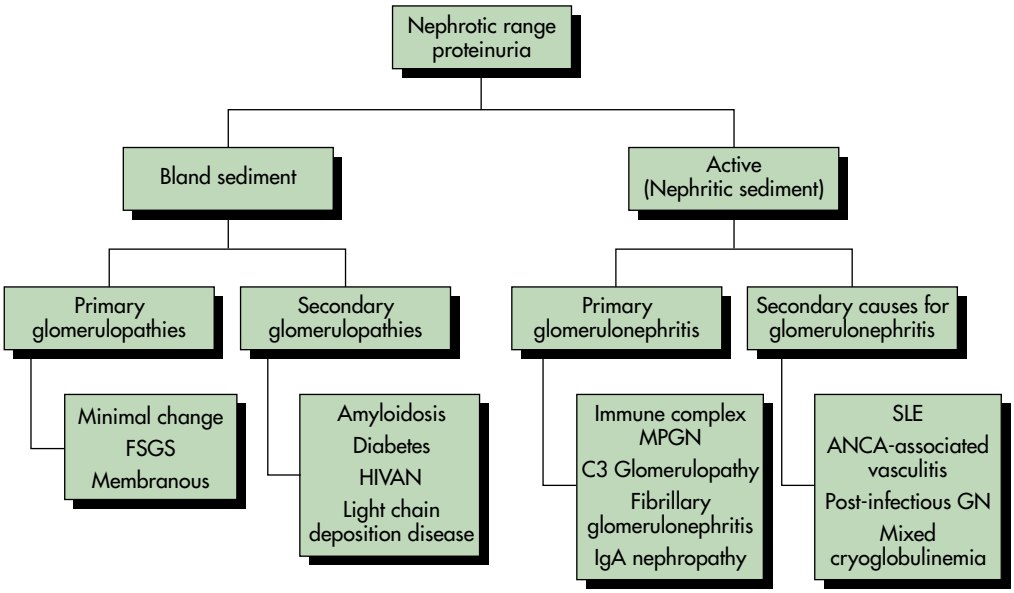

FIG. 1 An approach to nephrotic-range proteinuria. *ANCA,* Antineutrophil cytoplasmic antibody; *C3,* complement component 3; *FSGS,* focal and segmental glomerulosclerosis; *GN,* glomerulonephritis; *IgA,* immunoglobulin A; *HIVAN,* HIV-associated nephropathy; *MPGN,* membranoproliferative glomerulonephritis; *SLE,* systemic lupus erythematosus.

TABLE 1 Important Clinical, Serological, and Pathological Features of Selected Diseases Causing Nephrotic Syndrome

Disease	Important Clinical Features	Serological Features	Pathological Features
Minimal change disease	Rapid onset with heavy proteinuria and rapid remission with therapy. True steroid resistance is rare and should prompt repeat biopsy to rule out FSGS.	Complements are normal.	Light microscopy (LM) shows completely normal kidney architecture. Immunofluorescence microscopy: Normal. Electron microscopy (EM): Diffuse podocyte effacement.
Primary FSGS	Often heavier proteinuria and low serum albumin and edema. Tip lesion subtype and collapsing FSGS often have more explosive onset. Sediment usually bland, but RBCs can be seen. Usually no cellular casts.	Complements are normal.	LM: Only one glomerulus need show features of FSGS to make diagnosis. Immunofluorescence microscopy: Often devoid of immunoglobulin, although IgM can be seen. EM: Often has diffuse podocyte effacement.
Secondary FSGS	Proteinuria is often subnephrotic, or if nephrotic, serum albumin levels are maintained. Minimal edema.	HIV and parvovirus infection can cause phenotype identical to idiopathic collapsing FSGS.	LM: Often shows evidence of glomerulomegaly. EM: Foot process effacement is less diffuse.
Primary membranous nephropathy	Often seen in older Caucasian patients. More likely than other forms of nephrotic syndrome to be associated with thrombotic complications Sediment: Bland. RBCs can be found, although RBC casts are usually found.	Serum antiphospholipase A2 receptor antibodies are found in 70% of patients with idiopathic primary membranous nephropathy. Antineutral endopeptidase antibodies are found in a minority of others.	LM: Characterized by thickening of the GBM; "spikes" can be seen on silver stain. Immunofluorescence microscopy: C3 and IgG noted in granular pattern. Newer techniques stain for antiphospholipase A2 receptor antibody in situ. EM: Associated with subepithelial deposits.
Secondary membranous nephropathy	Associated with **malignancy,** lupus, syphilis, hepatitis B and C, medications (gold, captopril, penicillamine, etc.).	Notable for the absence of antiphospholipase A2 antibodies. ANA, hepatitis B, HCV serologies are helpful. RPR can be sent in context of appropriate history.	Morphology is exactly the same except when examined by EM. On high power, one sees both subendothelial and mesangial deposits in addition to classic subepithelial deposits.
Amyloidosis	Often found with massive proteinuria. Kidney size is enlarged. Bland sediment.	UPEP, SPEP, serum free light chains may be positive. The UPEP will show glomerular proteinuria, which can help differentiate from myeloma kidney.	LM: Often notable for nodular pattern. Diagnosis can be made by staining using Congo red or thioflavin T. Immunofluorescence microscopy: Antibody use can differentiate AA from AL amyloid. EM: Shows characteristic random 10-nm fibrils.
Diabetes	Often associated with nephrotic-range proteinuria in the setting of retinopathy. Kidney sizes are preserved.	No specific serologic tests are positive.	LM: Nodular pattern often seen, thickened GBM.
MPGN	Often associated with nephrotic-range proteinuria with a "nephritic" sediment. RBC casts often seen along with dysmorphic RBC.	C3 and C4 are often low in immune complex MPGN. Immune complex GN warrants checking SPEP and UPEP, as gammopathy is associated with MPGN. Hepatitis B, HCV, ANA, and cryoglobulins are also warranted. C3 alone is low in dense deposit disease and C3 glomerulonephritis, which may prompt specific tests for complement dysregulation.	The key point here is to look at the IF. If immunofluorescence shows both immunoglobulin and complement deposition, the diagnosis is immune complex MGPN. If only complement, the diagnosis is most likely C3 glomerulopathy (either dense deposit disease or C3 glomerulonephritis).

ANA, Anti-nuclear antibody; *C3,* complement component 3; *FSGS,* focal and segmental glomerulosclerosis; *GBM,* glomerular basement membrane; *GN,* glomerulonephritis; *HCV,* hepatitis C virus; *Ig,* immunoglobulin; *MPGN,* membranoproliferative glomerulonephritis; *RBC,* red blood cell; *RPR,* rapid plasma reagin; *SPEP,* serum protein electrophoresis; *UPEP,* urine protein electrophoresis.

in persons of African ancestry. Secondary FSGS is caused by a known etiology, including heroin use, sickle cell disease, scarring of any kind from prior injury, obesity, low nephron mass, HIV, etc. Most cases of secondary FSGS are associated with lower levels of proteinuria (often subnephrotic), higher albumin levels, and less significant edema (e.g., HIV-associated nephropathy is an important exception in that it is associated with heavy proteinuria and rapid progression when untreated). Distinguishing between primary and secondary FSGS is important for therapy (see following text). It should be noted that prior kidney injury can produce morphological features of FSGS over time. Essentially, proteinuric disease attributable to secondary FSGS can be seen in any progressive kidney disease and generally portends worse outcomes.

- Membranous nephropathy may be primary or secondary. Primary membranous nephropathy is due to in situ deposition of antibodies directed against a glomerular antigen. In 70% or more cases, the epitope is identified as phospholipase A2 receptor. A second, less-common epitope is thrombospondin type-1 domain-containing 7A (THSD7A). Proteinuria in membranous nephropathy may be massive. Secondary membranous nephropathy is often due to infection (e.g., hepatitis B, malaria, schistosomiasis, syphilis), autoimmune disease (e.g., systemic lupus erythematosus [SLE]), medications (e.g., D-penicillamine, gold), and malignancies. Distinguishing between the two subtypes is important for management (see following text).
- Amyloidosis is frequently due to overproduction of immunoglobulin light chains (AL amyloid) or a chronic inflammatory state (AA amyloid). Kidney size is often enlarged, and proteinuria may be massive. Congo red staining of amyloid often establishes the diagnosis.
- Diabetic nephropathy is often characterized by slowly progressive proteinuria with retinopathy and preserved kidney size. The correlation between retinopathy, proteinuria, and diabetic nephropathy is very strong in type 1 diabetic patients, and kidney biopsies

are usually not done. The relationship is less strong in type 2 diabetes, and absence of retinopathy does not preclude a diagnosis of diabetic nephropathy.

- Membranoproliferative glomerulonephritis (MPGN) is usually from immune complex deposition with complement, or activation of the alternate complement system without immune complex formation (e.g., C3 glomerulopathy). Prior classification schema involving types 1, 2, and 3 MGPN are now deemed obsolete after better understanding of the pathophysiology of this morphology. Common immune complex causes are from infections (e.g., hepatitis C), autoimmune disorders (e.g., SLE), disorders of the alternative complement pathway (C3 glomerulopathy), or dysproteinemias (e.g., monoclonal gammopathies). Distinguishing between these possibilities guides therapy. The urine is associated with heavy proteinuria. Urinary sediment often contains dysmorphic erythrocytes and erythrocyte casts, and is also associated with heavy proteinuria.

TABLE 2 Important Definitions in Dealing with Treatment of Primary Nephrotic Syndrome

	Adults	Children
Definition		
Complete Remission	Reduction in proteinuria to <0.3 g/24 hours	<4 mg/m^2/hr on at least 3 occasions within 7 days and serum albumin >3.5 g/dl
Partial Remission	Reduction in proteinuria between 0.3 g/24 hours and 3.5 g daily with ≥50% decrease in proteinuria from baseline	Disappearance of edema, increase in serum albumin >3.5 g/dl, and persistent proteinuria >4 mg mg/m^2/hr or >100 mg mg/m^2/hr
Relapse*	Increase in proteinuria to >3.5 g daily after one mo of complete or partial remission	Urine dipstick 3+ or proteinuria >40 mg/m^2/hr occurring on 3 days within 1 wk
Steroid Dependent*	Two consecutive relapses occurring during therapy or within 14 days of completing therapy	Two relapses of proteinuria within 14 days after stopping or during alternate-day steroid therapy
Steroid Resistant*	Persistence of proteinuria without significant reduction despite prednisone therapy at 1 mg/kg for 16 wk	Persistence of proteinuria despite prednisone therapy at 60 mg/m^2 for 4 wk

*These definitions only truly apply to diseases such as minimal change disease and FSGS.
(Adapted from Cattran DC et al: Cyclosporine in idiopathic glomerular disease associated with the nephrotic syndrome: workshop recommendations, *Kidney Int* 72(12):1429-1447, 2007, and *KDIGO clinical practice guidelines for glomerulonephritis*.)

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other states that present with edema (CHF, cirrhosis, protein-losing enteropathy, severe malnutrition)
- Glomerulonephritis from disorders commonly associated with inflammatory urinary sediment and glomerular inflammation
- Mimickers of glomerulonephritis (thrombotic microangiopathy due to malignant HTN, preeclampsia, or antiphospholipid syndrome)

WORKUP

- Evaluation includes determining the rate of change of serum creatinine, quantification of proteinuria by 24-hr collection, and urinary sediment examination.
- Abnormalities in any of the above tests should prompt nephrology consultation.
- Serologic testing may include urine and serum electrophoresis, HIV, hepatitis B surface antigen, hepatitis C virus (HCV) antibody, and antinuclear antibody (ANA). As urinary sediment examination is not 100% sensitive in ruling out an inflammatory process, C3 and C4 can be checked, as complement levels are often low in many inflammatory glomerulonephritides and often low in MPGN. Low complement levels may change the nature of the differential diagnosis before kidney biopsy. Depending on practice patterns, these tests are used selectively before or (in some cases) after biopsy to better define an etiology.
- A newer serological test available to clinicians commercially is an antiphospholipase A2 receptor antibody (anti-PLA2r) titer. Positive titers are seen in primary membranous nephropathy but less commonly in secondary membranous nephropathy. With treatment, patients may go into an immunologic remission (decreasing titers) prior to a clinical remission based on urine proteinuria. Thus, monitoring titers during the course of treatment may help guide treatment duration and limit toxic side effects of therapy.
- Patients should have a kidney ultrasound to document organ size and the presence of two kidneys prior to biopsy.

Rx TREATMENT

NON-IMMUNOSUPPRESSIVE THERAPY

- Control of proteinuria is key to mitigating risk of progression. Almost all trials of non-diabetic chronic kidney disease demonstrate that reducing proteinuria improves renal survival. Angiotensin-converting enzyme inhibitors or angiotensin II receptor blockers should be used at maximally tolerated doses, except in MCD, where proteinuria reduction is often seen rapidly with treatment. Dual angiotensin-converting enzyme inhibitor and angiotensin II receptor blocker therapy is generally not recommended due to increased risks of hyperkalemia and elevating the serum creatinine. Non-dihydropyridine calcium channel blockers (verapamil and diltiazem) can be used to in lieu of angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers when the latter are contraindicated.
- For proteinuria >1 gram per day, target blood pressure is <125/75 mm Hg.
- With the exception of MCD, patients with nephrotic-range proteinuria and hyperlipidemia should be treated with HMG CoA synthetase inhibitors (statins).
- Although some patients with nephrotic syndrome are hypercoagulable (particularly patients with membranous nephropathy), the role of prophylactic anticoagulation is not well-defined and controversial. For patients with membranous nephropathy and serum albumin levels <2.0 g/dl, anticoagulation should be considered if bleeding risk is low.
- Low sodium diet (<2 gram per day) with diuretics.
- Diuretic resistance is common due to gut wall edema and hypoalbuminemia. More bioavailable diuretics (bumetanide, torsemide) may increase urine output better than furosemide, along with thiazide diuretics.
- To prevent "diuretic braking," most loop diuretics should be dosed at least on a twice-daily basis.

IMMUNOSUPPRESSIVE THERAPY

Important terms in dealing with the management of nephrotic-range proteinuria due to primary glomerular diseases are listed in Table 2. First-line therapies for each disease are highlighted in the following.

- MCD: First-line therapy in adults is prednisone (1 mg/kg per day to a maximum of 80 mg per day) for a minimum of 4 wk and maximum of 16 wk. Steroids are tapered over 6 mo for favorable responses. Second-line options include cyclophosphamide and/or calcineurin inhibitors. Newer, randomized, controlled trial data from children (not adults) have suggested an impressive record for rituximab in steroid-dependent patients unable to be weaned off steroids without inducing relapse and frequently relapsing MCD. Consequently, rituximab may become a reasonable option for patients who do not respond to conventional therapy.
- FSGS: Primary FSGS is often treated with high-dose prednisone (maximum, 80 mg daily in adults) that is tapered over 6 mo. Alternative regimens include low-dose prednisone with cyclosporine. Mycophenolate mofetil (MMF) has also been used with success in primary FSGS. A new, randomized, controlled trial

aims to examine whether a novel agent that blocks endothelin-1 and angiotensin II receptors (RE-021) has efficacy in treatment of primary FSGS. Treatment of secondary FSGS is based on arresting the underlying cause and nonspecific therapy with blockade of the renin-angiotensin-aldosterone system, BP control, weight loss, and dietary protein restriction. Immunosuppression is avoided.

- Membranous nephropathy: Acceptable treatment options include alternating months of cyclophosphamide and steroids, calcineurin inhibitors with low dose steroids or without steroids, and rituximab. Given conflicting reports from the U.S. and Europe, exogenous ACTH can be viewed as a last-line resort when all other options have failed, but it is not the standard of care. Therapy for secondary membranous nephropathy is directed at treating the underlying cause (malignancy, SLE, etc.).
- Treatment of amyloidosis, diabetes, and immune complex MPGN is directed at the underlying disorder. In rapidly progressive HCV-related MPGN, immunosuppressive therapy with rituximab or glucocorticoids and cyclophosphamide can be administered during HCV therapy.
- More recently, reclassification of MPGN has shown that some forms of MPGN are caused by alternative complement cascade activation (C3 glomerulonephritis). There is renewed interest in using medications (e.g., eculizumab) that target the end product of this pathway (membrane attack complex). Prior non-targeted approaches (e.g., steroids) for MPGN have been largely unsuccessful except in selected pediatric cases.

REFERRAL

Nephrology consultation is recommended for all cases of nephrotic syndrome.

PEARLS & CONSIDERATIONS

- Albuminuria generally implies glomerular disease is present. The urine protein electrophoresis defines the type(s) of proteins excreted: albumin, immunoglobulins, and tubular.
- Massive proteinuria (>20 g per day) is rarely seen with inflammatory diseases and generally indicates MCD, FSGS, membranous nephropathy, or amyloidosis.
- Partial remissions and steroid resistance are rarely seen in primary minimal change disease. These circumstances mandate reexamination of the cause of nephrotic syndrome because repeat biopsy in these cases often demonstrates FSGS.
- Quantification of proteinuria should be done with a 24-hr urine collection with evaluation of urinary creatinine excretion to document validity of the collection. Spot collections have not been validated for heavy proteinuria or patients with rapidly changing creatinine values. A "spot" urine protein-to-creatinine ratio taken from the 24-hr collection defines the relationship between spot and "true" collections to monitor response to therapy.
- Most noninflammatory processes progress slowly. If a sediment without red blood cell casts is detected with a rapidly increasing serum creatinine and heavy proteinuria, the differential is relatively narrow:
  1. MCD with acute tubular necrosis or acute interstitial nephritis, as occurs with nonsteroidal anti-inflammatory drug administration
  2. Any form of nephrotic syndrome associated with acute tubular necrosis from hypovolemia
  3. Bilateral renal vein thrombosis superimposed on nephrotic syndrome
  4. Myeloma cast nephropathy
  5. Collapsing FSGS

BASIC INFORMATION

DEFINITION

Neuroblastomas are tumors of postganglionic sympathetic neurons that typically originate in the adrenal medulla or the sympathetic chain/ganglion. They are often present at birth, but not diagnosed until later, when the child shows symptoms of the disease. They are almost exclusively a disease of childhood.

ICD-10CM CODE

C74.90 Malignant neoplasm of unspecified part of unspecified adrenal gland

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 8% to 10% of all solid tumors of childhood (third most common childhood cancer, after leukemia and brain tumors); 10.54 cases per 1 million per yr in children younger than 15 yr.

PREDOMINANT SEX: Male/female ratio of 1:1.3

PEAK AGE: Early childhood. Mean age of onset is 18 mo; 33% onset by 1 yr; 75% onset by 5 yr; 97% by 10 yr. In rare cases, neuroblastoma can be discovered by fetal ultrasound.

GENETICS: Although the majority of neuroblastomas are sporadic, in 1% to 2% of cases, there are exceptions associated with familial neuroblastoma. Germline deletion at the 1p36 or 11q14-23 locus is associated with familial neuroblastoma, and the same deletions are found somatically in sporadic neuroblastomas. Amplification of *N-MYC* gene (2p23), which encodes a nuclear transcription factor in the basic helix-loop-helix leucine zipper family, is present. The prevalence of N-myc amplification is about 22% in neuroblastoma and is associated with advanced-stage disease and poor prognosis. ALK germline mutation is also seen in familial neuroblastoma (14% in the high-risk group, 6% in the intermediate-risk group, and 8% in the low-risk group). The ATRX mutation is seen almost exclusively in older children with high-risk neuroblastoma and is associated with telomere lengthening (alternative lengthening of telomeres).

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The most common presentation of neuroblastoma is an abdominal mass. Neuroblastomas can arise anywhere along the sympathetic nervous system. The most common primary site is the adrenal gland (40%), followed by a mass in the abdomen (25%), thorax (15%), neck (5%), and pelvis (5%). In approximately 1% of cases a primary site cannot be identified. Metastatic neuroblastoma are seen in 70% to 80% of children. The most common site for metastasis are regional lymph node involvement, bone marrow, cortical bone, orbits, liver, and skin at time of presentation
- Spinal cord/paraspinal: Can present with localized back pain, signs of cord compression—paraplegia or stool/urine retention, abdominal mass, pain, or constipation
- Horner syndrome (ptosis, miosis, anhidrosis) if it involves the stellate ganglion
- Thoracic: Difficulty breathing, dysphagia, infections, chronic cough
- Secondary symptoms referable to metastatic disease: Fatigue, chronic pain (typically bony pain), pancytopenia, periorbital ecchymosis, proptosis, anorexia, weight loss, unexplained fever, multiple subcutaneous bluish nodules, irritability
- Progressive cerebellar ataxia
- Paraneoplastic syndromes: Opsoclonus-myoclonus syndrome (OMS) is described as "dancing eyes, dancing feet," which manifest as myoclonic jerks and chaotic eye movements in all directions. This may be initial presentation before tumor diagnosis; present in 1% to 3% of patients with neuroblastoma; of all patients with opsoclonus-myoclonus, approximately 50% have an underlying neuroblastoma. Patients who present with this syndrome must be evaluated for neuroblastoma; when present, the neuroblastoma often has more favorable biologic features. The tumors may secrete a vasoactive intestinal peptide that, on rare occasions, causes a watery diarrhea. Another cause of diarrhea is protein-losing enteropathy secondary to intestinal lymphangiectasia

DIAGNOSIS

WORKUP

- Careful general physical examination to look for mass
- Biopsy and resection of tumor when possible

LABORATORY TESTS

- Complete blood count, coagulation studies, erythrocyte sedimentation rate
- 24-hour urine for catecholamines: Homovanillic acid (HVA) and vanillylmandelic acid (VMA) are secreted by up to 90% of tumors
- Nonspecific serum markers such as neuron-specific enolase, lactate dehydrogenase (marker for increased cell turnover), and ferritin
- Bone marrow biopsy and aspirate: Karyotype, DNA index, *N-MYC* copy number
- Minimum criteria for diagnosis are based on international consensus panel and require one of the following: (1) unequivocal pathologic diagnosis made from tumor tissue or (2) combination of bone marrow aspirate with unequivocal tumor cells and increased levels of serum or urinary catecholamine metabolites, as described above
- Genetic/biologic variables have been studied in children with neuroblastoma, in particular the histology, aneuploidy of tumor DNA, and amplification of the *N-MYC* oncogene within tumor tissue, because treatment decisions may be based on these factors
  1. Hyperdiploid DNA is associated with favorable prognosis, especially in infants.
  2. *N-MYC* amplification is associated with poor prognosis, regardless of patient age, likely due to association with deletion of chromosome 1p and gain of chromosome 17q.
  3. Other biologic factors studied include profile of GABAergic receptors, expression of neurotrophin receptors, level of telomerase RNA and serum ferritin and lactate dehydrogenase.

IMAGING STUDIES

- Chest x-ray, abdominal plain film, skeletal survey, abdominal and renal/bladder ultrasound
- CT scan or MRI of the chest and abdomen (Figs. E1, E2, E3) to provide information about regional lymph nodes, vessel invasion, and distant metastases
- Body scan with ^{131}I-MIBG (meta-iodobenzylguanidine), which is taken up by neuroblasts and is sensitive to metastases in the bone and soft tissue (64% of patients will develop thyroid dysfunction)
- Bone scan with Tc-99 MDP to visualize lytic bone lesions and metastases

Staging (staged according to the International Neuroblastoma Staging System [INSS])

I	Localized tumor with complete gross excision with or without microscopic residual disease
II_A	Localized tumor with incomplete gross resection; ipsilateral lymph nodes negative
II_B	Localized tumor with or without incomplete gross resection; ipsilateral lymph nodes positive
III	Unresectable unilateral tumor infiltrating across midline, with or without lymph node involvement
IV	Metastases to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs, except as defined for stage IVs.
IV_S	Localized primary tumor with dissemination limited to skin, liver, or bone marrow; limited to infants <18 mo of age

DIFFERENTIAL DIAGNOSIS

- Other small, round, blue-cell childhood tumors, such as lymphoma, rhabdomyosarcoma, soft tissue sarcoma, and primitive neuroectodermal tumors (PNETs).
- Wilms tumor. Table E1 describes features distinguishing between Wilms tumor and neuroblastoma. Opsoclonus myoclonus may occur with other tumors such as hepatoblastoma, infections (e.g., Coxsackie virus, Lyme disease, rickettsia, HIV), ingestions (phenytoin, amitriptyline, diazepam, lithium), toxic exposures, and metabolic derangements (biotin-responsive multiple carboxylase deficiency).

TREATMENT

- Overall, treatment will be determined by several factors, including age at diagnosis,

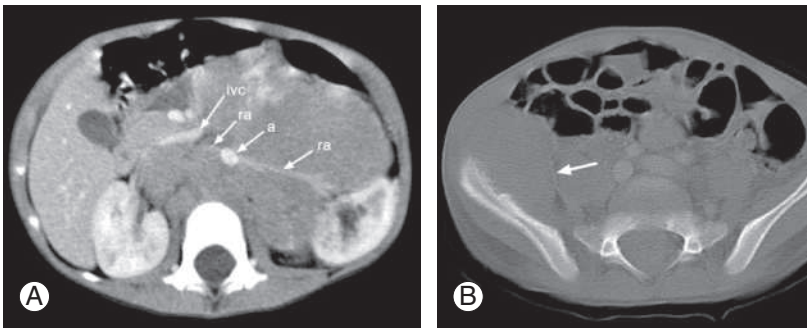

FIG. E1 Abdominal neuroblastoma: CECT. (A) A prevertebral tumor extends across the midline in the retroperitoneum, displaces and encases the aorta (a) anteriorly and encases the renal arteries (ra). The inferior vena cava (ivc), partially encased, is displaced anterolaterally and compressed by the tumor and nodes. The mass extends to both the renal hili. **(B)** Infiltrative lesion to the right iliac bone with a large soft tissue component *(arrow)* that projects inwards as a space-occupying mass. (From Grant LA: *Grainger & Allison's diagnostic radiology essentials*, ed 2, Philadelphia, 2019, Elsevier.)

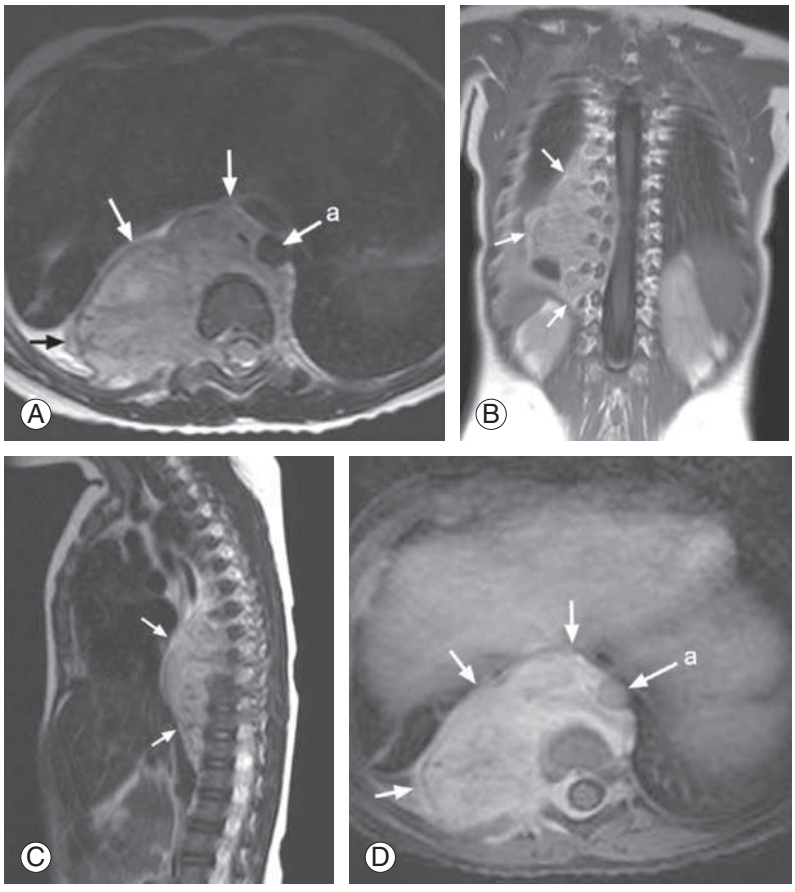

FIG. E2 Thoracic neuroblastoma with intraspinal extension: MRI. (A, B) Axial and coronal T1WI + Gad. **(C)** Sagittal T1WI + Gad. **(D)** Axial T2WI. Large posterior mediastinal mass *(arrows)* with anterior and lateral displacement of the aorta (a), which is encased. There is massive tumor extension into the canal through the right neural foramina to displace the spinal cord to the left. Extension into the right paraspinal soft tissues is evident. (From Grant LA: *Grainger & Allison's diagnostic radiology essentials,* ed 2, Philadelphia, 2019, Elsevier.)

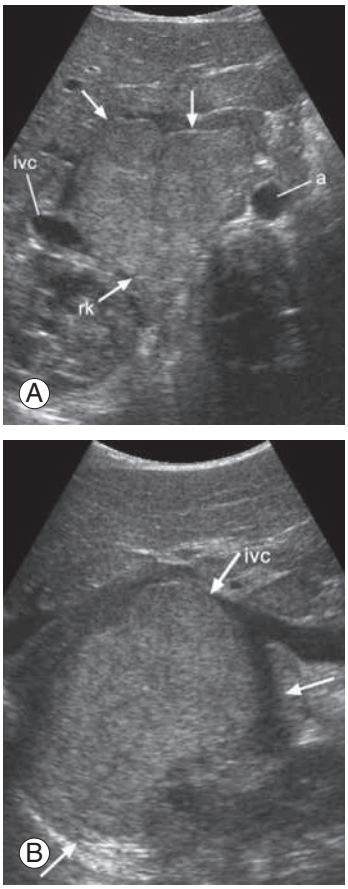

FIG. E3 Abdominal neuroblastoma. (A) Transverse US through the right abdomen shows a solid paraspinal mass *(arrows)* anterior to the right kidney *(rk).* The aorta *(a)* and inferior vena cava *(ivc)* are displaced by the mass. **(B)** Longitudinal image through the right flank shows the mass *(lower arrows)* and the stretched inferior vena cava *(ivc).* (From Grant LA: *Grainger & Allison's diagnostic radiology essentials,* ed 2, Philadelphia, 2019, Elsevier.)

stage of disease, site of primary tumor and metastases, tumor histology, and quantitative DNA content of the tumor.
- Surgery: Particularly for low-risk tumors.
- Radiation therapy may be tried for unresectable tumors or tumors that are not responsive to chemotherapy.
- Multiagent chemotherapy is mainstay of treatment (e.g., cisplatinum, etoposide, doxorubicin, cyclophosphamide).
- Autologous bone marrow transplantation following aggressive chemotherapy for stage IV disease or patients who are at highest risk based on presence of disseminated disease or unfavorable markers such as *N-MYC* amplification.
- Novel therapies include immunotherapy using monoclonal antibodies and vaccines that attempt to initiate an immune reaction against the disease and targeting of tumor cells with drugs that induce apoptosis or have antiangiogenic effect. Immunotherapy with ch14.18, a monoclonal antibody against the tumor-associated disialoganglioside (GD2), has activity against neuroblastoma. Recent trials have shown that immunotherapy with ch14.18, GM-CSF, and interleukin-2 is associated with a significantly improved outcome as compared with standard therapy in patients with high-risk neuroblastoma. Children with opsoclonus/myoclonus syndrome may benefit from immunologic treatment (e.g., prednisone, pulse dexamethasone, IVIG, plasma exchange, cyclophosphamide, or mycophenolate).

DISPOSITION

- Overall survival is >40%. Children under the age of 1 yr have a cure rate as high as 90%.
- Approximately 70% of patients with neuroblastoma have metastases at diagnoses.
- Prognosis is related to age at time of diagnosis, clinical stage, and regional lymph node involvement. Children with localized disease and infants <1 yr at diagnosis and favorable disease characteristics have better

TABLE E1 Features Distinguishing Between Wilms Tumor and Neuroblastoma

Feature	Wilms Tumor	Neuroblastoma
Age	2-3 yr	<2 yr
Origin	Kidney	Retroperitoneal neural crest
Renal mass effect	Intrinsic mass effect	External compression
Laterality	10% bilateral	Almost always
Calcification	<15%	85%-95%
Vessel involvement	Renal vein invasion in 5%-10%	Frequent encasement

From Weissleder R et al: *Primer of diagnostic imaging,* ed 5, St Louis, 2011, Mosby.

prognosis, whereas poorer prognosis is noted in older children with stage IV disease (20% survival compared with >95% in stage I), age >1 yr at diagnosis, increased number of *N-MYC* copies, adrenal tumor, and chronic 1p deletion.

- Children treated for neuroblastoma may be at risk for second malignancies, including renal cell carcinoma, myelodysplastic syndrome, and leukemia, especially after treatment of high-risk neuroblastoma with chemotherapy. Other long-term effects include thyroid dysfunction (^{131}I-MIBG), cardiac toxicity (doxorubicin), and hearing loss (cisplatin).

REFERRAL

To multidisciplinary oncology team with experience in treating cancers of childhood and adolescence

PEARLS & CONSIDERATIONS

- Neuroblastoma is predominantly a tumor of early childhood that originates in the sites where the sympathetic nervous system tissue is present.
- Symptoms occur due to tumor mass or bone pain from metastases.
- Children can present with classic paraneoplastic neurologic symptoms, including cerebellar ataxia and opsoclonus myoclonus.
- Recent trials have shown a very high rate of survival among patients with intermediate-risk neuroblastoma with biologically based treatment assignment involving a substantially reduced duration of chemotherapy and reduced doses of chemotherapeutic agents as compared with regimens used in earlier trials. These data provide support for further reduction in chemotherapy with more refined risk stratifications.
- Despite recent advances, 50% to 60% of patients with high-risk neuroblastoma have a relapse, and currently no salvage treatment regimens are known to be curative.

BASIC INFORMATION

DEFINITION

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders,* 5th edition (DSM-5), includes delirium and major and mild neurocognitive disorders, as well as their subtypes, under the grouping *neurocognitive disorders*.

The core features of neurocognitive disorders (NCDs) are deficits in cognitive function. The cognitive dysfunction is acquired rather than developmental and thus represents a decline from a previously attained level of functioning. The NCDs are subtyped according to known or presumed etiologic/pathologic entities underlying the decline. The subtypes may be distinguished by clinical characteristics such as time course, physical examination, and cognitive domains affected. It is possible for more than one NCD to be identified in a given patient at a given time.

In major and mild NCDs, the cognitive deficits are present in one or more cognitive domains. The initial evidence is based on concern brought forth by the patient, a knowledgeable informant, or the clinician and is often supported by performance on objective standardized assessments such as neuropsychological testing. In major NCDs, the deficits interfere with independence in everyday activity, whereas in minor NCDs, the impairment is more modest and does not interfere with capacity for independence in everyday activity.

In the DSM-5, *delirium* (acute encephalopathy) is subsumed under the category *neurocognitive disorders*. Although it shares the core feature of acquired deficit in cognitive function, it is discussed as a distinct entity from major and minor neurocognitive disorders and is discussed separately in this text. The DSM-IV term *dementia* (chronic encephalopathy) is subsumed under the entity *major neurocognitive disorder* in the DSM-5, and the DSM-IV term *amnestic disorder* and its subtypes are subsumed under the category *major neurocognitive disorder due to another medical condition* in the DSM-5.

Some of the more commonly seen NCDs include major or mild NCD due to Alzheimer disease, major or mild vascular NCD, and major or mild NCD due to Lewy body disease.

ICD-10CM CODES	
F02.80	Major or mild neurocognitive disorder, without behavior disturbance
F02.81	Major or mild neurocognitive disorder, with behavior disturbance
DSM-5 CODES	
294.10	Major or mild neurocognitive disorder, without behavior disturbance
294.11	Major or mild neurocognitive disorder, with behavior disturbance

EPIDEMIOLOGY & DEMOGRAPHICS

The prevalence varies depending on the etiology of the neurocognitive disorder and age of the patient. Among patients >60 yr, the prevalence tends to increase sharply for the most common neurocognitive disorders. Overall prevalence estimates for major NCDs are approximately 1% to 2% at 65 yr old and as high as 30% at 85 yr. Mild NCD prevalence is variable, ranging from 2% to 10% at age 65 and 5% to 25% at age 85. The strongest risk factor for major and mild NCD is age. Female gender is associated with a higher prevalence in major and mild NCD due to Alzheimer disease.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Neurocognitive domains that are affected in NCDs include:

- Complex attention, including sustained attention, divided attention, selective attention, and processing speed
- Executive functioning, such as planning, decision making, working memory, and mental flexibility
- Learning and memory, including immediate memory, recent memory
- Language expression and reception, including word recall, grammar, and syntax
- Perceptual motor skills, including visual construction, praxis, and gnosis
- Social cognition, including recognition of emotions

Associated physical findings, time course of illness, and response to treatment depend on etiology of the NCD. Mood disturbance, psychosis, and behavior disturbances are recognized as common neuropsychiatric symptoms associated with NCDs. Mood symptoms are common early in the course of NCDs due to Alzheimer disease, NCD with Lewy bodies, and vascular NCD. Psychoses, including delusions and paranoia, may present across the spectrum of illness but are more common in mild to moderate stages of NCD with Lewy bodies and in moderate to severe stages of NCD due to Alzheimer disease. Psychosis, agitation, and other behavioral disturbances lead to increased rate of hospitalization, early admission to assisted living environments or nursing homes, and increased level of caregiver depression and distress. Apathy manifests early in the course of NCDs and is the most common neuropsychiatric symptom of NCD due to Alzheimer disease across the spectrum of the disease.

ASSOCIATED SIGNS AND SYMPTOMS BY ETIOLOGY

(For each etiology, the criteria are met for major or mild neurocognitive disorder.)

- **Major or mild neurocognitive disorder due to Alzheimer disease:** Insidious onset and gradual progression, occasionally with brief plateaus. Impairment in memory, learning, and executive function are prominent early in the disease. In moderate to severe disease, language deficits manifest and problematic behaviors, including agitation, combativeness, and psychosis, may arise. Apathy, agitation, and psychosis are often more distressing to caregivers than the cognitive deficits.
- **Major or mild frontotemporal neurocognitive disorder:** Behavior and language variants are characterized by progressive development of personality changes, behavior changes including disinhibition, and/or language impairment. Patients with behavior variant may present with impaired insight, socially inappropriate behaviors, apathy, hyperorality, or compulsive behaviors. Learning and memory dysfunction may be spared in the early stages. It now is recognized that the *C9orf72* gene can lead to hereditary frontotemporal degeneration (FTD) with amyotrophic lateral sclerosis. Symptoms of FTD usually come before motor symptoms.
- **Major or mild neurocognitive disorder with Lewy bodies:** Cognitive decline occurs prior to or within 1 yr of the onset of parkinsonism motor symptoms. Recurrent, well-formed, and detailed visual hallucinations and fluctuating cognition that can resemble delirium are core features. Mood disturbances, autonomic dysfunction, and REM sleep disorder are suggestive of this diagnosis. Patients with major or mild neurocognitive disorder with Lewy bodies are sensitive to neuroleptics, which can often worsen symptoms and should be used with caution. Individuals with major or mild neurocognitive disorder with Lewy bodies are typically functionally more impaired than would be expected for their cognitive deficits because of the motor and autonomic impairments. They can present with multifocal myoclonus and visual hallucinations.
- **Major or mild neurocognitive disorder due to Parkinson disease:** Parkinson disease onset precedes the onset of major neurocognitive decline by at least 1 yr. Apathy, depression, hallucinations, and REM sleep disorder are suggestive of this diagnosis. The atypical parkinsonian syndrome progressive supranuclear palsy presents with early postural instability and retropulsion, supranuclear gaze palsy, and early cognitive impairment with depression, apathy, and anxiety. Corticobasal degeneration is a progressive asymmetric movement disorder with attentional deficits, slow processing speed, extreme rigidity, aphasia, apraxia, and alien-limb syndrome.
- **Major or mild vascular neurocognitive disorder:** The onset of cognitive decline is temporally related to one or more cerebrovascular events. The diagnosis is supported by neuroimaging evidence of parenchymal injury, including large vessel infarcts or hemorrhages, two or more lacunar infarcts outside the brainstem, or confluent white matter lesions attributed to cerebrovascular disease. Patients typically present with decline in processing speed, complex attention, and executive dysfunction. Stepwise and/or fluctuating decline is described. Prominent depression, apathy, and personality changes are common.
- **Major or mild neurocognitive disorder due to traumatic brain injury (TBI):** This NCD presents immediately after the occurrence of or can be attributed to a traumatic brain injury that causes loss of consciousness, posttraumatic amnesia, disorientation, or neurologic signs such as seizure or hemiparesis. Cognitive presentation may be variable but may include difficulty with complex attention, executive dysfunction, or deficits in learning and memory. Associated findings include disturbances in emotional function and personality change. The features of major or mild NCD due to TBI vary by age of patient and specifics

of the injury as well as other factors, such as premorbid functioning of the patient. Chronic traumatic encephalopathy can be seen in individuals susceptible to multiple concussive episodes of the kind that may occur playing certain sports or working in a dangerous job.

- **Substance/medication-induced major or mild neurocognitive disorder:** An NCD that persists beyond the duration of intoxication and acute withdrawal from a substance. NCD due to alcohol frequently manifests with memory, learning, and executive impairments. Wernicke syndrome is an acute neurologic disorder caused by thiamine deficiency manifesting with a clinic triad of encephalopathy, oculomotor dysfunction, and gait ataxia. Korsakoff syndrome is a late manifestation of Wernicke syndrome manifesting with dense anterograde amnesia and confabulation. MRI may show mammillary body or medial dorsal thalamic nucleus atrophy. Major or mild NCD may be induced by medication or combinations of medications, including those with sedating and pain-ameliorating properties and those with anticholinergic properties. Particular attention should be paid to review of medications in any patient with major or mild NCD, especially those in the geriatric population.
- **Major or mild neurocognitive disorder due to HIV infection:** Neurocognitive deficits may show a subcortical pattern with prominent impairment of executive function with slowed processing speed and difficulty with learning new information.
- **Major or mild neurocognitive disorder due to Prion disease:** Neurocognitive deficits occur rapidly, typically over 6 mo as occurs in Creutzfeldt-Jakob disease. In some variants, prominent psychiatric symptoms such as depression and anxiety may occur prior to neurocognitive deficits. Ataxia, myoclonus, chorea, and a prominent startle reflex are typically present.
- **Major or mild neurocognitive disorder due to Huntington disease:** Early prominent changes in processing speed, organization, and planning rather than learning and memory are common. Behavior changes, changes in mood, anxiety, obsessive-compulsive symptoms, irritability, and apathy often precede motor symptoms.
- **Major or mild neurocognitive disorder due to another medical condition:** Many medical conditions can cause NCDs. Examples include structural brain lesions such as primary or secondary brain tumors, subdural hematomas or those seen in normal pressure hydrocephalus, hypoxia, infectious causes, endocrine conditions, immune disorders, and metabolic conditions. The temporal association between the onset or exacerbation of the medical condition and the development of the cognitive deficit supports the diagnosis.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Etiology is assessed by a detailed history from the patient, family members, or other informants, complete physical examination, and ancillary tests, including neuropsychological testing and imaging studies.

LABORATORY TESTS & IMAGING STUDIES

- Detailed physical examination and neuropsychological testing and neuroimaging are indicated. In some cases, serology and lab testing, including B12 and thyroid-stimulating hormone (TSH) levels, are useful or diagnostic. Biomarkers and genetic screening tests are diagnostic in some cases. Particular attention should be paid to rule out underlying medical causes of the major or mild NCD.
- Alzheimer disease: Detailed history and physical examination including neuropsychological testing often points to the diagnosis. MRI may show hippocampal and temporoparietal cortical atrophy. PET scan may reveal hypometabolism in temporoparietal regions. Cerebrospinal fluid biomarkers include elevated total tau and phosphorylated tau levels with reduced amyloid beta-42. Amyloid PET scanning may have diagnostic value. *APOE* testing may detect APOE4, a risk factor for development of Alzheimer disease. For early onset, autosomal dominant inheritance mutation in *APP, PSEN1,* or *PSEN2* may be detected.
- Frontotemporal disorder: In cases with early-onset behavior or language disorders, an MRI or CT scan may show atrophy in frontal lobes and/or corresponding parts of anterior or inferior temporal lobes either bilaterally or asymmetrically. Functional imaging may show hypoperfusion in the corresponding regions. In familial cases, genetic mutations in genes encoding the microtubule-associated protein tau and the granulin gene may confirm the diagnosis.
- Lewy body disease: Sleep study may help to confirm a diagnosis of REM sleep behavior disorder. Nuclear medicine testing including single photon emission computed tomography (SPECT) or PET may show low striatal dopamine transporter uptake.
- Parkinson disease: Abnormal dopamine transporter scans are supportive of the diagnosis.
- Vascular disorder: Neurologic assessment often reveals a history of stroke or transient ischemic attack (TIA). MRI or CT scan may show significant parenchymal injury attributed to cerebrovascular disease.
- TBI: May be associated with abnormal CT or MRI scan showing petechial hemorrhages, diffuse axonal injury, subdural or subarachnoid hemorrhage, or evidence of contusion.
- Prion disease: May be suspected in patients with appropriate clinical presentation, including rapidly progressive course. MRI may show gray matter hyperintensities in the subcortical region, particularly in the putamen and head of caudate nuclei. Electroencephalogram (EEG) reveals periodic synchronous biphasic or triphasic sharp waves complexes. Cerebrospinal fluid (CSF) biomarkers including 14-3-3, tau, S100 protein, or neuron-specific enolase are suggestive, though not diagnostic.
- Huntington disease: Genetic testing for trinucleotide cytosine-adenine-guanine (CAG) repeat expansion in the gene that encodes Huntington protein on chromosome 4 is diagnostic.

Rx TREATMENT

- Initial treatment is directed to the underlying etiology.
- Treatment of memory disturbance may be indicated in some causes of major or mild NCDs, such as those caused by Alzheimer disease.
- Treatment both acutely and chronically is often supportive and aimed at ameliorating behavior and other neuropsychiatric disturbances that may be present.
- Behavioral treatments should be considered first line for most behavior manifestations, although management of agitation in dementia is notoriously difficult. Acetylcholinesterase inhibitors and memantine can be prescribed for cognitive enhancement, and nighttime agitation can be treated with trazodone. If agitation persists, citalopram can be tried with attention paid to potential prolongation of the QTc, or another selective serotonin reuptake inhibitor (SSRI) can be tried. Treatment with low doses of atypical antipsychotics such as quetiapine can be effective if Lewy body dementia has been ruled out after appropriate consideration of and disclosure of potential adverse effects including QTc prolongation, torsade des pointes, extrapyramidal symptoms/neuroleptic malignant syndrome (NMS) and stroke, and risk vs. benefit has been calculated. Recently, Nuedexta (dextromethorphan/quinidine) has been tried with preliminary benefit for agitation as well as pathological affect. Pharmacologic treatments for behavior disturbance have a limited role in improving overall quality of life for most causes of major or minor NCD, although they may have short-term efficacy in acute circumstances.
- Pharmacologic and cognitive behavior treatment may be helpful for associated psychiatric symptoms such as mood disorders, psychosis, and anxiety.
- Patient safety, including risks associated with driving, wandering, and cooking, should be addressed early in the course of the illness.
- Family education and support may help reduce the need for a skilled nursing facility and reduce caregiver stress and burnout.
- Cognitive rehabilitation to promote recovery may be helpful.
- Supervised living may ensure appropriate long-term care in late stages of progressive illness.

BASIC INFORMATION

DEFINITION

Neurofibromatosis (NF) is an autosomal-dominant disorder affecting bone, the nervous system, soft tissue, and skin. There are three major subtypes of NF disorders: NF type 1 (NF1), NF type 2 (NF2), and schwannomatosis (SWN). SWN has only recently been recognized as a distinct disorder; currently very little is known about it.

SYNONYMS

NF1: von Recklinghausen disease, peripheral NF
NF2: Bilateral acoustic neurofibromatosis, central NF

ICD-10CM CODES

Q85.00 Neurofibromatosis, unspecified
Q85.01 Neurofibromatosis, type 1
Q85.02 Neurofibromatosis, type 2

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence of NF1 (one case/3000 live births), NF2 (one case/25,000 live births).
- Prevalence of NF1 (one case/5000 persons), NF2 (one case/210,000 persons).
- NF1 and NF2 are autosomal dominant; approximately 50% of cases have no family history.
- The two disorders affect approximately 100,000 people in the U.S.
- Affects males and females equally.
- NF1 may be associated with optic gliomas, astrocytomas, spinal neurofibromas, pheochromocytomas, and chronic myeloid leukemia.
- NF2 may be associated with meningiomas, spinal schwannomas, and cataracts.
- For SWN, the incidence is one per 30,000 persons, and the disease is mostly sporadic in nature.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Common features of NF1 include:
  1. Café-au-lait macules (100% of children by age 2 yr)
     a. Hyperpigmented skin lesions (Fig. 1) occurring anywhere on the body except the face, palms, and soles
     b. Appear early in life and increase in size and number during puberty
     c. Are focal or diffuse
  2. Axillary and inguinal freckling (70%)
  3. Multiple neurofibromas (Fig. 2) can be soft or firm; three subtypes:
     a. Cutaneous: Circumscribed, not specific for NF1
     b. Subcutaneous: Circumscribed, not specific for NF1
     c. Plexiform: Noncircumscribed, thick and irregular; can cause disfigurement of supportive structures and specific for NF1
  4. Lisch nodule (small hamartoma of the iris) found in >90% of adult cases
  5. Visual defects possibly related to optic gliomas (2% to 5%)
  6. Neurodevelopment problems such as learning disability and mental retardation (30% to 40%)
  7. Skeletal disorders, including long bone dysplasia, pseudoarthrosis, scoliosis, short stature, and decreased bone mineral density
- Common features of NF2 include:
  1. Hearing loss and tinnitus related to bilateral acoustic neuromas (>90% of adults)
  2. Cataracts (81%)
  3. Headache (may be due to intracranial meningiomas, which are present in 80% of patients)
  4. Unsteady gait
  5. Cutaneous and subcutaneous neurofibromas but fewer than in NF1
  6. Café-au-lait macules (1%) (Fig. 3)
- Common features of SWN include painful multiple schwannomas of the spinal (74%), peripheral (89%), or cranial nerves *except* the vestibular nerve (9%)

ETIOLOGY

- NF1 is caused by DNA mutations located on the long arm of chromosome 17 responsible for encoding the protein neurofibromin.
- NF2 is caused by DNA mutations located in the middle of the long arm of chromosome 22 responsible for encoding the protein merlin, which is a potent inhibitor of glioma growth.
- Both proteins are speculated to act as tumor suppressors.
- The etiology of SWN remains unclear; however, most cases are attributed to mutations on chromosome 22, which inactivate two distinct tumor-suppressor genes.

DIAGNOSIS

- NF1 is diagnosed if the person has two or more of the following features:
  1. Six or more café-au-lait macules >5 mm in prepubertal patients and >15 mm in postpubertal patients
  2. Two or more neurofibromas of any type or one plexiform neurofibroma
  3. Axillary or inguinal freckling
  4. Optic glioma
  5. Two or more Lisch nodules (iris hamartomas)
  6. Sphenoid wing dysplasia or cortical thinning of long bones, with or without pseudoarthrosis
  7. A first-degree relative (parent, sibling, or child) with NF1 based on the previous criteria
- NF2 is diagnosed if the person has either of the following two criteria:
  1. Bilateral eighth nerve masses seen by appropriate imaging studies (e.g., CT, MRI)
  2. A first-degree relative with NF2 and either a unilateral eighth nerve mass or two of the following: Neurofibroma, meningioma, glioma, schwannoma, or juvenile posterior subcapsular lenticular opacity

FIG. 1 Systemic features of Neurofibromatosis type 1. A, Discrete neurofibromas. **B,** Nodular plexiform neurofibroma of the eyelid. **C,** Elephantiasis nervosa. **D,** Cafe-au-lait spots. (Courtesy S. Kumar Puri; From Kanski JJ, Bowling B: *Clinical ophthalmology, a systematic approach,* ed 7, Philadelphia, 2010, WB Saunders.)

FIG. 2 Multiple neurofibromas are present in this individual. (From Callen JP et al: *Dermatological signs of systemic disease,* ed 5, Philadelphia, 2017, Elsevier.)

FIG. 3 A café-au-lait spot and multiple freckles (Crowe sign) in the axillary vault is seen in this patient with neurofibromatosis. (From Callen JP et al: *Dermatological signs of systemic disease,* ed 5, Philadelphia, 2017, Elsevier.)

- SWN is diagnosed in an individual >30 yr having either of the following two criteria:
  1. Two nonintradermal schwannomas, no vestibular tumor found on MRI scan, no NF2 mutation
  2. One nonvestibular schwannoma and a first-degree relative fitting the above criteria

DIFFERENTIAL DIAGNOSIS

- Abdominal NF
- Myxoid lipoma
- Nodular fasciitis
- Fibrous histiocytoma
- Segmental NF

WORKUP

The diagnosis of NF is usually self-evident. Workup is dictated by clinical symptoms in NF1 and usually includes MRI evaluation of the head and spine in NF2 and SWN. In fact, if NF2 is suspected but no vestibular nerve schwannomas are found, the diagnosis points to SWN.

LABORATORY TESTS

- Genetic testing is possible in individuals who desire prenatal diagnosis for NF1. There is no single standard test and multiple tests are required. Results can only tell if an individual is affected but cannot predict the severity of the disease due to variable expression.
- In NF2, linkage analysis testing provides a >99% certainty the individual has NF2.

IMAGING STUDIES

- MRI with gadolinium is the imaging study of choice in both NF1 and NF2 patients. MRI increases detection of optic gliomas, tumors of the spine, acoustic neuromas, and "bright spots" believed to represent hamartomas.
- MRI of the spine is recommended in all patients diagnosed with NF2 to exclude intramedullary tumors.

OTHER TESTS

- Wood's lamp examination may be useful in patients with very pale skin for visualizing café-au-lait spots.
- Slit-lamp examination is recommended for children >6 yr to confirm the presence of Lisch nodules and subcapsular opacity.

Rx TREATMENT

Treatment is directed primarily at symptoms and complications of NF1 and NF2. As for SWN, resection should be reserved for tumors that are symptomatic or threaten to cause spinal cord compression.

NONPHARMACOLOGIC THERAPY

- Counseling addressing prognosis and genetic, psychological, and social issues.
- Hearing testing and speech pathology evaluation.

ACUTE GENERAL Rx

- Surgery is usually not done on skin tumors unless cosmetically requested or if suspicion of malignant transformation exists.
- Surgery may be indicated for spinal or cranial neurofibromas, gliomas, or meningiomas.
- Acoustic neuromas can be treated by surgical excision.

CHRONIC Rx

- Radiation may be indicated in optic nerve gliomas and patients whose central nervous system tumors show radiographic progression.
- Stereotactic radiosurgery with a gamma knife may be an alternative approach to surgery for acoustic neuromas.
- Bevacizumab continues to be studied as a treatment option for NF2 meningiomas (which express vascular endothelial growth factor [VEGF]).

DISPOSITION

- Prognosis varies according to the severity of involvement.
- There is no cure for NF.

REFERRAL

A multidisciplinary team of consultants is needed in patients with NF, including neurosurgeon, otolaryngologist, dermatologist, neurologist, audiologist, speech pathologist, geneticist, and neuropsychologist.

PEARLS & CONSIDERATIONS

- Friedrich Daniel von Recklinghausen first reported his cases in 1882, although there had been similar accounts dating back to the 1600s.
- A high SPRED1 mutation detection rate has been identified in NF1 mutation-negative families with an autosomal dominant phenotype of café-au-lait macules with or without freckling and no other NF1 features.

Neuroleptic Malignant Syndrome

BASIC INFORMATION

DEFINITION

Neuroleptic malignant syndrome (NMS) is a disorder characterized by hyperthermia, muscular rigidity, autonomic dysfunction, and depressed/fluctuating levels of arousal that evolve over 24 to 72 hr. This occurs as an idiosyncratic adverse reaction to medications that affect the central dopaminergic system, usually D2 receptors blockade.

SYNONYM

NMS

ICD-10CM CODE
G21.0 Malignant neuroleptic syndrome

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 0.02% to 0.2% annual incidence in psychiatric population
PREDOMINANT SEX: More than two thirds of patients are male.
PREDOMINANT AGE: Young and middle-aged adults
PREDISPOSING FACTORS: History of intake of dopamine antagonists, e.g., antipsychotics

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Syndrome typically begins abruptly while the patient is taking therapeutic (not toxic) dosages of neuroleptics and reaches maximum severity within 72 hr
- Severe muscle rigidity (hypertonia, cogwheeling, or "lead pipe" rigidity)
- Hyperthermia (38.6° to 42.3° C [101.48° to 108.14° F], usually <40° C [104° F])
- Autonomic symptoms: Diaphoresis, dysphagia, sialorrhea, skin pallor, urinary incontinence
- Tachycardia, tachypnea
- Labile blood pressure (hypertension or postural hypotension)
- Agitation, catatonia, fluctuating consciousness, obtundation

ETIOLOGY

- Exact etiology is unknown, but it has been suggested that sudden and marked dopamine receptor blockade in nigrostriatal, hypothalamic, mesolimbic, and mesocortical pathways leads to clinical manifestations seen in NMS.
- Neuroleptic drugs have different potencies for inducing NMS:
  1. Typical neuroleptics:
     a. High potency: Haloperidol
     b. Medium potency: Chlorpromazine, fluphenazine
     c. Low potency: Levomepromazine, loxapine
  2. Atypical neuroleptics:
     a. Low potency: Risperidone, olanzapine, clozapine, quetiapine

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Infectious: Encephalitis, meningitis, brain abscess, rabies, tetanus, sepsis
- Endocrine: Pheochromocytoma, thyrotoxicosis
- Toxic: Substances of abuse (ecstasy, phencyclidine), heavy metals (lead, arsenic), lithium, salicylates
- Pharmacologic: Serotonin syndrome, malignant hyperthermia, drug withdrawal, or overdose
- Environmental: Heatstroke, spider envenomation
- Neuropsychiatric: Catatonia, acute psychosis with agitation, status epilepticus
- Table E1 summarizes the differential diagnosis of neuroleptic malignant syndrome

WORKUP

A careful and thorough drug history should be obtained. There is a significant overlap in

TABLE E1 Differential Diagnosis of Neuroleptic Malignant Syndrome

Disease*	Pathologic Mechanism	Differentiating Factor	Time Course	Treatment
Neuroleptic malignant syndrome	Impaired thermoregulation in hypothalamus and basal ganglia due to relative lack of dopamine activity	Antipsychotic medication use, muscle rigidity	Gradual, progresses over several days	Stop offending medication Hydration Active cooling Intravenous benzodiazepines to relax muscles and control agitation Neuromuscular blockade (nondepolarizing agents) Controversial Bromocriptine or amantadine Dantrolene
Serotonin syndrome	Excess serotonin and dopamine levels in central nervous system	Medications (usually a combination) that increase serotonin levels (e.g., SSRIs, MAOIs, dextromethorphan, lithium, meperidine, tramadol, tryptophan); muscle rigidity	Usually rapid after introduction of new medication or increase in dose; can be gradual	Stop offending medication Hydration Active cooling Cyproheptadine
Heat stroke	Environmental heat stress	Environmental exposure history; muscle rigidity rare	Rapid or gradual	Hydration Active cooling
Malignant hyperthermia	Genetic instability of sarcoplasmic reticulum, causing massive calcium release after administration of triggering medication	Occurs after administration of inhalational anesthetic or succinylcholine; muscle rigidity	Sudden, provoked by administration of anesthetic	Stop anesthetic Hydration Active cooling Dantrolene

*Other clinical entities to consider in the diagnosis of these conditions include Addison syndrome, central nervous system infection, delirium tremens, hypocalcemia, hypoglycemia, hyponatremia, intracranial hemorrhage, lethal catatonia, poisoning (e.g., amphetamines, anticholinergics, cocaine, nicotine, salicylates, sympathomimetics, strychnine, theophylline), sedative-hypnotic drug withdrawal, sepsis, status epilepticus (including nonconvulsive status), tetanus, thalamic infarct, thyroid storm, and psychotic agitation.
MAOIs, Monoamine oxidase inhibitors; *SSRIs,* selective serotonin reuptake inhibitors.
From Marx JA et al: *Rosen's emergency medicine,* ed 8, Philadelphia, 2014, WB Saunders.

the features of NMS and serotonin syndrome. The major difference is the presence of hyperreflexia and myoclonus with serotonin syndrome.

LABORATORY TESTS

- Elevated creatine phosphokinase (CPK) (sensitivity 0.71)
- Urinary myoglobin
- Leukocytosis, usually 10,000 to 40,000/mm3
- Electrolytes and renal function
- Blood gases
- Drug levels

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Stop all neuroleptic drugs and reinstitute any recently discontinued dopaminergic agonists.
- Remember that metoclopramide is also an antidopaminergic drug that must be discontinued and avoided.
- Respiratory and nutritional support as required.
- Careful fluid balance monitoring with adequate hydration (intravenous in severe cases).
- Active cooling (cooling blanket and antipyretics).
- Skilled nursing care is necessary to prevent decubitus ulcers in bed-confined patients.

ACUTE GENERAL Rx

- Bromocriptine, a dopamine receptor agonist, is the mainstay of therapy for patients with NMS. Initial doses of 2.5 to 10 mg are given IV q8h and are increased by 5 mg/day until clinical improvement is seen. The drug should be continued for at least 10 days after the syndrome has been controlled and then tapered slowly.
- Dantrolene, which blocks calcium efflux from the sarcoplasmic reticulum of skeletal muscles, inhibits the excessive muscle contractions that generate myoglobinemia. Initially, patients can be given 0.25 mg/kg IV q6 to 12h, followed by a maintenance dose up to 3 mg/kg/day. After 2 to 3 days, patients may be given the drug orally (25 to 600 mg/day in divided doses). Oral dantrolene therapy (50 to 600 mg/day) may be continued for several days afterward.
- Amantadine, an N-Methyl-D-aspartate (NMDA) receptor antagonist with possible dopaminergic properties, can be administered orally at doses of 100 to 200 mg PO bid for moderate to severe cases. As an adjunctive treatment, it has been shown to reduce mortality in comparison to supportive therapy alone.
- IV benzodiazepines (e.g., diazepam 2 to 10 mg, with total daily dose of 10 to 60 mg) to relax muscles and control agitation.
- Electroconvulsive therapy with neuromuscular blockage may be beneficial in pharmacologically refractory cases. Succinylcholine should not be used because it may cause hyperkalemia and cardiac arrhythmias in patients with rhabdomyolysis or dysautonomia.

CHRONIC Rx

- Respiratory care, nutritional support, and physical therapy may be required in more severe cases.
- Appropriate therapy would be required in patients with persistent neuropsychiatric sequelae of NMS (e.g., antidepressants for depression, cognitive behavioral therapy for cognitive deficits, rehabilitation for contractures).

DISPOSITION

- Mortality rate is currently 5% to 10% despite therapeutic measures. Serious sequelae may occur in a further 20%. Complete recovery occurs in >70% of patients.
- Rhabdomyolysis is the most common complication. Other complications include acute kidney injury, respiratory failure, pneumonia, and sepsis.
- Causes of death include cardiac arrhythmias, myocardial infarction, renal failure secondary to rhabdomyolysis, seizures, pulmonary edema, and bronchopneumonia.
- Factors adversely affecting mortality are increased age, acute respiratory failure, renal failure, and core temperature >104° F (40° C).
- Patients should be monitored closely for future complications of pharmacologic therapy.

REFERRAL

If the patient's condition is critical, it is preferable to treat the patient in a medical/neurologic ICU.

PEARLS & CONSIDERATIONS

COMMENTS

- Early detection and diagnosis lead to a more favorable outcome. Refer to recent consensus diagnostic criteria as a guide. Treatment is a medical emergency.
- Sudden withdrawal from dopaminergic agents (such as those used in Parkinson disease) may lead to "levodopa withdrawal syndrome" that presents with similar clinical manifestations.
- Patients with dementia with Lewy bodies have increased susceptibility to neuroleptic malignant syndrome.

BASIC INFORMATION

DEFINITION

Neuropathic pain is not itself a disease but rather a symptom that is associated with multiple different diseases. Thus, it is not enough to define its presence without searching for a cause. It is defined as the sensation derived from the abnormal discharges of impaired or injured neural structures in either the peripheral or central nervous system. Descriptors include:

- Hyperesthesia: Heightened sensitivity to nonpainful stimuli (e.g., light touch)
- Hyperalgesia: Heightened sensitivity to painful stimuli (e.g., pinprick), or reduced threshold to feel pain
- Allodynia: Pain provoked by a stimulus that is not normally painful

SYNONYM

Neuralgia

ICD-10CM CODES

B02.29	Postherpetic neuralgia
G50.0	Trigeminal neuralgia
G58.0	Intercostal neuropathy
G58.7	Mononeuritis multiplex
G58.8	Other specified mononeuropathies
G58.9	Mononeuropathy, unspecified
G61.9	Inflammatory polyneuropathy, unspecified
G62.0	Drug-induced polyneuropathy
G62.1	Alcoholic polyneuropathy
G62.9	Polyneuropathy, unspecified
G63.2	Diabetic polyneuropathy
G63.5	Polyneuropathy in systemic connective tissue disease
G63.8	Polyneuropathy in other diseases classified elsewhere
M79.2	Neuralgia and neuritis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- Estimates of the prevalence of neuropathic pain in the general population range from 1.6% to 8.2%
- Demographics vary widely depending on etiology, for example:
  1. Postherpetic neuralgia: Affects elderly, pain seen in almost 100% of cases
  2. AIDS: 30% of patients affected
  3. Diabetes mellitus: 20% to 24% affected (prevalence rates vary, increasing with longer disease duration)
  4. Fabry disease: Affects mostly children, pain in 81% to 90% of patients

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- History: Localize the disease with questions
  1. Quality (description) of neuropathic pain: Burning, hot or cold, "icy hot," "pins and needles," stinging, lancinating, sharp, shooting
  2. Distribution of symptoms may aid in localization (i.e., "stocking-glove" symptoms in generalized neuropathy, numbness in a peripheral nerve territory in focal neuropathy)
  3. Generalized small fiber neuropathy: Dysesthesias without numbness common, but many etiologies (e.g., diabetes) cause both small and large fiber dysfunction
  4. Large fiber neuropathy (LFPN): Coexisting numbness, hyporeflexia, or weakness may be seen, usually worse distally
  5. Nerve root: Coexisting neck or low back pain that radiates along a specific dermatome; most common cause is structural compression
  6. Spinal cord symptoms: Coexisting spasticity, bowel or bladder involvement, sensory level
  7. Prior history of thalamic stroke in central thalamic pain syndrome (Dejerine-Roussy syndrome)
  8. Family history may suggest a genetic cause
- Examination: See Table 1. Table 2 describes joint involvement in neuropathic arthropathy. Fig. 1 illustrates a diagnostic approach to neuropathic pain. Fig. 2 shows a neuropathic ankle

ETIOLOGY & LABORATORY EVALUATION (Table 3)

- Metabolic: Diabetes mellitus; malnutrition and alcoholism; vitamin B_{12} deficiency; thiamine deficiency; porphyria; Fabry disease
- Inflammatory: Autoimmune diseases (systemic vasculitides, systemic lupus erythematosus, Sjögren syndrome, etc.), acute inflammatory demyelinating polyneuropathy (classically presents with ascending weakness and numbness, although pain is also a common feature), chronic inflammatory demyelinating polyneuropathy, sarcoidosis, multiple sclerosis
- Infiltrative: Amyloidosis, paraproteinemias (e.g., monoclonal gammopathy of uncertain significance [MGUS] associated neuropathy)
- Infectious: Postviral (brachial neuritis), HIV/AIDS, HSV, varicella-zoster virus (VZV; postherpetic neuralgia), Lyme disease, leprosy (thickened nerves and skin lesions), syphilis
- Neoplastic and paraneoplastic-carcinomatous infiltration of nerve/nerve root, anti-Hu
- Drugs/toxins: History of exposure to alcohol, chemotherapeutic agents (paclitaxel, vincristine), isoniazid, metronidazole, or heavy metals (thallium, arsenic)

DIAGNOSIS

LABORATORY TESTS

- Fasting blood glucose (FBG)
- 2-hour oral glucose tolerance test (OGTT)
- Vitamin B_{12} level
- If B_{12} level normal: Serum methylmalonic acid and homocysteine levels
- Serum erythrocyte sedimentation rate (ESR), ANA, SS-A and SS-B, c-ANCA, p-ANCA
- RPR or FTA-ABS
- Serum ACE level (sarcoid)
- HIV antibody
- SPEP, UPEP, immunofixation
- Urine and stool protoporphyrins, if porphyria is suspected clinically

TABLE 1 Examination

Exam Finding	Localization
Pinprick/temperature loss alone	Small fibers only
Pinprick/temperature loss + vibratory/proprioceptive loss	Small and large fibers
Sensory loss and motor dysfunction worse distally than proximal	Large fiber neuropathy
Sensory loss and motor dysfunction along single nerve distribution	Single nerve
Sensory loss and motor dysfunction along multiple single nerves	Multiple mononeuropathies (i.e., mononeuropathy multiplex)
Motor and sensory loss involving multiple nerves belonging to specific region of brachial or lumbar plexus	Plexopathy
Sensory loss along dermatome with multiple myotomal muscles affected	Nerve root lesion
Asymmetric sensory loss without weakness and pseudoathetosis	Dorsal root ganglion
Vibratory/proprioceptive loss without pinprick/temperature loss	Dorsal column dysfunction (from compressive lesion, B_{12} deficiency, or tabes dorsalis from neurosyphilis)
Sensory level with weakness below the level of lesion and long tract signs (spasticity/Babinski sign)	Spinal cord lesion
Hemisensory hyperalgesia	Contralateral thalamus

TABLE 2 Joint Involvement in Neuropathic Arthropathy

Disease	Site of Involvement
Diabetes mellitus	Midtarsal, metatarsophalangeal, tarsometatarsal
Syringomyelia	Shoulder, elbow, wrist
Amyloidosis	Knee, ankle
Congenital sensory neuropathy	Knee, ankle, intertarsal, metatarsophalangeal
Tabes dorsalis	Knee, hip, ankle
Leprosy	Tarsal, tarsometatarsal

From Hochberg MC et al: *Rheumatology,* ed 5, St Louis, 2011, Mosby.

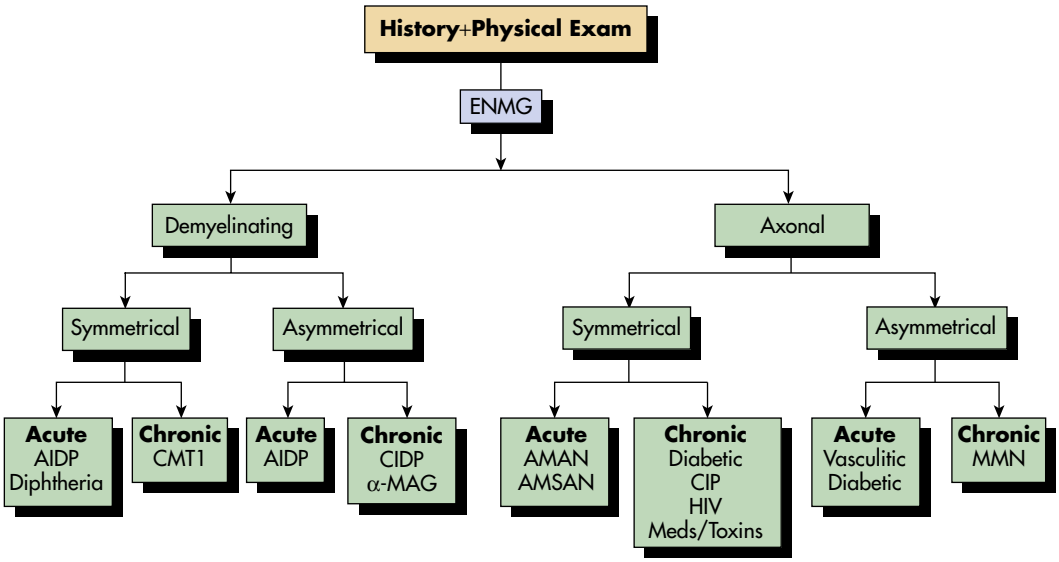

FIG. 1 A systematic approach to evaluate neuropathy. The diseases listed are examples of neuropathies associated with specific neurophysiologic and clinical findings. Diabetic distal, predominantly sensory neuropathies are manifested as chronic axonal neuropathies; acute asymmetric neuropathies can also occur with diabetes. Most neuropathies caused by toxins or by side effects of medication are chronic, symmetric axonal neuropathies. AIDP, AMAN, and AMSAN are subtypes of Guillain-Barré syndrome. These and other examples are discussed in more detail in the text. *AIDP,* Acute inflammatory demyelinating polyradiculoneuropathy; *AMAN,* acute motor axonal neuropathy; *AMSAN,* acute motor and sensory axonal neuropathy; *CIDP,* chronic inflammatory polyradiculoneuropathy; *CIP,* chronic illness polyneuropathy; *CMT1,* Charcot-Marie-Tooth disease type 1, a genetic disorder; *ENMG,* electroneuromyography; *HIV,* human immunodeficiency virus–related neuropathy; *α-MAG,* alpha-myelin-associated glycoprotein; *MMN,* multifocal motor neuropathy. (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.)

FIG. 2 Neuropathic ankle. Marked instability of the subtalar and midtarsal joints is seen with collapse on weight bearing. (From Hochberg MC et al: *Rheumatology,* ed 5, St Louis, 2011, Mosby.)

- Hu antibody: Can be seen in both small cell and non–small cell lung cancers, may be positive without evidence of lung cancer
- Lumbar puncture: Protein elevation, oligoclonal bands, CSF/serum IgG index

ELECTROPHYSIOLOGY STUDIES

- Electrophysiologic testing (electromyography with nerve conduction studies): May be normal in small fiber neuropathies or CNS lesion, but is often abnormal in large fiber neuropathies
- Quantitative sensory testing: Abnormal in small and large fiber neuropathy
- Evoked potentials (only if suspicion for spinal cord lesion)

PATHOLOGY STUDIES

- Nerve biopsy is occasionally useful in selected cases, particularly when vasculitis, sarcoidosis, or amyloid neuropathy are in the differential.
- Skin biopsy for intraepidermal nerve fiber (IENF) density may be useful for small fiber neuropathy when other studies are normal.
- Rectal or abdominal fat pad biopsy may show amyloid deposition in systemic amyloidosis.

IMAGING STUDIES

Based on localization:

- MRI (with and without contrast):
  1. Of the brain to exclude thalamic pathology if symptoms and signs are consistent with thalamic lesion (hemibody pain)
  2. Of the spinal cord and nerve roots to exclude structural, inflammatory, neoplastic, or infectious causes
  3. Of the lumbar spine to evaluate for arachnoiditis
- If MRI cannot be performed, consider:
  1. CT of the brain for thalamic pathology
  2. CT myelography of the spinal cord to evaluate for structural/neoplastic disease, but only if clinical signs of spinal or nerve root compromise are present

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Counseling should be initiated at the beginning of therapy to address psychological issues exacerbating physiologic pain.
- Physical therapy: Especially in cases of chronic neck and low back pain.
- Cognitive behavioral therapy

ACUTE GENERAL Rx

- Treatment of the underlying cause if possible will help slow or prevent worsening.
- Medications may reduce or alleviate pain but do not affect numbness.
- Antidepressants:
  1. Tricyclic antidepressants (TCAs): Nortriptyline preferred over amitriptyline (fewer anticholinergic side effects with nortriptyline). Begin 25 mg PO qd in adults, or 10 mg qd in elderly. Increase dose by 25 mg every wk as tolerated until usual maximal effective dose of 150 mg/day.
  2. Duloxetine: Begin 30 mg daily, increase to 60 to 120 mg daily. Duloxetine is effective in diabetic neuropathy, post-herpetic neuropathy, and chemotherapy-induced painful peripheral neuropathy.
  3. Venlafaxine.
- Antiepileptics:
  1. Gabapentin: Begin 300 mg PO qd, advance to 300 mg PO tid by the end of the first wk. Effective dose: Higher than 1600 mg/day. Max dose: 1200 mg PO tid.
  2. Carbamazepine: For trigeminal neuralgia. Begin 400 mg PO bid, increase to tid if necessary. Side effects and drug levels help to determine optimal dosing. Risk of aplastic anemia and hyponatremia (monitor CBC and chemistries). Risk of Stevens-Johnson syndrome, especially in Asian population (check HLA before starting).

TABLE 3 Clinical Presentation and Laboratory Findings

Neuropathy Type	Predisposition	Examination Findings	EMG/NCS	Laboratory Analysis
Idiopathic small fiber PN	Age >50	Strength: Normal Reflexes: Normal Pos/vib: Normal Pain/temp: Decreased distally	Normal	Serum studies: Normal skin biopsy: Abnormal sudomotor studies: Abnormal
Diabetic PN	Long-standing disease Family history	Strength normal to reduced, sensation reduced distally	Abnormal	Abnormal glucose tolerance: High fasting glucose
Inherited PN	Family history	Pes cavus, hammer toes, reduced reflexes, sensation reduced distally	Abnormal	Genetic studies may be abnormal, other studies normal
Familial amyloid PN	Family history	Pain/temp loss, reduced reflexes, orthostasis	Abnormal if large fibers affected; also carpal tunnel syndrome	Transthyretin genetic study
Acquired amyloid PN	Monoclonal gammopathy	Pain/temp loss, reduced reflexes, orthostasis	Abnormal if large fibers affected; also carpal tunnel syndrome	SPEP, UPEP, immunofixation abnormal
Fabry disease	Age, renal failure, strokes	Normal; possible reduced pain/temp sensation	Normal	α-Galactosidase levels in cultured fibroblasts
PN + mixed connective tissue disease	History of lupus, rheumatoid arthritis, Sjögren syndrome	Reduced reflexes and distal sensation	Abnormal	ANA, RF, SS-A/SS-B may be abnormal
Peripheral nerve vasculitis	Asymmetric disease	Multiple peripheral nerves involved	Abnormal	ANA, RF, SS-A/SS-B, ANCA, cryoglobulins may be abnormal
Paraneoplastic neuropathy	Lung cancer risk factors, chemical exposures	Asymmetric sensory loss, pseudoathetosis, relatively preserved strength	Abnormal	Anti-Hu
Sarcoidosis	Pulmonary sarcoid	Multiple mononeuropathies	Abnormal	Abnormal biopsy, elevated serum ACE, CXR abnormal
Arsenic	Pesticides, copper smelting	Reduced reflexes and distal sensation	Abnormal	Elevated arsenic in plasma, urine, and hair
HIV	Promiscuity, unprotected sex, IV drug abuse, blood transfusion	Variable, but most often reduced reflexes and distal sensation	Abnormal if large fibers involved	HIV antibody

ACE, Angiotensin-converting enzyme; *ANA,* antibody to nuclear antigens; *ANCA,* antineutrophil cytoplasmic antibodies; *CXR,* chest x-ray; *EMG,* electromyography; *HIV,* human immunodeficiency virus; *IV,* intravenous; *NCS,* nerve conduction studies; *PN,* polyneuropathy; *Pos,* position sensation; *RF,* rheumatoid factor; *SPEP,* serum protein electrophoresis; *SS-A,* Sjögren syndrome A; *SS-B,* Sjögren syndrome B; *Temp,* temperature sensation; *UPEP,* urine protein electrophoresis; *Vib,* vibration sensation.
Adapted from Mendell JR, Sahenk Z: Painful sensory neuropathy, *N Engl J Med* 348(13):1243, 2003.

3. Oxcarbazepine: Better tolerated than carbamazepine. Start 150 mg PO bid and gradually increase to a dose of 600 mg bid. Maximum dose is 1200 mg bid.
4. Pregabalin: Begin 50 mg PO tid, increase slowly to 100 to 200 mg PO tid.

- Analgesics: When first-line agents are ineffective. While effective, the use of opioids is associated with substantial adverse effects as well as novel pain syndromes. Chronic use of opioids leads to tolerance and escalation of dose:
  1. Tramadol: 150 mg/day (50 mg tid), increase by 50 mg/wk, max 200 to 400 mg/day.
  2. Morphine (oral): 15 to 30 mg q8h, max 90 to 360 mg/day.
  3. Oxycodone: 20 mg q12h, increase by 10 mg/wk, max 40 to 160 mg/day.
  4. Fentanyl patch: 25 to 100 mcg transdermally q3 days.
- Topical anesthetics:
  1. 5% lidocaine patch, apply to area of pain, max three patches every 12 hr.
  2. Capsaicin cream and patches are inconsistent in their ability to relieve pain and may exacerbate it. A capsaicin 8% patch is approved specifically for post-herpetic neuralgia and is applied for 60 min under medical supervision.
- Procedural/surgical: This option is considered mostly when the patient suffers from pain secondary to spinal cord or cauda equina injury. Studies are limited and benefit is not completely established. Procedures should be considered only when all other therapeutic modalities have failed. In addition, the patient should be cautioned that surgical procedures may not result in pain relief and may be associated with significant morbidity and even mortality.
  1. Dorsal root rhizotomy.
  2. Nerve blocks.
  3. Spinal cord stimulator.

DISPOSITION

Prognosis depends on multiple factors, including:
- Etiology of pain
- Treatment of any underlying condition
- Initiation of appropriate (often multiple) therapeutic modalities
- Patient compliance with prescribed regimen

Most care is accomplished in the outpatient setting, except when surgery is required.

REFERRAL

- Pain clinic
- Neurology
- Psychiatry
- Psychology
- Physiatry
- Anesthesiology (nerve blocks)
- Neurosurgery if considering surgical management

PEARLS & CONSIDERATIONS

- Factitious disorder and malingering frequently manifest with pain complaints. These are diagnoses of exclusion and require negative evaluation for organic etiologies before diagnosis is made.
- Peripheral neuropathy in diabetics increases the risk of foot ulceration by sevenfold. Abnormal results in monofilament testing and vibratory perception (alone or in combination with the appearance of the feet, ulceration, and ankle reflexes) are the most helpful sign for the detection of LFPN.

Neuropathy, Hereditary

BASIC INFORMATION

DEFINITION

Any disorder affecting the peripheral nervous system, including nerve roots, plexuses, and individual peripheral nerves, that has a genetic basis of inheritance and has been or is capable of being transmitted along generations.

There are many different types of hereditary peripheral neuropathies, including Dejerine-Sottas disease, inherited metabolic neuropathies, hereditary sensory and autonomic neuropathies (HSANs), and hereditary motor neuropathies. Most disorders are diagnosed in infancy or childhood; as such, adult clinicians rarely see these patients. For this reason, this chapter discusses only the hereditary motor and sensory neuropathies that an adult clinician might encounter.

SYNONYMS

Charcot-Marie-Tooth (CMT) disease
Hereditary motor-sensory neuropathy (HMSN)
Hereditary neuropathy with liability to pressure-sensitive palsies (HNPP)

ICD-10CM CODES

G60.0	Hereditary motor and sensory neuropathy
G60.8	Other hereditary and idiopathic neuropathies
G60.9	Hereditary and idiopathic neuropathy, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

All CMT: Approximately 30 per 100,000
- CMT type 1 (demyelinating pathophysiology): 1 in 2500
- CMT type 2 (axonal pathophysiology): 7 in 1000
- CMT type 4 and CMT-X: Rare (either axonal or demyelinating pathophysiology)

HNPP: 2 to 5 per 100,000

PHYSICAL FINDINGS & CLINICAL PRESENTATION

CMT: Highly variable
- Age at onset earlier for CMT-1 than CMT-2, but both may present from childhood to old age.
- Severely affected patients have severe distal weakness and muscle atrophy with hand (prominently affecting interossei) and foot deformities (pes cavus, high arched feet, hammer toes).
- Mildly affected patients may have only foot deformity (pes cavus) with little or no weakness/sensory loss.
- Legs can be affected greater than arms, and patients will complain of gait abnormalities (steppage), which cause them to trip and fall.
- Sensory complaints (paresthesias, numbness, dysesthesia) are uncommon despite physical findings of impaired sensation.
- Decreased or absent reflexes.
- Some patients may have postural tremor of the upper limbs.

HNPP (a.k.a. tomaculous neuropathy):
- Age at onset is commonly adolescence.
- Disorder is characterized by recurrent entrapment of peripheral nerves with accompanying signs and symptoms (paresthesias and/or weakness in anatomic distributions). Most common are:
  1. Median nerve at the wrist (carpal tunnel syndrome)
  2. Ulnar nerve at the elbow (cubital tunnel syndrome)
  3. Painless brachial plexopathies
  4. Lateral femoral cutaneous nerve (meralgia paresthetica)
  5. Peroneal nerve at the fibular head
- May be associated with a generalized polyneuropathy.

ETIOLOGY

CMT: More than 30 subgroups have been identified and have various chromosomal abnormalities.
- Most common mutation is PMP-22 duplication, giving rise to CMT 1A demyelinating phenotype.
- Other mutations include P0 (demyelinating) and neurofilament light chain mutations (demyelinating or axonal phenotype)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

CMT: Other genetic, metabolic, and multisystem disorders including:
- Spinocerebellar ataxias
- Friedreich ataxia
- Leukodystrophies
- Refsum disease (elevated serum phytanic acid)
- Distal spinal muscular atrophies and distal myopathies, which can present with pes cavus and other foot deformities
- Chronic inflammatory demyelinating polyneuropathy (CIDP)

HNPP:
- Hereditary neuralgic amyotrophy (HNA), which typically is painful rather than painless. In addition, in HNA, there is no evidence of generalized polyneuropathy
- Multifocal motor neuropathy with conduction block (MMNCB)—autoimmune-mediated pure motor neuropathy
- Neuropathy associated with renal failure
- Lead neuropathy
- Neuropathy relating to paraproteinemia (demyelinating pathophysiology)

EVALUATION

CMT:
- History of gradual onset symptoms is important to distinguish CMT from other forms of neuropathy.
- Detailed family history with pedigree is essential. Consider examination of multiple family members.
- History should evaluate for potential heavy metal exposure.
- History of dysesthesias is uncommon and should prompt search for acquired neuropathy or other inherited neuropathies (e.g., Fabry disease).

HNPP: Genetic testing after identification of multiple entrapment neuropathies on electromyography (EMG) and nerve conduction studies

LABORATORY TESTS

- Neurophysiology: EMG and nerve conduction studies (NCSs) must be done first to determine type of pathophysiology: demyelinating or axonal. This will guide genetic testing.
- NCSs in CMT-1 will reveal demyelinating physiology characterized by very slow conduction velocities (around 15 to 30 m/s) with prolonged distal latencies. Inherited demyelinating disorders can be distinguished from acquired demyelinating disorders (e.g., chronic inflammatory demyelinating polyneuropathy or CIDP) by the presence of conduction block in the latter.
- In HNPP, diffusely prolonged distal latencies with superimposed entrapment neuropathies at common sites will be seen on NCSs.
- EMG will reveal reinnervation characterized by long-duration, large-amplitude, polyphasic motor unit potentials (MUPs) with decreased MUP recruitment.
- Genetic tests are available for some CMT subtypes:
  1. CMT-1A: Chromosome 17p11-PMP-22 duplication
  2. CMT-1B: Chromosome 1q22-P0 mutation
  3. CMT-2E: Chromosome 8p21-neurofilament light chain (NF-L) point mutation
  4. CMT-X: Connexin 32 mutations
  5. HNPP: Chromosome 17p11 deletion, which includes the *PMP-22* gene
- Serum and 24-hour urine levels of heavy metals (arsenic, lead, etc.).
- Serum protein electrophoresis (SPEP), urine protein electrophoresis (UPEP), immunofixation (for paraprotein).
- Anti-GM1 antibody (positive in ~50% of patients with MMNCB).
- Lumbar puncture may reveal elevated CSF protein in CIDP.
- Peripheral nerve biopsy:
  1. Demyelination with "onion bulb formation." Tomaculae, or focal thickening of myelin sheaths, is seen in HNPP.
  2. Generally not indicated unless diagnosis is uncertain.

IMAGING STUDIES

- Spine plain films: For evaluation of scoliosis.
- MRI: Indicated if dissociative sensory loss (dorsal column dysfunction with intact spinothalamic tract function) or if upper motor neuron findings (spasticity, Babinski sign, clonus, increased tendon reflexes) are present.
- Exclusion of involvement of brain or spinal cord compressive lesions causing arm or leg weakness.
- Some inherited peripheral demyelinating disorders (i.e., CMT-X) are associated with intracerebral white matter abnormalities on MRI.
- Exclusion of structural, infectious, or inflammatory nerve root pathology.

TREATMENT

There is no known cure for any of these disorders. Management is supportive.

NONPHARMACOLOGIC THERAPY

- Physical therapy (PT) and occupational therapy (OT) to provide assistance with gait and coordination
- PT and OT might provide walking aid such as ankle foot orthosis (AFO), cane, walker, or wheelchair depending on the severity of the neuropathy
- Wrist splints for superimposed carpal tunnel syndrome
- Elbow pads (Heelbo Pads) to cushion the ulnar nerve at the elbow
- Heel-cord strengthening
- Stretching exercises
- Analgesics for pain associated with foot deformity
- Surgical correction of foot deformities by orthopedic surgeons if indicated

Vincristine may worsen existing neuropathy (important for oncologist to know if patient develops cancer requiring chemotherapy).

SURGICAL TREATMENT

- Patients with HNPP should probably not undergo surgical decompression of the median nerve at the wrist or the ulnar nerve at the elbow; these nerves are sensitive to manipulation. Poor results have been reported with ulnar nerve transposition.
- Anesthesiologists should be aware of HNPP diagnosis in patients undergoing surgery to prevent compression neuropathies from occurring during surgical procedures.

GENETIC COUNSELING

Must be routinely done for patient and family when diagnosis is established. Many aspects of the patient and family's life are affected, including:

- Future progeny of patient and/or patient's parents or children
- Psychosocial aspects including social functioning, marriage, employment
- Financial needs
- Medical and life insurability

PROGNOSIS

- CMT: Slowly progressive, and patients often remain ambulatory until late in life. Life expectancy is normal. Patients with respiratory involvement (i.e., phrenic nerve involvement with diaphragm paresis) may have shorter life expectancy.
- HNPP: Benign prognosis.

DISPOSITION

Outpatient care. Routine follow-up appointments should be done initially every 6 mo, and then every 1 to 2 yr.

REFERRAL

- Neurology and/or neuromuscular disease specialist
- Podiatry for recurrent foot problems, including appropriate arches

PEARLS & CONSIDERATIONS

PATIENT & FAMILY EDUCATION

Patients can benefit from use of Muscular Dystrophy Association (MDA) resources.

New Onset Seizures ALG

BASIC INFORMATION

DEFINITION

An unprovoked seizure is a seizure that occurs without triggers or precipitating factors. In contrast, an acute symptomatic seizure occurs in the setting of an insult to the brain (infectious, toxic, etc.). The presentation of a new seizure can vary greatly depending on the type (focal or generalized), progression, and severity.

SYNONYM

Convulsions

ICD-10CM CODES

G40.001	Localization-related (focal) (partial) idiopathic epilepsy and epileptic syndromes with seizures of localized onset, not intractable, with status epilepticus
G40.009	Localization-related (focal) (partial) idiopathic epilepsy and epileptic syndromes with seizures of localized onset, not intractable, without status epilepticus
G40.10	Localization-related (focal) (partial) symptomatic epilepsy and epileptic syndromes with simple partial seizures, not intractable
G40.101	Localization-related (focal) (partial) symptomatic epilepsy and epileptic syndromes with simple partial seizures, not intractable, with status epilepticus
G40.109	Localization-related (focal) (partial) symptomatic epilepsy and epileptic syndromes with simple partial seizures, not intractable, without status epilepticus
G40.201	Localization-related (focal) (partial) symptomatic epilepsy and epileptic syndromes with complex partial seizures, not intractable, with status epilepticus
G40.209	Localization-related (focal) (partial) symptomatic epilepsy and epileptic syndromes with complex partial seizures, not intractable, without status epilepticus
G40.301	Generalized idiopathic epilepsy and epileptic syndromes, not intractable, with status epilepticus
G40.309	Generalized idiopathic epilepsy and epileptic syndromes, not intractable, without status epilepticus
G40.A01	Absence epileptic syndrome, not intractable, with status epilepticus
G40.A09	Absence epileptic syndrome, not intractable, without status epilepticus
G40.4	Other generalized epilepsy and epileptic syndromes
G40.401	Other generalized epilepsy and epileptic syndromes, not intractable, with status epilepticus
G40.409	Other generalized epilepsy and epileptic syndromes, not intractable, without status epilepticus
G40.501	Epileptic seizures related to external causes, not intractable, with status epilepticus
G40.509	Epileptic seizures related to external causes, not intractable, without status epilepticus
G40.909	Epilepsy, unspecified, not intractable, without status epilepticus

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 29 to 39 per 100,000 per yr for acute symptomatic seizures. 23 to 61 per 100,000 person-yr for unprovoked seizures. Approximately 8% to 10% of the population will experience a seizure during their lifetime; however, less than 3% go on to develop epilepsy.
PREVALENCE: 5 to 8.4 cases per 1000 persons
PREDOMINANT SEX AND AGE: Males younger than 12 mo and older than 65 yr
RISK FACTORS:

- Age of onset
- Family history of epilepsy
- Excessive sleep deprivation, use of alcohol, or illicit drugs
- History of head trauma, diseases of the brain, brain surgeries, and strokes
- History of congenital cerebral anomalies or developmental delay

GENETICS

Although some new onset seizures are related to specific genes, most are not.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients with generalized seizures will typically have normal physical exams. Patients with focal seizures due to persistent structural CNS damage may have exam findings consistent with the location of the lesion.
- A generalized seizure may start without warning and can typically last from 30 to 120 seconds, during which the patient will be unconscious and may have increased rigidity and/or jerking of the whole body, or staring spells. Cyanosis (especially of the lips and face) can result from temporary airway compromise due to muscle spasms. Tonic-clonic seizures can cause injuries, tongue biting, and bladder incontinence. Patients are usually unaware of the seizure afterwards. A postictal state characterized by confusion, lethargy, headaches, or drowsiness may result and can last from min to hours depending on the severity of the seizure.
- During a focal seizure, a patient may be aware (focal aware seizure) or have impaired consciousness (focal impaired awareness seizures). A focal impaired awareness seizure may be associated with an aura (itself a focal aware seizure) and lasts between 30 and 120 seconds. Motor or nonmotor symptoms may predominate in focal seizures, including jerking of one limb, automatisms, head turning, auditory hallucinations, or feelings of derealization. A focal seizure may progress to a generalized seizure, which usually involves the head and eye turning to one side. Postictal weakness may result after focal seizures and can last for hours but usually resolves within 1 day. Persistent neurological deficits beyond this time may indicate other causes and should be investigated.

ETIOLOGY

- New, unprovoked seizures are often idiopathic.
- Acute symptomatic seizures can be due to cerebral abnormalities (e.g., infections/abscesses, subarachnoid hemorrhages, ischemic strokes, tumors, arteriovenous malformations, venous malformations) or systemic causes (e.g., electrolyte abnormalities, hypoglycemia, hyperthyroidism, drug intoxication or withdrawal).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Syncope
- Transient ischemic attacks
- Migraines
- Sleep disorders
- Paroxysmal movement disorders
- Panic attacks, hallucinations, and other psychiatric disorders

WORKUP

- Ambulatory 30-min EEG if patient fully recovers after seizure within 30 to 60 min. May be delayed if treatment does not depend on EEG result.
- Consider inpatient continuous EEG if patient does not fully recover within 60 min or for recurrent seizures.
- ECG.
- Fig. 1 illustrates an algorithm for the approach to the child with a suspected convulsive disorder.

LABORATORY TESTS

Comprehensive metabolic panel and urine drug screen

IMAGING STUDIES

- Acutely, CT of the head with and without contrast to evaluate for hemorrhage and space-occupying lesions
- Brain MRI with and without contrast with epilepsy protocol in patients with recurrent seizures, in consultation with a neurologist

TREATMENT

- Provoked seizures do not need long-term treatment.
- The choice of treatment depends largely on seizure type and etiology. Antiepileptics may be thought of as narrow- or wide-spectrum drugs. Treatment with wide-spectrum antiepileptics is advisable in generalized seizures or those of unknown type, whereas partial seizures are better controlled with narrow-spectrum antiepileptics.
- Narrow-spectrum drugs include carbamazepine, oxcarbazepine, gabapentin, pregabalin, lacosamide, and phenytoin. Wide-spectrum drugs include valproate, topiramate, zonisamide, lamotrigine, and levetiracetam.

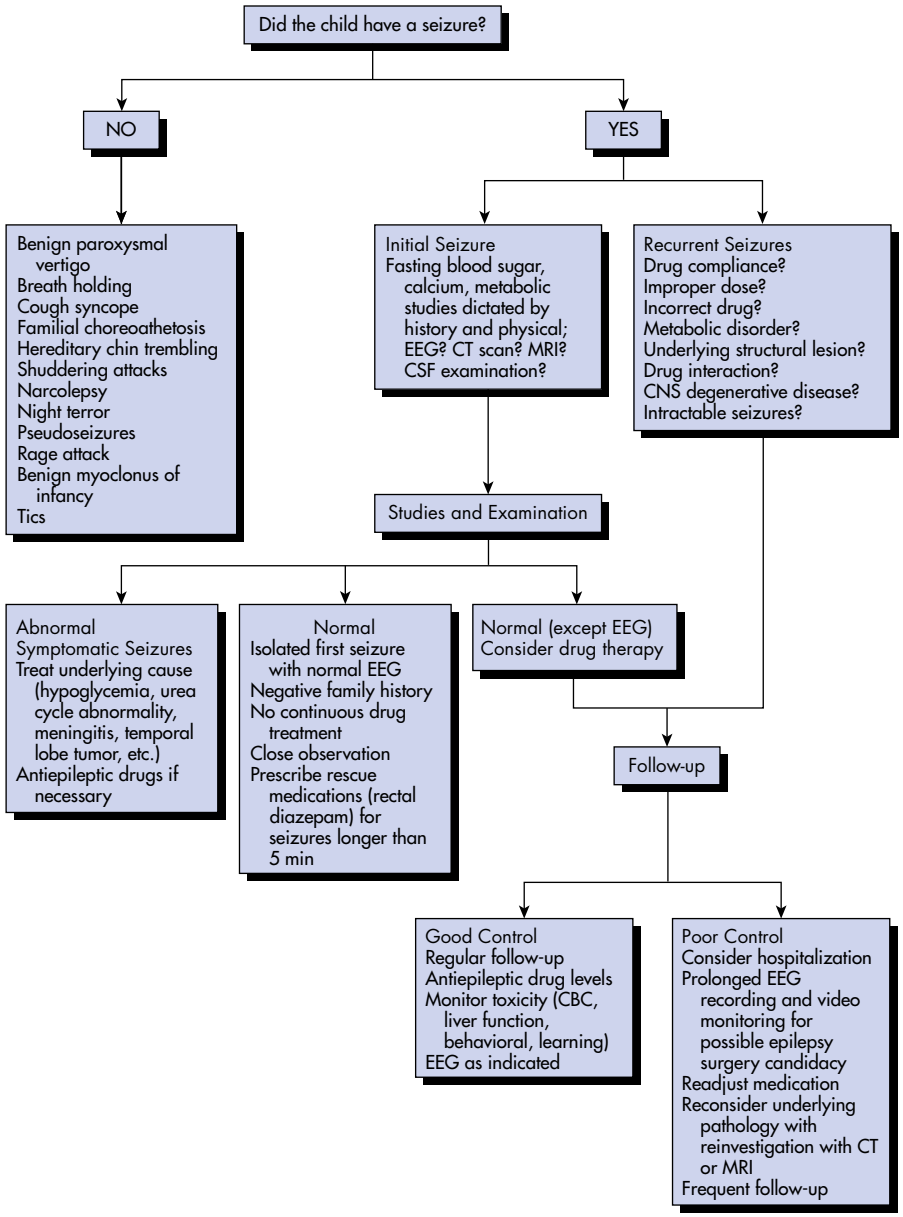

FIG. 1 Algorithm for the approach to the child with a suspected convulsive disorder. *CBC,* Complete blood count; *CT,* computed tomography; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *EEG,* electroencephalogram; *MRI,* magnetic resonance imaging. (From Kliegman RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.)

- In patients with significant comorbidities, the use of antiepileptics with limited drug interactions is advised (lamotrigine, levetiracetam, lacosamide).
- Older patients may benefit from lamotrigine, levetiracetam, or gabapentin due to a lower risk of adverse events.

NONPHARMACOLOGIC THERAPY

None

ACUTE GENERAL Rx

- Patients with a first unprovoked seizure who have a normal EEG, imaging, lab values, and physical exam do not require treatment with antiepileptic drugs but may be offered therapy because the use of an antiepileptic drug after a first unprovoked seizure in an adult reduces the absolute risk of seizure recurrence at 2 yr by 35%. However, there is no difference at 3 yr.
- For generalized seizures: **Levetiracetam** initial dose of 500 mg bid. If recurrent seizures, increase by 500 mg every 1 to 2 wk until maximum dose of 1500 mg bid is reached.
- For partial seizures: **Oxcarbazepine** initial dose 300 mg bid, increase by 300mg/day every 3 days to 600 mg bid. If recurrent seizures, continue to titrate by 300 mg/day every 3 days to 1200 mg bid.

CHRONIC Rx

Patients with two or more unprovoked seizures, or those with one seizure and an abnormal workup consistent with epilepsy findings, should be continued on antiepileptic drugs. Patients electing antiepileptic therapy after first unprovoked seizure with negative workup may be weaned off antiepileptic drug if seizure-free after 2 yr.

COMPLEMENTARY & ALTERNATIVE MEDICINE

Not applicable

DISPOSITION

- Patients should avoid swimming unobserved, bathing alone, working at heights, using heavy machinery, or other activities that may be high-risk in the event of a seizure.
- Discontinue driving until seizures are well controlled and in accordance with state laws.

REFERRAL

Patients may be referred to a neurologist.

PEARLS & CONSIDERATIONS

COMMENTS

- Driving: Physicians should be aware of the law in their jurisdiction about driving after a seizure. Although a few U.S. states require physicians to notify the state government authority that issues driver's licenses, most do not impose such an obligation on physicians. However, states do require patients to self-report and abstain from driving until seizure-free for a specified period of time, depending on the state.
- Recurrence risk: Greatest recurrence risk in an adult with a first unprovoked seizure is within the first 2 yr and is between 21% and 45%. The recurrence risk is lower in patients treated with an antiepileptic drug and higher in patients with a brain MRI abnormality causing the seizure or an EEG showing epileptiform activity.

PREVENTION

Patients with recurrent seizures should be extensively counseled on avoiding seizure triggers such as sleep deprivation, alcohol or drug use, stress, and exposure to excessive flashing lights. Such patients may need dose titration of antiepileptic drug and referral to a neurologist.

PATIENT & FAMILY EDUCATION

- Physicians should inform patients with first-time seizures that they are subject to state law restrictions on driving after a seizure. Physicians should also counsel patients with epilepsy about not swimming unattended, not climbing heights, and taking showers rather than baths (because of the risk of drowning in a bathtub during a generalized seizure). Physicians should counsel women of childbearing potential about effects of antiepileptic drugs on both oral contraceptive efficacy and on a developing fetus. They should recommend supplemental folic acid for such women if they are taking antiepileptic drugs. They should also recommend that women plan pregnancy if they are on antiepileptic drugs to minimize adverse effects on the pregnancy. All such counseling should be documented in the medical record.
- A diagnosis of epilepsy has significant medical, social, and emotional consequences. Patient information on seizures and locating support groups can be found at the Epilepsy Foundation website: http://www.epilepsy.com.

BASIC INFORMATION

DEFINITION

Nocardiosis is an infection caused by aerobic actinomycetes found in soil and characterized by lung, soft tissue, or central nervous system (CNS) involvement.

SYNONYMS

Mycetoma
Nocardia

ICD-10CM CODES
A42.9 Actinomycosis, unspecified
A43.0 Pulmonary nocardiosis
A43.1 Cutaneous nocardiosis
A43.8 Other forms of nocardiosis
A43.9 Nocardiosis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- *Nocardia* species are found worldwide in the soil.
- Nocardiosis is found most commonly in patients who are immunocompromised (e.g., chronic corticosteroid or immunosuppressive therapy, lymphoma, leukemia, AIDS, lung cancer, transplant recipients, chronic pulmonary infections).
- Other underlying conditions associated with nocardiosis are pemphigus vulgaris, Whipple disease, Goodpasture syndrome, Cushing disease, liver cirrhosis, ulcerative colitis, rheumatoid arthritis, and pulmonary alveolar proteinosis.
- Use of steroids is an independent risk factor for developing nocardiosis.
- Between 500 and 1000 new cases are diagnosed each yr in the U.S. Approximately 2% of patients with AIDS develop nocardiosis.
- Occurs more commonly in men than in women (2:1).
- Adults are affected more often than children.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Inhalation of *Nocardia* organisms is the most common mode of entry, and pneumonia is the most common presentation, with 75% manifesting with fever, chills, dyspnea, and a productive cough (Fig. E1).
  1. Presentation can be acute, subacute, or chronic.
  2. Nocardiosis should be suspected if soft tissue abscesses or CNS tumors or abscesses form in conjunction with the pulmonary infection.
  3. Pulmonary infection may spread into the pericardium, mediastinum, and superior vena cava.
- Cutaneous disease usually occurs by direct inoculation of the organism as a result of skin puncture by a thorn or splinter, surgery, IV catheter use, or animal scratches or bites manifesting in:
  1. Cellulitis.
  2. Lymphocutaneous nodules appearing along lymphatic sites draining the infected puncture wound.
  3. Mycetoma (Madura foot), a chronic deep nodular infection usually involving the hands or feet that can cause skin breakdown or fistula formation and that spreads along the fascial planes to infect surrounding skin, subcutaneous tissue, and bone.
- The CNS is infected in approximately one third of all cases. Brain abscess is the most common pathologic finding.
- Dissemination of nocardiosis may infect other tissues and organs, including the kidney, heart, skin, and bone.

ETIOLOGY

- The most common *Nocardia* species leading to infection in human beings are:
  1. *N. asteroides* (causing more than 80% of the cases of pulmonary nocardiosis)
  2. *N. brasiliensis* (most common cause of mycetoma)
  3. *N. otitidiscaviarum*
- *N. asteroides* has two subgroups:
  1. *N. farcinica*
  2. *N. nova*

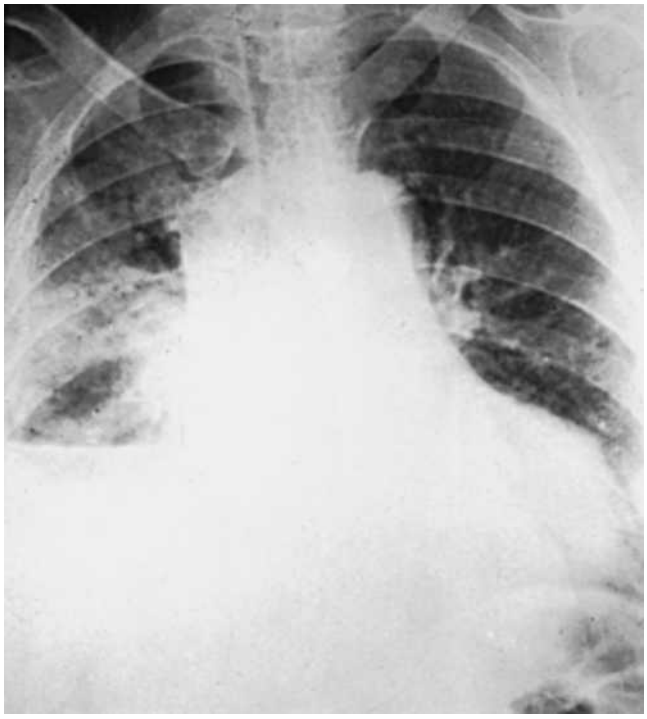

FIG. E1 Right lower lobe *Nocardia* pneumonia in a kidney transplant recipient. (From Gorbach SL: *Infectious diseases,* ed 2, Philadelphia, 1998, WB Saunders.)

DIAGNOSIS

The diagnosis of nocardiosis requires a high index of clinical suspicion in the proper clinical setting and is confirmed by bacteriologic staining and growth of the organism in culture.

DIFFERENTIAL DIAGNOSIS

There are no pathognomonic findings separating nocardiosis pneumonia from other infectious etiologies of the lung. Diagnoses presenting in a similar manner and often confused for nocardiosis include:

- Tuberculosis
- Lung abscess
- Lung tumor
- Other causes of pneumonia
- Actinomycosis
- Mycosis
- Cellulitis
- Coccidioidomycosis
- Histoplasmosis
- Aspergillosis
- Kaposi sarcoma

WORKUP

All patients with suspected nocardiosis need laboratory identification of the microorganism by obtaining sputum in the case of pneumonia, cultures of the infected skin lesions in mycetoma or lymphocutaneous disease, or the sampling of any purulent material (e.g., brain abscess, lung abscess, or pleural effusion).

LABORATORY TESTS

- Blood tests are not very sensitive in the diagnosis of nocardiosis.
- Gram stain shows gram-positive beaded filaments with multiple branches (Fig. E2). Gomori methenamine silver staining may detect the organism.
- *Nocardia* species are acid-fast on a modified Ziehl-Neelsen stain.
- *Nocardia* are slow-growing organisms; colony growth in cultures may take up to 2 to 3 wk.

IMAGING STUDIES

- Chest radiograph or CT of chest (Fig. E3) may demonstrate infiltrates, densities, nodules, cavitary masses, or multiple abscesses.
- CT scan of the brain is indicated in the appropriate clinical setting to exclude CNS brain abscesses.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Supportive therapy with oxygen in patients with pneumonia
- Chest physiotherapy
- For any abscess formation, surgical drainage is indicated (e.g., skin, lung, or brain)

ACUTE GENERAL Rx

- There are no prospective, randomized trials to date highlighting the most effective treatment of nocardiosis. Culture and sensitivity should always be done on the specimen
- For cutaneous infection, trimethoprim-sulfamethoxazole (TMX-SMX) 5 mg/kg of the trimethoprim component divided in 2 doses
- *Nocardia* infection that does not involve CNS: TMX-SMX (15 mg/kg/day of TMP component IV in 2 to 4 divided doses) *plus* (amikacin 7.5 mg/kg q12h). An alternate regimen consists of imipenem 500 mg IV q6h *plus* amikacin 7.5 mg/kg IV q12h
- In patients with CNS disease, TMX-SMX 15 mg/kg/day of TMP component IV divided in 2 to 4 doses *plus* imipenem 500 mg q6h IV. If multiorgan involvement, add amikacin 7.5 mg/kg q12h. Measure peak sulfonamide levels; target is 100 to 150 mcg/ml 2 hr post dose. An alternative regimen consists of linezolid 600 mg IV or PO q12h *plus* meropenem 2 g q8h. For infections without involvement of the CNS the patient can be switched to oral therapy after the initial IV therapy for 3 to 6 wk or until clinical improvement. For infections involving CNS the initial IV therapy should be continued for minimum of 6 wk and clear evidence of clinical improvement before switching to combination oral therapy. The combination oral antibiotics that can be used following initial IV therapy include:
  1. TMP/SMX (10 mg/kg per day of the trimethoprim component in two to three divided doses) and/or
  2. Minocycline (100 mg twice daily) and/or
  3. Amoxicillin/clavulanic acid (875 mg) twice daily
- Alternative drug treatment includes:
  1. Third-generation cephalosporin
  2. Minocycline 100 to 200 mg bid
  3. Extended-spectrum fluoroquinolones (moxifloxacin)
  4. Linezolid (use of linezolid >4 wk is associated with hematologic toxicity)
  5. Tigecycline
  6. Dapsone

CHRONIC Rx

- Although the optimal duration of therapy has not been determined, long-term therapy is generally recommended for all infections caused by *Nocardia.*
- Patients with cellulitis and lymphocutaneous syndrome are treated for 2 to 4 mo depending on whether there is bone involvement.
- Mycetomas are best treated with antibiotics for 6 to 12 mo but may require surgical drainage.
- Pulmonary and systemic nocardiosis excluding the CNS is treated for at least 6 mo in immunocompromised hosts.
- CNS involvement is treated with drainage and antibiotics for 12 mo.
- All immunosuppressed patients should receive 12 mo of antibiotic therapy.

DISPOSITION

- Patients with pulmonary nocardiosis have a mortality rate of 15% to 30%.

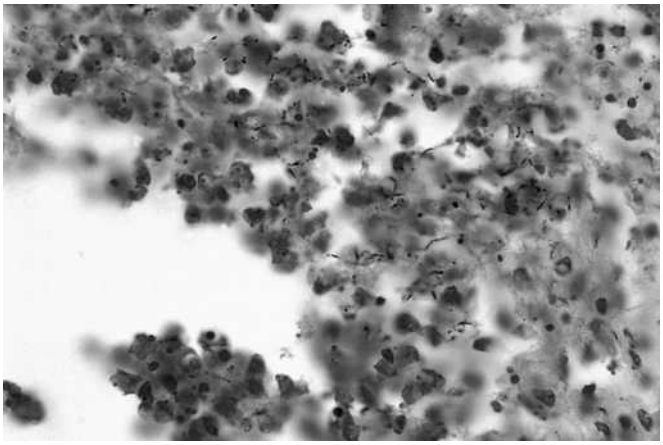

FIG. E2 *Nocardia* pneumonia. Thin, branching, irregularly staining gram-positive bacilli course through necrotic pulmonary tissue (Brown-Hopps Gram, ×1000). (From Silverberg SG et al [eds]: *Silverberg's principles and practice of surgical pathology and cytopathology,* ed 4, Philadelphia, 2006, Churchill Livingstone.)

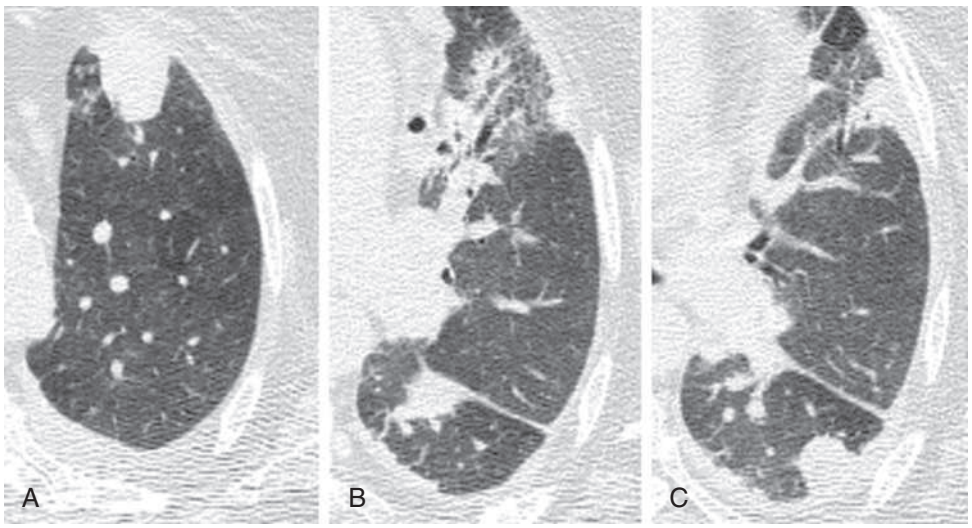

FIG. E3 Nocardiosis with multiple nodules. A to **C,** Multiple ill-defined nodules reflect nocardia pneumonia in an immunosuppressed patient. (From Webb WR et al: *Fundamentals of body CT,* ed 4, Philadelphia, 2015, WB Saunders.)

- CNS involvement carries a >40% mortality rate.
- Isolated skin lesions have a low mortality rate.

REFERRAL

Whenever the diagnosis of nocardiosis is suspected, consultation with infectious disease is indicated. Pulmonary evaluation and assistance may be needed in pulmonary nocardiosis. Neurosurgery consultation is indicated in patients with single or multiple brain abscesses.

PEARLS & CONSIDERATIONS

- Nocardiosis does not spread from animal to animal.
- Nocardiosis is not transmitted from person to person.
- Nocardiosis is distinguished by its ability to disseminate to any organ and its tendency to relapse despite appropriate antibiotic therapy.

COMMENTS

Tuberculosis and nocardiosis may coexist in the same patient.

Nocardiosis (Patient Information)

AUTHOR: **Maher Tabba, MD, FACP, FCCP**

BASIC INFORMATION

DEFINITION

- *Nonalcoholic fatty liver disease* (NAFLD) is a spectrum of diseases based on histopathologic findings and representing a morphologic rather than a clinical diagnosis. It is liver disease occurring in patients who do not abuse alcohol and manifesting histologically by mononuclear cells and/or polymorphonuclear cells, hepatocyte ballooning, and spotty necrosis. Nonalcoholic steatohepatitis (NASH) is a subset of NAFLD. Patients with NASH have progressive disease that can result in fibrosis and cirrhosis. A diagnosis of NAFLD is contingent on the following factors:
  1. Alcohol consumption in amounts less than those considered hepatotoxic.
  2. Absence of serologic evidence of other hepatic diseases or disorders.
  3. Liver biopsy showing predominant macrovesicular steatosis or steatohepatitis.
- NAFL is defined as ≥5% hepatic steatosis without evidence of hepatocellular injury or fibrosis.
- NASH is ≥5% hepatic fibrosis with inflammation and hepatocellular injury with or without fibrosis.
- *NASH cirrhosis* is the presence of cirrhosis with current or past evidence of steatosis.

SYNONYMS

Nonalcoholic steatohepatitis (NASH)
NAFLD
Fatty liver hepatitis
Diabetes hepatitis
Alcohol-like liver disease
Laënnec disease

ICD-10CM CODE
K76.0 Fatty (change of) liver, not elsewhere classified

EPIDEMIOLOGY & DEMOGRAPHICS

- NAFLD affects 30% to 40% of the adult general population in the U.S.
- Increased prevalence in obese persons (57% to 74%), type 2 diabetes mellitus, and hyperlipidemia (primarily hypertriglyceridemia).
- Most common cause of abnormal liver test results in adults in the United States (accounts for up to 90% of cases of asymptomatic ALT elevations).
- NAFLD is more prevalent in men than women.
- NAFLD is more prevalent in the Hispanic population.
- Approximately 20% of patients with NAFLD have NASH, and 10% to 30% of patients with NASH have NASH cirrhosis.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most patients are asymptomatic.
- Patients may report a sensation of fullness or discomfort on the right side of the upper abdomen.
- Nonspecific complaints of fatigue or malaise may be reported.
- Hepatomegaly (Table 1) is generally the only positive finding on physical examination.
- Acanthosis nigricans may be found in children.

ETIOLOGY

- Metabolic syndrome and insulin resistance are the most reproducible factors in the development of NAFLD and accumulation of triglycerides within the liver. High baseline and continuously increasing fasting insulin levels are independent determinants for future development of NAFLD. The transition from NAFLD to NASH is poorly understood; there may be a genetic component. The presence of the I48M variant of PNPLA3 increases risk for and severity of NAFLD.

TABLE 1 Symptoms, Signs, and Laboratory Features of Nonalcoholic Fatty Liver Disease

Symptoms	Signs	Laboratory Features
Common		
None (48%-100% of patients)	Hepatomegaly	2- to 4-fold elevation of serum ALT and AST levels AST/ALT ratio <1 in most patients Serum alkaline phosphatase level slightly elevated in one third of patients Normal serum bilirubin, serum albumin, and prothrombin time Elevated serum ferritin level
Uncommon		
Vague right upper quadrant pain Fatigue Malaise	Splenomegaly Spider telangiectasias Palmar erythema Ascites	Low-titer (<1:320) antinuclear antibodies

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase.
From Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease,* ed 10, Philadelphia, 2016, Elsevier.

BOX 1 Causes of Fatty Liver Disease

Acquired Metabolic Disorders
Diabetes mellitus
Dyslipidemia
Kwashiorkor and marasmus
Obesity
Rapid weight loss
Starvation

Cytotoxic and Cytostatic Drugs
L-Asparaginase
Azacitidine
Bleomycin
Cisplatin
5-Fluorouracil
Methotrexate
Tetracyclines (inhibit mitochondrial beta oxidation)

Other Drugs and Toxins
Amiodarone
Camphor
Chloroform
Cocaine
Ethanol
Ethyl bromide
Estrogens
Glucocorticoids
Griseofulvin
HAART (zidovudine, stavudine, didanosine)
Lycopodium serratum (Jin Bu Huan, an herbal supplement)
Nifedipine
Nitrofurantoin
NSAIDs (piroxicam, ibuprofen, indomethacin, sulindac)
Tamoxifen
Valproic acid

Metals
Antimony
Barium salts
Chromates
Mercury
Phosphorus
Rare earth metals of low atomic number
Thallium compounds
Uranium compounds

Inborn Errors of Metabolism
Abetalipoproteinemia
Familial hepatosteatosis
Galactosemia
Glycogen storage disease
Hereditary fructose intolerance
Homocystinuria
Systemic carnitine deficiency
Tyrosinemia
Weber-Christian syndrome
Wilson disease

Surgical Procedures
Biliopancreatic diversion
Extensive small bowel resection
Jejunoileal bypass

Miscellaneous Conditions
Industrial exposure to petrochemicals
IBD
Jejunal diverticulosis with bacterial overgrowth
Partial lipodystrophy
TPN

HAART, Highly active antiretroviral therapy; *IBD,* inflammatory bowel disease; *NSAIDs,* nonsteroidal antiinflammatory drugs; *TPN,* total parenteral nutrition.

TABLE 2 NAFLD Activity Score on a Liver Biopsy Specimen

Steatosis	
5%	1
5%-33%	2
33%-66%	3
Ballooning	
None	0
Few	1
Many	2
Lobular Inflammation	
Mild	1
Moderate	2
Severe	3
Total Score	
0-2	Likely not NASH
3-4	Intermediate
5-8	Likely NASH

NAFLD, Nonalcoholic fatty liver disease; *NASH,* nonalcoholic steatohepatitis.
From Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease,* ed 10, Philadelphia, 2016, Elsevier.

Genetic polymorphism (TM6SF2) also increases NAFLD risk.
- Risk factors are obesity (especially truncal obesity), diabetes mellitus, hyperlipidemia.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Alcohol-induced liver disease (a daily alcohol intake of 20 g in females and 30 g in males [three 12-oz beers or 12 oz of wine] may be enough to cause alcohol-induced liver disease)
- Viral hepatitis
- Autoimmune hepatitis
- Toxin- or drug-induced liver disease
- Box 1 summarizes the various causes of fatty liver disease

WORKUP

Diagnosis is usually suspected on the basis of hepatomegaly, asymptomatic elevations of transaminases, or "fatty liver" on sonogram of abdomen in obese patients with little or no alcohol use. Fig. E1 describes an algorithm for the diagnostic approach to NAFLD. Transient elastography is a noninvasive imaging modality that can be used to screen for the development of hepatic fibrosis. In obese patients newer "XL" FibroScan machines are more accurate. Liver biopsy can confirm diagnosis and provide prognostic information. It should be considered in patients with suspected advanced liver fibrosis (presence of obesity or type 2 diabetes, AST/ALT ratio 1, age 45 yr). NAFLD activity score on liver biopsy is described in Table 2.

LABORATORY TESTS

- Elevated ALT, AST: AST/ALT ratio is usually <1, but can increase as fibrosis advances. In advanced fibrosis AST to ALT ratio is >1 and platelet count is low.
- Negative serology for infectious hepatitis; generally normal GGTP and serum alkaline phosphatase.
- Hyperlipidemia (primarily hypertriglyceridemia) may be present.
- Elevated glucose levels may be present.
- Prolonged prothrombin time, hypoalbuminemia, and elevated bilirubin may be present in advanced stages.
- Elevated serum ferritin and increased transferrin saturation may be found in up to 10% of patients; however, hepatic iron index and hepatic iron level are normal.
- Antismooth muscle antibodies and antinuclear antibodies at low titer are not uncommon.

IMAGING STUDIES

- Ultrasound generally reveals diffuse increase in echogenicity as compared with that of the kidneys; CT scan reveals diffuse low-density hepatic parenchyma. The sensitivity of ultrasound and CT scan for detection of fat in liver is over 90% if hepatic steatosis exceeds 33%.
- Occasionally patients may have focal rather than diffuse steatosis, which may be misinterpreted as a liver mass on ultrasound or CT (Fig. E2); use of MRI in these cases will identify focal fatty infiltration.
- Ultrasound elastography (FibroScan) can also be used to evaluate hepatic fibrosis and to further stratify patients.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Weight reduction in all obese patients. The American Gastroenterological Association recommends that the initial target weight loss be 10% of baseline weight at a rate of 1 to 2 lb (0.45 to 0.90 kg) per week.
- Increase physical activity. Vigorous and moderate exercise are equally effective in reducing intrahepatic triglyceride content, the effect being largely mediated by weight loss.
- Alcohol has a deleterious effect on NAFLD and should be avoided.

ACUTE GENERAL Rx

- There are no drugs currently approved by FDA for NAFLD. Medications to control hyperlipidemia (e.g., fenofibrates for elevated triglycerides) and hyperglycemia (e.g., pioglitazone, insulin, metformin) can lead to improvement in abnormal liver test results.
- A 3-yr trial with pioglitazone (30 mg/day), an insulin-sensitizing thiazolidinedione, revealed that pioglitazone treatment was associated with long-term metabolic and histologic improvement in patients with prediabetes or type 2 diabetes mellitus and NASH. These results suggest that that NASH progression may be halted and the natural history of the disease may be modified with the use of pioglitazone in patients with prediabetes or type 2 diabetes mellitus.[1]

DISPOSITION

- Patients with pure steatosis on liver biopsy generally have a relatively benign course.
- The presence of steatohepatitis or advanced fibrosis on liver biopsy is associated with a worse prognosis.

REFERRAL

Liver transplantation should be considered in patients with decompensated, end-stage disease; however, in these patients there may be a recurrence of NAFLD posttransplantation.

PEARLS & CONSIDERATIONS

COMMENTS

- NAFLD is closely associated with metabolic disorders, even in nonobese, nondiabetic subjects. It can be considered an early predictor of metabolic disorders, particularly in the normal-weight population. The presence of metabolic syndrome is a strong predictor of NAFLD.
- NAFLD is associated with an increased risk of incident cardiovascular disease that is independent of the risk conferred by traditional risk factors and components of the metabolic syndrome.
- 10% of patients with NASH have progression to advanced fibrosis. Most common in patients older than 50, ALT > twice normal, BMI >28, triglycerides >150 mg/dl.
- Statins are not contraindicated in patients with NASH and should be considered in hypercholesterolemic patients.
- A recent trial has shown that daily aspirin use is associated with reduced risk for fibrosis progression in patients with NAFLD.[2]

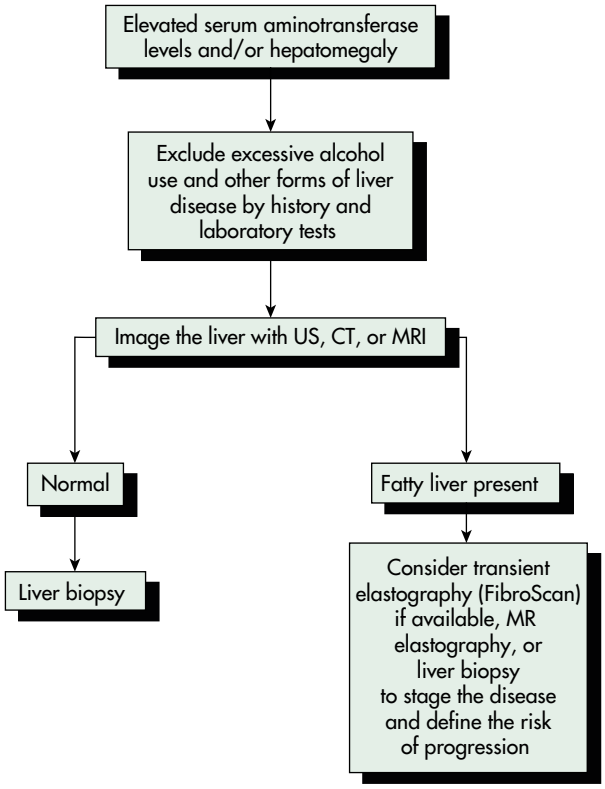

FIG. E1 Algorithm for a diagnostic approach to the patient with suspected nonalcoholic fatty liver disease (NAFLD). The diagnosis of NAFLD is based on clinical and histologic criteria. Most patients are evaluated because of elevated serum aminotransferase levels and/or hepatomegaly. The diagnosis of NAFLD should be considered when excessive alcohol use is absent and laboratory test results exclude other causes of liver disease. Imaging studies may demonstrate fatty liver. Liver biopsy is the standard means of diagnosis and the only test that can reliably differentiate simple steatosis from NASH, although noninvasive methods for assessing fibrosis, such as transient elastography, are being used increasingly to identify hepatic fibrosis. *CT,* Computed tomography; *MR,* magnetic resonance; *MRI,* magnetic resonance imaging; *NASH,* nonalcoholic steatohepatitis; *US,* ultrasound. (Modified from Feldman M et al: *Sleisenger and Fordtran's gastrointestinal and liver disease,* ed 10, Philadelphia, 2016, Elsevier.)

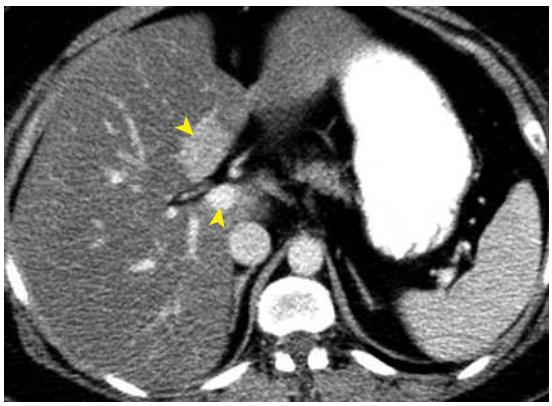

FIG. E2 Focal sparing. Two islands of normal parenchyma (*arrowheads*) in segment IVb and the caudate lobe (segment 1) simulate mass lesions in a liver with extensive fatty infiltration. Most of the liver parenchyma shows fatty infiltration, making these islands of normal parenchyma appear of high attenuation by comparison. (Webb WR et al: *Fundamentals of body CT,* ed 4, Philadelphia, 2015, WB Saunders.)

BASIC INFORMATION

DEFINITION

Nonallergic rhinitis (NAR) is characterized by chronic episodic or perennial symptoms of rhinitis (congestion, rhinorrhea, and postnasal drainage) that are not the result of IgE-mediated events. It is a heterogeneous group of diseases classified as inflammatory (infectious rhinosinusitis, nonallergic rhinitis with eosinophilia syndrome) or noninflammatory (including but not limited to gustatory rhinitis, atrophic rhinitis, rhinitis medicamentosa, hormone-induced rhinitis, rhinitis in the elderly, rhinitis associated with systemic disease). Vasomotor rhinitis has previously been used interchangeably with NAR but is being phased out, as the term is too narrow with regard to the multiple mechanisms of action associated with NAR.

SYNONYMS

Chronic nonallergic rhinitis
Idiopathic rhinitis
Intrinsic rhinitis
NAR
Nonallergic-noninfectious chronic rhinitis
Vasomotor rhinitis

ICD-10CM CODES	
J30.0	Vasomotor rhinitis
J31.0	Chronic rhinitis NOS (atrophic, granulomatous, hypertrophic, obstructive rhinitis)

EPIDEMIOLOGY & DEMOGRAPHICS

- Nonallergic rhinitis affects approximately 17 to 22 million individuals in the U.S.
- Approximately 50% of patients presenting with rhinitis may have NAR alone or a "mixed form" that includes both allergic and nonallergic components.
- Nonallergic rhinitis usually presents in adulthood with 70% of patients presenting after 20 yr of age. Onset of allergic rhinitis typically occurs in childhood.
- Risk factors for nonallergic rhinitis include female sex and age of >40 yr.
- May have genetic component in those individuals whose parents have allergic rhinitis.
- Medications that can cause chronic nasal symptoms are summarized in Table 1.
- Table 2 describes occupations with increased prevalence of work-related rhinitis.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients tend to present with a specific set of symptoms, predominantly rhinorrhea, postnasal drip, and throat clearing. Conversely, allergic symptoms such as nasal pruritus, sneezing, and conjunctival irritation are traditionally absent but can be variably present in mixed disease.
- Physical exam can be completely unremarkable, but it can present with the following features:
  1. Clear nasal secretions
  2. Nasal crusting
  3. Anosmia can be consistent with some forms (e.g., atrophic rhinitis)
  4. Inspection of turbinates may be erythematous or pale

ETIOLOGY

- NAR is composed of a heterogeneous group of diseases without a clear unifying theory of pathogenesis. In general, inflammatory NAR involves elevated numbers of immune cells (eosinophils, mast cells, neutrophils) leading to mediator release and inflammatory changes. For noninflammatory NAR, it is postulated that an abnormality in the autonomic nervous system is present with increased concentrations of intranasal neuropeptides. These are often triggered by perfumes, strong odors, changes in climate, and smoke. Specific subtypes likely have unique pathophysiologies:
  1. Infectious rhinosinusitis: Viral, bacterial, or fungal infections. Typically occurs following an acute viral infection.
  2. Nonallergic rhinitis with eosinophilia syndrome (NARES): Unknown etiology.
  3. Gustatory rhinitis: Abnormal vagally mediated rhinitis after ingestion of any food.
  4. Atrophic rhinitis: Unknown etiology but bacterial infection is thought to be involved.
  5. Rhinitis medicamentosa: Rebound nasal congestion from prolonged use of decongestant/vasoconstrictor agents (phenylephrine, oxymetazoline). Can also occur from cocaine, α-receptor antagonist, or phosphodiesterase-5-selective inhibitors.
  6. Hormone-induced rhinitis: Pregnancy-associated, menstrual cycle–associated, and oral contraceptive–related hormonal changes.
  7. Rhinitis associated with systemic disease: Severe hypothyroidism, diabetes mellitus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Allergic rhinitis (sensitivity to pollens, indoor allergens, occupational allergens)
- Systemic diseases with nasal manifestations (e.g., systemic lupus erythematosus, granulomatous disease, GERD)
- Mechanical obstruction (e.g., deviated septum, nasal polyps, nasal neoplasms, foreign bodies)
- Cerebral spinal fluid (CSF) leak from head trauma as it may represent a skull base fracture, postoperative complication from sinus surgery, or spontaneous leak
- Local allergic rhinitis
- Chronic rhinosinusitis
- Box 1 summarizes the differential diagnosis in chronic rhinitis

WORKUP

- A detailed history and physical examination can be helpful to determine if diagnostic testing is necessary.
- Distinguishing NAR from allergic rhinitis or other forms of rhinitis can be difficult, but a detailed history (lack of allergic symptoms such as sneezing, nasal pruritus) can be helpful. Questionnaires, including the Cincinnati Irritant Index Scale, have proven useful in differentiating NAR from allergic rhinitis.
  1. Because allergic rhinitis cannot be definitively ruled out with history alone, skin testing or assessment for serum-specific IgE should be considered. Adding to the diagnostic complexity, many individuals have a "mixed form" of rhinitis including both allergic and nonallergic types.
  2. Given the common overlap between NAR and AR, it may be reasonable to revisit diagnostic testing if patients do not respond to therapy as expected.
- Although not typically performed routinely in a clinical setting, examination of nasal smears for the presence of neutrophils and eosinophils may be helpful.

TABLE 1 Medications Associated with Chronic Nasal Symptoms

Category	Example(s)
Antihypertensives	Angiotensin-converting enzyme inhibitors
	β-Adrenergic blockers
	Amiloride
	Prazocin
	Hydralazine
Psychotropics	Risperidone
	Chlorpromazine
	Amitriptyline
Phosphodiesterase-5 inhibitors	Sildenafil
	Tadalafil
	Vardenafil
Nonsteroidal antiinflammatory drugs	Ibuprofen
Others	Gabapentin

From Adkinson NF et al: *Middleton's allergy principles and practice,* ed 8, Philadelphia, 2014, Elsevier.

TABLE 2 Occupations with Increased Prevalence of Work-Related Rhinitis

Category	Occupation	Likely Trigger
Irritant	Drywall installer	Gypsum dust
	Makeup artist	Cosmetic powder, perfume
Corrosive	Janitor	Ammonia
	Chemistry technician	Hydrochloric acid
Immunologic		
Immunoglobulin E	Baker	Grain flour
	Furrier	Animal dander
	Livestock breeder	Animal dander
	Veterinarian	Animal dander
	Food-processing worker	Foodstuffs
	Pharmacist	Medication powders
Low-molecular-weight substances	Boat builder	Anhydrides

From Adkinson NF et al: *Middleton's allergy principles and practice,* ed 8, Philadelphia, 2014, Elsevier.

- Anterior rhinoscopy or nasal endoscopy may be necessary to rule out nasal polyps or anatomic deformity, which may contribute to chronic rhinorrhea.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Identification and avoidance of specific triggers (e.g., smoke/smog, specific foods, perfumes, strong odors, occupational irritants) may provide relief.
- Discontinuing any medication/drugs that could be contributing, including topical decongestants/vasoconstrictors, oral contraceptives (OCPs), cocaine, and alcohol (Table 1).
- Daily nasal lavage (distilled water mixed with saline packets) and over-the-counter nasal saline sprays have been shown to improve symptoms.
- Surgical intervention (turbinectomy, vidian nerve resection, turbinoplasty) may be considered if medical measures fail, but such surgeries are not commonly performed in the U.S. There is limited data showing the efficacy of turbinoplasty with regard to symptom reduction, although there is a risk of empty nose syndrome (ENS).

ACUTE AND CHRONIC Rx

- Second-generation antihistamines have not been shown to be beneficial in nonallergic rhinitis. Although first-generation antihistamines may improve rhinorrhea due to their anticholinergic properties, topical therapies including intranasal steroids (fluticasone propionate, triamcinolone, mometasone), intranasal antihistamines (azelastine, olopatadine), and intranasal anticholinergics (ipratropium bromide) have been shown to be most efficacious.
- Treatments should be individualized to the underlying pathophysiology.
  1. *Vasomotor rhinitis:* Initial therapy typically involves intranasal steroids with the addition of an intranasal antihistamine or intranasal ipratropium bromide if symptoms are not well controlled. A combination intranasal steroid and intranasal antihistamine is now available that may be more convenient.
  2. *Infectious rhinosinusitis:* Supportive care and intranasal saline spray. May take up to 6 to 8 wk to improve after resolution of acute infection.
  3. *Nonallergic rhinitis with eosinophilia syndrome (NARES):* Topical nasal corticosteroids.
  4. *Gustatory rhinitis*: Preprandial intranasal ipratropium bromide and/or dietary modification also may be useful in patients with specific triggers.
  5. *Atrophic rhinitis:* Frequent irrigation with nasal saline, antibiotics to treat potential underlying bacterial infection; debridement and possible surgical intervention to reduce nasal cavity size can be considered.
  6. *Rhinitis medicamentosa:* Discontinuation of offending agent (topical decongestant/vasoconstrictor agent, cocaine, α-receptor antagonist or phosphodiesterase-5-selective inhibitors). Patient may require short course of nasal or oral corticosteroids during withdrawal process.
  7. *Hormone-induced rhinitis:* Typically resolves with delivery if during pregnancy. Consider discontinuing OCP if offending agent. Nasal saline spray alone can be efficacious.
  8. *Rhinitis associated with systemic disease:* Optimally managing the underlying condition.
  9. *Rhinitis in the elderly:* Intranasal ipratropium bromide.
- Several studies have shown that repeated administration of topical capsaicin has a long-term beneficial effect on symptoms in patients with idiopathic rhinitis. Comparative studies on NAR with capsaicin vs. steroids demonstrate the superiority of capsaicin; however, the exact dose and frequency have not been determined.
- Alternative treatments: Silver nitrate, acupuncture.

DISPOSITION

Most patients experience mild to moderate symptomatic relief with avoidance of triggers and appropriate use of medications. Up to 52% of patients with NAR report worsening symptoms at 3- to 7-yr follow-ups. Periodic reevaluations should be performed, as there is evidence supporting increase in comorbidities (asthma, allergic rhinitis, conjunctivitis) with length of NAR diagnosis.

Furthermore, diagnostic testing is not precise for NAR versus AR. In a systematic review published in 2017, Nasal Allergen Provocation Testing (NAPT) was shown to better separate patients with NAR versus AR. Approximately 26% of patients presumed to have NAR had positive testing with NAPT despite negative skin-prick and/or serum IgE testing. It would be reasonable to revisit the diagnosis periodically and adjust management.

BOX 1 Differential Diagnosis in Chronic Rhinitis

- Concha bullosa
- Nasal septal deviation
- Adenoidal enlargement
- Nasal polyps
- Nasal cancer
- Nasal foreign body
- Basilar skull fracture
- Allergic rhinitis
- Cholinergic toxidromes
- Relapsing polychondritis
- Hypertrophic turbinates without rhinitis
- Choanal atresia
- Sarcoidosis
- Primary ciliary dyskinesia

Adapted from Adkinson NF et al: *Middleton's allergy principles and practice,* ed 8, Philadelphia, 2014, Elsevier.

REFERRAL

Referral to allergist and/or ENT may be appropriate when severe symptoms are unresponsive to standard therapy and/or diagnosis is uncertain.

PEARLS & CONSIDERATIONS

COMMENTS

- Nonallergic rhinitis symptoms are nonspecific, and a specific trigger is often never identified. Compared to allergic rhinitis, patients typically lack symptoms of sneezing, nasal pruritus, and conjunctival symptoms.
- Second-generation oral antihistamines are typically not efficacious, and the treatment of nonallergic rhinitis should be individualized based on its underlying pathophysiology.

BASIC INFORMATION

DEFINITION

Non-celiac gluten sensitivity (NCGS) is an intestinal and/or extraintestinal reaction to ingested gluten or wheat that improves once gluten-containing foods have been eliminated from the diet. Gluten is a group of proteins found in grains (wheat, rye, barley, and oats). The two main protein components of gluten are gliadin and glutenin. Celiac disease and wheat allergy must be excluded before the diagnosis of NCGS can be made.

SYNONYMS

Non-celiac wheat sensitivity (NCWS)
NCGS

ICD-10CM CODE
K90.41 Non-celiac gluten sensitivity

EPIDEMIOLOGY & DEMOGRAPHICS

- Prevalence of NCGS ranges from 0.6% to 13% in the general population. Its actual prevalence is not well established due to the absence of diagnostic markers and is based primarily on self-reported questionnaires for gluten sensitivity.
- Reported prevalence has increased significantly over the past decade, directly correlating to the increase in sales of gluten-free foods, which have doubled since 2011.
- NCGS is reported more often in women than in men.
- It is more commonly reported in urban areas.
- The median age of diagnosis is in the fourth decade of life.

PHYSICAL FINDINGS AND CLINICAL PRESENTATION

- Intestinal symptoms include abdominal pain, bloating, diarrhea (with or without alternating constipation), and flatulence.
- Extraintestinal findings may include constitutional symptoms such as fatigue and weight loss as well as neurological changes (headache, brain fog, numbness) and psychological changes (anxiety). Less commonly, anemia and dermatological findings such as eczema may be seen.
- Symptoms of NCGS greatly overlap with IBS and therefore may be difficult to distinguish.

ETIOLOGY

- There is no known biomarker or diagnostic test for NCGS, making the pathogenesis unclear.
- It has been suggested that in patients with NCGS, ingestion of gluten may lead to increased intestinal permeability by increasing serum concentration of zonulin, a protein that increases permeability through changes in epithelial tight junctions. The rise in zonulin leads to breaks and leakage through the intestinal epithelial wall.
- Several studies have found changes in the intestinal microbiome of patients with NCGS compared with those in healthy controls. These changes revert to normal following initiation of a gluten-free diet (GFD).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Celiac disease
- Wheat allergy
- Irritable bowel syndrome (IBS)

WORKUP

- There are no strict diagnostic criteria; therefore, there is a great deal of dependence on the patient's perception of symptoms and nocebo effect.
- Salerno Experts' Criteria is the most widely used method for diagnosing NCGS.
  1. Patient must be on a normal gluten-containing diet for at least 6 weeks. During this time, the patient is assessed by a diagnostic questionnaire (Table E1) at week –2, –1, and 0 to establish baseline symptoms.
  2. At time 0, patient begins a strict GFD as instructed by a dietician. Patient will remain on GFD for 6 weeks with weekly data recording via the questionnaire.
  3. Response is assessed, with a positive result defined as a decrease of ≥30% in the baseline score in 1 to 3 categories for ≥50% of the observation time.
  4. The diagnosis of NCGS is excluded in subjects failing to show symptomatic improvement after six weeks. These patients should be worked up for other causes of IBS-like symptoms, including intolerance to fermentable oligo-, di- and monosaccharides and polyols (FODMAPS) or small bowel bacterial overgrowth.
  5. This 6-wk test study is followed by a double-blind placebo-controlled challenge of ≥8 g/day of gluten (or placebo) for a week of each. Gluten is given in a "vehicle" such as a bar, bread, or muffin. Gluten and placebo must be indistinguishable in look, texture, and taste.
  6. Again, a positive result is defined as a variation of ≥30% between gluten and placebo.
  7. While the Salerno Expert Criteria is the proposed method for diagnosis of NCGS, it is often impractical to perform in the primary care setting. Therefore, simply asking the patient to adopt a GFD will achieve the same desired clinical outcome.

LABORATORY TESTS

- Mainly a clinical diagnosis as there are no diagnostic tests or biomarkers for NCGS
- Celiac disease and wheat allergy must be excluded through their respective laboratory tests prior to the diagnosis of NCGS

TREATMENT

NONPHARMACOLOGIC THERAPY

Treatment of NCGS is strict elimination of gluten from the diet. A low-FODMAPS diet may be indicated if symptoms are not responding to a GFD.

ACUTE GENERAL Rx

- Correct nutritional deficiencies
- Lifelong elimination of gluten or wheat

DISPOSITION

Unlike celiac disease, which requires a strict, lifelong gluten-free diet, it is unclear whether NCGS is a permanent condition. Some authors have suggested reintroduction of gluten after 1 to 2 yr.

REFERRAL

A multidisciplinary team approach is recommended for patients with NCGS, with involvement of the primary doctor, gastroenterologist, and nutritionist.

PEARLS AND CONSIDERATIONS

COMMENTS

- The gluten-free market is rising, likely due to the perceived health benefits of a GFD. This, however, is debatable, as grains should be the main energy source in the human diet. A GFD is poor in trace elements and vitamins such as zinc, iron, magnesium, calcium, vitamin D, vitamin B_{12}, folate, and fiber. It is also high in calories, fat, sugar, and salt.
- Studies show that intake of gluten through whole grains is associated with a lower risk of elevated triglycerides and lower risk of cardiovascular disease.

Non-Hodgkin Lymphoma ALG PTG

BASIC INFORMATION

DEFINITION

Non-Hodgkin lymphoma (NHL) is a heterogeneous group of malignancies of the lymphoreticular system. There are approximately 60 different NHL subtypes. The WHO classification of lymphomas is summarized in Table 1 and Fig. 1.

SYNONYM

NHL

ICD-10CM CODES

C85.90 Non-Hodgkin lymphoma, unspecified, unspecified site
C85.91 Non-Hodgkin lymphoma, unspecified, lymph nodes of head, face, and neck
C85.92 Non-Hodgkin lymphoma, unspecified, intrathoracic lymph nodes
C85.93 Non-Hodgkin lymphoma, unspecified, intra-abdominal lymph nodes
C85.94 Non-Hodgkin lymphoma, unspecified, lymph nodes of axilla and upper limb
C85.95 Non-Hodgkin lymphoma, unspecified, lymph nodes of inguinal region and lower limb
C85.96 Non-Hodgkin lymphoma, unspecified, intrapelvic lymph nodes
C85.97 Non-Hodgkin lymphoma, unspecified, spleen
C85.98 Non-Hodgkin lymphoma, unspecified, lymph nodes of multiple sites
C85.99 Non-Hodgkin lymphoma, unspecified, extranodal and solid organ sites

EPIDEMIOLOGY

- Sixth most common neoplasm in the U.S. (>70,000 new cases annually). Incidence increases with age; majority of patients are above 60 yr of age.
- In the U.S. and Europe, diffuse large B-cell lymphoma (DLBCL) is the most common subtype (30% of the cases), and follicular lymphoma (FL) is the second most common subtype (25% of the cases).
- In patients with HIV, NHL is the most common tumor (followed by Kaposi sarcoma). DLBCL accounts for 80% to 90% of the cases of HIV-associated NHL.
- Factors associated with an increased risk of non-Hodgkin lymphoma are summarized in Box 1.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients often present with lymphadenopathy.
- Approximately one third of the NHL involve extranodal sites, which can result in

TABLE 1 World Health Organization Classification of Lymphomas[a]

Mature B-Cell Neoplasms

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma

- B-cell prolymphocytic leukemia
- Splenic B-cell marginal zone lymphoma
- Hairy cell leukemia
- *Splenic B-cell lymphoma/leukemia, unclassifiable*
- *Splenic diffuse red pulp small B-cell lymphoma*
- *Hairy cell leukemia-variant*
- Lymphoplasmacytic lymphoma
- Waldenström macroglobulinemia
- Heavy chain diseases
- Alpha heavy chain disease
- Gamma heavy chain disease
- Mu heavy chain disease

Plasma Cell Myeloma

- Solitary plasmacytoma of bone
- Extraosseous plasmacytoma

Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT Lymphoma)

- Nodal marginal zone lymphoma
- *Pediatric nodal marginal zone lymphoma*

Follicular Lymphoma

- *Pediatric-type follicular lymphoma*
- Primary cutaneous follicle center lymphoma

Mantle Cell Lymphoma

Diffuse Large B-Cell Lymphoma (DLBCL), NOS

- T-cell/histiocyte–rich large B-cell lymphoma
- Primary DLBCL of the CNS
- Primary cutaneous DLBCL, leg type
- EBV-positive DLBCL
- DLBCL associated with chronic inflammation
- Lymphomatoid granulomatosis
- Primary mediastinal (thymic) large B-cell lymphoma
- Intravascular large B-cell lymphoma
- ALK-positive large B-cell lymphoma
- Plasmablastic lymphoma
- HHV8-positive diffuse large B-cell lymphoma and primary effusion lymphoma
- Burkitt lymphoma
- High grade B-cell lymphomas, with *MYC* and *BCL2* and/or *BCL6* rearrangements
- B-cell lymphoma unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classic Hodgkin lymphoma

Mature T-Cell and NK-Cell Neoplasms

- T-cell prolymphocytic leukemia
- T-cell large granular lymphocytic leukemia
- *Chronic lymphoproliferative disorder of NK-cells*
- Aggressive NK leukemia
- Systemic EBV-positive T-cell lymphoma of childhood
- Hydroa vacciniforme-like lymphoma
- Adult T-cell leukemia/lymphoma
- Extranodal NK/T-cell lymphoma, nasal type
- Enteropathy-associated T-cell lymphoma
- Monomorphic epitheliotropic intestinal T-cell lymphoma
- Hepatosplenic T-cell lymphoma
- Subcutaneous panniculitis-like T-cell lymphoma

Mycosis Fungoides

- Sézary syndrome
- Primary cutaneous CD30-positive T-cell lymphoproliferative disorders
- Lymphoid papulosis
- Primary cutaneous anaplastic large cell lymphoma
- Primary cutaneous gamma-delta T-cell lymphoma
- Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
- Primary cutaneous CD4-positive small/medium T-cell lymphoproliferative disease

Peripheral T-Cell Lymphoma, NOS

Angioimmunoblastic T-Cell Lymphoma

Anaplastic Large Cell Lymphoma, ALK-Positive

- Anaplastic large cell lymphoma, ALK-negative

Hodgkin Lymphoma

Nodular Lymphocyte Predominant Hodgkin Lymphoma

Classic Hodgkin Lymphoma

Nodular Sclerosis Hodgkin Lymphoma

- Lymphocyte-rich classic Hodgkin lymphoma
- Mixed cellularity classic Hodgkin lymphoma
- Lymphocyte-depleted classic Hodgkin lymphoma

[a]Most common entities are underlined. Provisional entities are in italics. Some rare entities or variants are omitted.

BOX 1 Factors Associated with an Increased Risk of Non-Hodgkin Lymphoma

- Immunosuppression, acquired
  - After solid-organ or hematopoietic stem cell transplantation
  - HIV/AIDS
- Congenital immunodeficiency syndromes
- Increasing age (waning immunity)
- Previous history of HL or NHL
- Family history of NHL
- Drugs
  - Methotrexate
  - TNF-α inhibitors
- Occupational exposures
  - Herbicides, pesticides, wood dust, epoxy glue, organic solvents
  - Farming, forestry, painting, carpentry, tanning

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus; *HL,* Hodgkin lymphoma; *NHL,* non-Hodgkin lymphoma; *TNF,* Tumor necrosis factor.
From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

unusual presentations (e.g., gastrointestinal tract involvement can simulate peptic ulcer disease).
- Presence of B symptoms like unexplained weight loss, fever, fatigue, and night sweats are seen typically in aggressive or highly aggressive lymphomas.
- Aggressive lymphomas have acute or subacute presentation with increasing size of the mass and B symptoms.
- Indolent lymphomas have a more chronic course, with asymptomatic lymphadenopathy and/or slowly progressive cytopenias.
- Hepatomegaly and splenomegaly may be present.
- Cough, dyspnea with bulky mediastinal involvement.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hodgkin lymphoma
- Viral infections
- Metastatic carcinoma
- Autoimmune conditions
- Sarcoidosis

WORKUP

Initial laboratory evaluation may be entirely normal. Elevated LDH may be seen in aggressive lymphoma or in indolent lymphoma with high disease bulk. In cases of highly aggressive NHL (e.g., Burkitt lymphoma), spontaneous tumor lysis syndrome (TLS) may be seen, but rarely; it is characterized by hyperkalemia, hyperuricemia, hypocalcemia, hyperphosphatemia, and acidosis. TLS can be life threatening and is considered a medical emergency. Acute management includes aggressive IV fluid repletion and rasburicase. Proper staging of NHL includes the following:
- A thorough history and physical examination.
- Excisional or incisional surgical biopsy is preferred. Image-guided core needle biopsies may be acceptable in patients without peripheral adenopathy. Fine needle aspirates are not adequate for precise lymphoma subclassification. Laparoscopic lymph node biopsy or mediastinoscopy can be used on an outpatient basis for most patients with intraabdominal or mediastinal lymphoma, respectively.
- Tissue biopsy with histologic, immunophenotypic, and genetic studies interpretation.

TABLE 2 Major Molecular Alterations in Non-Hodgkin Lymphomas

NHL Histologic Type	Alteration	Cases Affected (%)	Proto-Oncogene Involved	Mechanism of Proto-Oncogene Activation	Proto-Oncogene Function
Lymphoplasmacytic lymphoma	*MYD88* L265P mutation	95	*MYD88*	Activation	B-cell signaling
Follicular lymphoma	t(14;18)(q32;q21)	90	*BCL-2*	Transcription deregulation	Negative regulator of apoptosis
Mantle cell lymphoma	t(11;14)(q13;q32)	70	*BCL-1/cyclin D1*	Transcription deregulation	Cell cycle regulator
MALT lymphoma	t(11;18)(q21;q21)	50	*API_2/MLT*	Fusion protein	*API_2* has antiapoptotic activity
	t(1;14)(p22;q32)		*BCL-10*	Transcription deregulation	Antiapoptosis
Diffuse large B-cell lymphoma	der(3)(q27)	35	*BCL-6*	Transcription deregulation	Transcriptional repressor required for GC formation
	t(14;18)(q32;q21)	15	*BCL-2*	Transcription deregulation	Negative regulator of apoptosis
	t(8;14)(q24;q32)	10	MYC	Transcription deregulation	Transcription factor regulating cell proliferation and growth
Burkitt lymphoma	t(8;14)(q24;q32)	80	MYC	Transcription deregulation	Transcription factor regulating cell proliferation and growth
	t(2;8)(p11;q24)	15	MYC		
	t(8;22)(q24;q11)	5	MYC		
Anaplastic large T-cell lymphoma	t(2;5)(p23;q35)	60	NPM/ALK	Fusion protein	*ALK* is a tyrosine kinase

GC, Gastric cancer; *MALT,* mucosa-associated lymphoid tissue; *NHL,* non-Hodgkin lymphoma.
From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

Major molecular alterations in non-Hodgkin lymphomas are summarized in Table 2.

- Routine laboratory evaluation (complete blood count, flow cytometry in selected circumstances, ESR, urinalysis, LDH, blood urea nitrogen, creatinine, serum calcium, uric acid, liver function tests, serum protein electrophoresis).
- HIV and hepatitis B testing.
- Bone marrow evaluation (aspirate and biopsy) (Fig. E2).
- CT scan of chest, abdomen, and pelvis with IV contrast, if possible.
- Fluorine-18 fluorodeoxyglucose (FDG) positron emission tomography (PET) integrated with CT (Fig. E3) has emerged as a powerful tool for staging, response evaluation, and posttreatment surveillance in patients with aggressive subtypes of NHL.
- Depending on the histopathology, the results of the previous studies, and the planned therapy, some other tests may be performed.
- Lumbar puncture is needed in some patients with aggressive NHL, and most patients with HIV-associated NHL, to evaluate for CNS involvement by lymphoma.
- The evaluation of a new patient with non-Hodgkin lymphoma is summarized in Table 3.

CLASSIFICATION: For clinical approach, NHL is subdivided lymphomas into indolent, aggressive, and highly aggressive disease.

STAGING: The Ann Arbor staging system that was initially developed for Hodgkin lymphoma (HL) was revised as the Lugano criteria and remains the current standard; but unlike HL, NHL does not spread predictably via lymphatic channels to contiguous nodal regions, so stage is only one of multiple contributors to prognosis (Table 4). Histopathology has greater therapeutic implications in NHL than in Hodgkin lymphoma.

TABLE 3 Evaluation of a New Patient with Non-Hodgkin Lymphoma

Evaluation	Mandatory	As Indicated
Confirm diagnosis	Adequate biopsy reviewed by experienced hematopathologists	Immunophenotyping with immunohistochemistry +/– flow cytometry Cytogenetics/molecular studies
General overview and risks of therapy	History and physical examination Complete blood cell count Chemistry screen (including liver and renal function studies) HIV serology Hepatitis B serologies	Blood coagulation studies EBV serology and PCR assay Hepatitis C serology Serum electrolytes, uric acid Assessment of cardiac ejection fraction Pregnancy testing in women Discussion of fertility issues
Prognostic categorization	Serum lactate dehydrogenase Serum albumin	Erythrocyte sedimentation rate Serum β_2-microglobulin
Anatomic disease	Chest, abdominal, and pelvic CT with contrast enhancement	Ultrasonography FDG-PET/CT MRI
Occult sites of involvement		Unilateral bone marrow biopsy with aspirate Lumbar puncture with flow cytometry of CSF Biopsy of suspicious sites Blood flow cytometry

TABLE 4 Non-Hodgkin Lymphoma: Lugano Staging Classification

Stage	Features
I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring), or a single extranodal location without nodal involvement (IE)
II	Involvement of two or more lymph node regions on the same side of the diaphragm or limited nodal disease with limited contiguous extranodal involvement (IIE)
III	Involvement of lymph node regions or structures on both sides of the diaphragm
IV	Involvement of diffuse or noncontiguous extranodal site(s)

From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

Fig. 4 illustrates a diagnostic algorithm outlining the steps in classification of B-cell lymphomas composed of cells of small to intermediate size.

Rx TREATMENT

ACUTE GENERAL Rx

The therapeutic regimen varies with specific lymphoma subtype and pathologic stage. Following are the commonly used therapeutic modalities:

INDOLENT NHL:

- Deferment of therapy and careful observation in asymptomatic patients with low volume disease.
- Local radiotherapy for stage I disease.
- Rituximab, an anti-CD20 monoclonal antibody, with or without chemotherapy is used in patients with symptomatic or progressive disease.
- The addition of rituximab to chemotherapy is generally well tolerated and has increased response and survival rates in NHL patients. Patients who received rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisone (R-CHOP) had higher response rates (96% vs. 90%) with a better 2-yr overall survival rate (95% vs. 90%) than patients who received CHOP without rituximab. Similarly, patients who received rituximab, cyclophosphamide, vincristine, and prednisone (R-CVP) had higher response rates (81% vs. 57%) and better overall survival at 4 yr (83% vs. 77%) than patients who were treated with CVP without rituximab.
- In a recent phase III noninferiority study, the combination of bendamustine and rituximab was associated with better progression-free survival rates than R-CHOP (70 vs. 31 mo) with fewer toxic effects. Subset analyses showed better progression-free survival in patients with follicular lymphoma, mantle cell lymphoma, and lymphoplasmacytic lymphoma.
- Maintenance rituximab after rituximab-containing regimens has been associated with a better progression-free survival at 3 yr (75% vs. 58%) than observation alone without a difference in overall survival.
- The combination of obinutuzumab and chemotherapy followed by obinutuzumab maintenance was approved by the FDA in previously untreated patients with follicular lymphoma based on a randomized study, in which obinutuzumab and chemotherapy were associated with longer median progression-free survival than rituximab and chemotherapy.

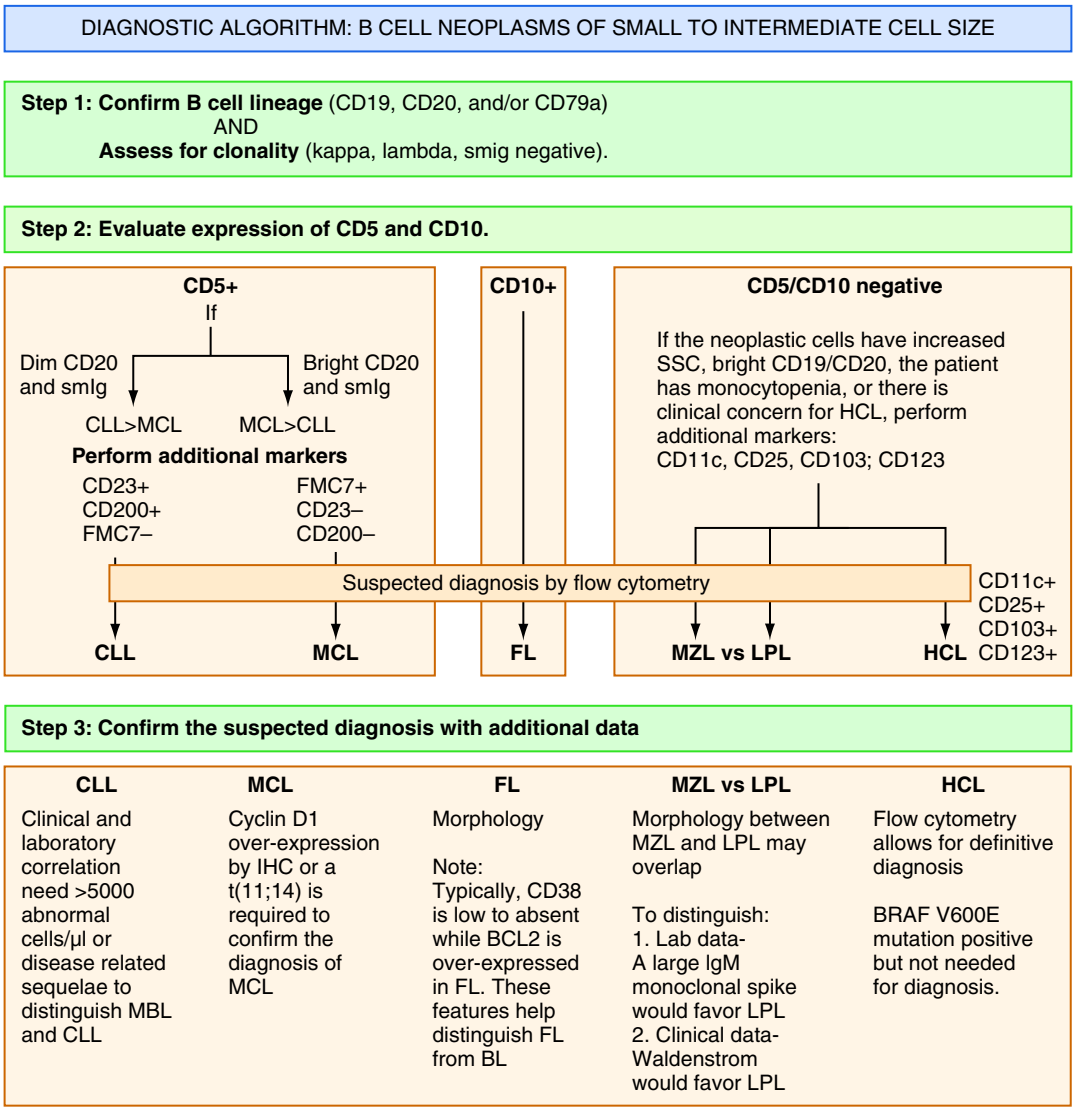

FIG. 4 This diagnostic algorithm outlines the steps in classification of B-cell lymphomas composed of cells of small to intermediate size. *BL,* Burkitt lymphoma; *CLL,* chronic lymphocytic leukemia; *FL,* follicular lymphoma; *HCL,* hairy cell leukemia; *IgM,* immunoglobulin M; *IHC,* immunohistochemistry; *LPL,* lymphoplasmacytic lymphoma; *MBL,* monoclonal B-cell lymphocytosis; *MCL,* mantle cell lymphoma; *MZL,* marginal zone lymphoma; *SmIg,* surface immunoglobulin; *SSC,* scleroderma and systemic sclerosis. (From McPherson RA, Pincus MR: *Henry's clinical diagnosis and management by laboratory methods,* ed 23, Philadelphia, 2017, Elsevier.)

- The combination of obinutuzumab and bendamustine followed by obinutuzumab maintenance was approved by the FDA for the treatment of patients with rituximab-refractory follicular lymphoma.
- The oral BTK inhibitor ibrutinib is FDA-approved for the treatment of patients with relapsed mantle cell lymphoma, lymphoplasmacytic lymphoma, and marginal zone lymphoma. Acalabrutinib, a second-generation BTK inhibitor, has also been approved for relapsed mantle cell lymphoma.
- The oral PI3K inhibitors idelalisib and copanlisib, as well as the novel anti-CD20 monoclonal antibody obinutuzumab, have been FDA-approved for the treatment of relapsed follicular lymphoma.
- The proteasome inhibitor bortezomib and the immunomodulating agent lenalidomide are FDA-approved for the treatment of relapsed mantle cell lymphoma.
- *H. pylori*-associated gastric marginal zone lymphoma can be treated with a course of antibiotics. For persistent cases after eradication or *H. pylori*-negative cases, radiotherapy is highly effective.
- Splenic marginal zone lymphoma is typically treated with rituximab or splenectomy. Chemoimmunotherapy or ibrutinib may be appropriate in relapsed disease.
- Stem cell transplantation (autologous or allogeneic) may confer long-term disease control in multiple relapsed or refractory disease.
- Table 5 summarizes chemotherapy regimens in indolent lymphomas.

AGGRESSIVE NHL: The most common aggressive NHL is DLBCL. The addition of rituximab against CD20 B-cell lymphoma to the CHOP regimen (R-CHOP) increased the complete response rate and prolonged overall survival in patients with DLBCL, based on randomized controlled trials, without clinically significant increase in toxicity. R-CHOP has shown to be safe and effective in patients with HIV-associated NHL with CD4+ counts >50 cells/mm^3.

Most common regimens used in DLBCL include:

- Three cycles of R-CHOP followed by involved-field radiotherapy or 6 cycles of R-CHOP alone are appropriate approaches in patients with localized DLBCL.
- 6 cycles of R-CHOP with or without radiotherapy are appropriate in patients with advanced-stage DLBCL.
- For patients with double-hit lymphomas (defined as harboring rearrangement of MYC, BCL-2, and/or BCL-6), who have poorer outcomes to R-CHOP than regular DLBCL, the use of R-EPOCH (infusional etoposide, doxorubicin, and vincristine, along with cyclophosphamide, prednisone, and rituximab) might also be effective.
- Granulocyte-colony stimulating factor (e.g., filgrastim, MYC) may be effective in reducing the risk of febrile neutropenia in patients over 65 yr with aggressive lymphoma undergoing chemotherapy.
- Treatment with high-dose chemotherapy and autologous bone marrow transplant: Compared with conventional chemotherapy, increases overall survival in patients with chemotherapy-sensitive relapsed DLBCL.
- Chimeric antigen receptor T-cell therapy was recently approved for patients with relapsed or refractory diffuse large B-cell lymphoma after two prior lines of chemotherapy.
- Combination chemotherapy regimens for NHL are described in Table 6.

HIGHLY AGGRESSIVE NHL: The most common high-grade NHL subtype is Burkitt lymphoma (BL). BL affects younger patients than DLBCL and is common in HIV-infected individuals. Regimens more intensive than R-CHOP are needed to cure patients with high-grade NHL. The most commonly used multi-agent regimens include hyper-CVAD, CODOX-M/IVAC, and dose-adjusted EPOCH, usually in combination with rituximab. The 5-yr survival approximates 75%.

DISPOSITION

- Patients with indolent NHL in the rituximab era experience long survival despite the

TABLE 5 Chemotherapy Regimens in Indolent Lymphomas

BR (Every 28 Days)
- Bendamustine 120 mg/m^2 days 1 and 2
- Rituximab 375 mg/m^2 IV day 1

CVP-R (Every 21 Days)
- Cyclophosphamide 750 mg/m^2 IV on day 1
- Vincristine 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- Prednisone 40 mg/m^2 daily PO days 1-5
- Rituximab 375 mg/m^2 IV day 1[32]

R-CHOP (Every 21 Days)
- Cyclophosphamide 750 mg/m^2 IV on day 1
- Doxorubicin 50 mg/m^2 IV on day 1
- Vincristine 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- Prednisone 100 mg daily orally on days 1-5
- Rituximab 375 mg/m^2 IV on day 1 of each therapy cycle[33] or by alternate schedule[34]

CNOP (Every 21 Days)
- Cyclophosphamide 750 mg/m^2 IV on day 1
- Mitoxantrone 10 mg/m^2 IV on day 1
- Vincristine 1.4 mg/m^2, up to a maximal dose of 2 mg IV, on day 1
- Prednisone 50 mg/m^2 daily orally on days 1-5

R-CHVP-IFN (Every 28 Days for 6 Mo, Then Every 2 Mo for 6 Mo). [35]
- Cyclophosphamide 600 mg/m^2
- Doxorubicin 25 mg/m^2
- Etoposide 100 mg/m^2 on day 1 (replaces original teniposide 60 mg/m^2 on day 1)
- Prednisolone 40 mg/m^2 on days 1-5
- Interferon-α 5-3 times a wk
- Patients being treated with R-CHVP also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle for 6 cycles

FMD (Every 28 Days)
- Fludarabine 25 mg/m^2 IV on day 1-3
- Mitoxantrone 10 mg/m^2 IV on day 1
- Dexamethasone 20 mg/day PO days 1-5
- Patients being treated with R-FMD also received 375 mg/m^2 of rituximab IV on day 1 of each therapy cycle

ProMACE-MOPP
- Cycles repeated every 28 days

Day 1
- Cyclophosphamide 650 mg/m^2 IV
- Doxorubicin 25 mg/m^2 IV
- Etoposide 120 mg/m^2 IV
- Prednisone 60 mg/m^2 orally daily days 1-14

Day 8
- Mechlorethamine 6 mg/m^2 IV
- Vincristine 1.4 mg/m^2 (maximum 2 mg) IV on day 8
- Procarbazine 100 mg/m^2 orally daily days 8-14

Day 15
- Methotrexate 500 mg/m^2 IV on day 15 with leucovorin 50 mg/m^2 orally every 6 hours for four doses beginning 24 hours after methotrexate

R-Hyper-CVAD (Every 21 Days)[36]

Cycles 1, 3, 5, and 7
- Rituximab 375 mg/m^2 IV on day 1
- Cyclophosphamide (with mesna) 300 mg/m^2 IV over 3 hours every 12 hours on days 2-4 (total 6 doses)
- Vincristine 1.4 mg/m^2 (maximum 2 mg) IV on days 5 and 12
- Doxorubicin 16.6 mg/m^2 IV by continuous infusion on days 5-7
- Dexamethasone 40 mg/day PO/IV on days 2–5 and days 12-15

Cycles 2, 4, 6, and 8
- Rituximab 375 mg/m^2 IV on day 1
- Methotrexate 200 mg/m^2 IV over 2 hours, followed by 800 mg/m^2 IV continuous infusion over 22 hours on day 2
- Leucovorin 50 mg PO starting 12 hours after completion of methotrexate infusion, followed by 15 mg PO every 6 hours for 8 dosed until the methotrexate level is less than 0.1 μM/L
- Cytarabine 3000 mg/m^2 IV over 2 hours every 12 hours on days 3 and 4 (4 doses total)

Rituximab Monotherapy

Rituximab 375 mg/m^2 weekly for 4 wk

From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

lack of curative potential of chemoimmunotherapy. Patients with aggressive NHL may achieve a cure with chemoimmunotherapy.

- Complete remission occurs in 50% to 60% of patients with aggressive NHL. Prognostic factors include the lymphoma subtype, age of patient, and extent of disease. Table 7 describes the International Prognostic Index (IPI) for aggressive lymphomas. More recently, studies of the IPI in the modern era incorporating the anti-CD20 monoclonal antibody rituximab show an overall improved prognosis with 33% of the highest-risk patients alive 5 yr from diagnosis and 96% in the lowest risk.
- Patients who present with HIV-related NHL and low CD4+ cell count have a poor prognosis (median duration of survival is 15 to 34 mo). Despite therapeutic advances, the management of HIV-associated lymphomas is challenging due to potential pharmacologic interactions and increased risk of infectious complications. It is important to optimize the CD4 cell count during treatment. Referral to an HIV oncologist is recommended.

BASIC INFORMATION

DEFINITION

Obesity refers to having an excess amount of body fat in relation to lean body mass, or a body mass index (BMI) of ≥30 kg/m^2. Overweight is defined as BMI of 25 to 29.9 kg/m^2, and morbid obesity refers to adults with a BMI ≥40 kg/m^2. BMI is used as a surrogate measure of obesity. Abdominal obesity is defined as waist circumference >102 cm (40 inches) in men and >88 cm (35 inches) in women.

ICD-10CM CODES

E66.01	Morbid (severe) obesity due to excess calories
E66.09	Other obesity due to excess calories
E66.1	Drug-induced obesity
E66.2	Morbid (severe) obesity with alveolar hypoventilation
E66.8	Other obesity
E66.9	Obesity, unspecified
O99.210	Obesity complicating pregnancy, unspecified trimester
O99.211	Obesity complicating pregnancy, first trimester
O99.212	Obesity complicating pregnancy, second trimester
O99.213	Obesity complicating pregnancy, third trimester
O99.214	Obesity complicating childbirth
O99.215	Obesity complicating the puerperium

EPIDEMIOLOGY & DEMOGRAPHICS

- The World Health Organization first recognized obesity as a worldwide epidemic in 1997. As of 2005, 1.6 billion adults worldwide were classified as overweight, 400 million of whom were obese. It is predicted that the combination of overweight and obesity will soon eclipse public health issues such as malnutrition and infectious diseases as the most significant cause of poor health.
- Worldwide, data from the Global Burden of Disease Study from 1980 to 2013 indicate the prevalence of adult obesity has increased from 28.8% to 36.9% in men and 29.8% to 38% in women. The prevalence of childhood and adolescent obesity has also substantially increased.
- Based on U.S. NHANES data from 2011 to 2012, the prevalence of abdominal obesity was 54%. It is estimated that by 2020, 2 in every 5 adults and 1 in every 4 children in the U.S. will be categorized as obese.
- The present cost of obesity in the U.S. population is estimated at $100 billion annually. Approximately two thirds of people living in the United States are overweight, which is the highest percentage in the world (Marie Ng, 2014).
- For persons with a BMI ≥30 kg/m^2, all-cause mortality is increased by 50% to 100% above that of persons with BMI in the range of 20 to 25 kg/m^2.
- Obesity is an independent risk factor for cardiovascular disease (CVD), type 2 diabetes, hypertension, cancer (particularly colon, prostate, breast, and gynecologic malignancies), sleep apnea, degenerative joint disease, thromboembolic disorders, digestive tract diseases (gallstones), and dermatologic disorders.
- Significant morbidity and risk of death are projected to begin in young adulthood, resulting in >100,000 excess cases of CHD by 2035, even with the most modest projection of future obesity.
- When children enter kindergarten, 12.4% are obese, and another 14.9% are overweight. Data show that incident obesity between the ages of 5 and 14 yr is more likely to have occurred at younger ages.[1]
- Obesity in adolescence is significantly associated with increased risk of incident severe obesity in adulthood, with variations by sex and race/ethnicity. Overweight or obese adults who were obese as children have increased risk of type 2 DM, dyslipidemia, hypertension, and carotid artery atherosclerosis.
- Obesity is a major preventable cause of death and disability in the U.S. (the other is tobacco).
- Extensive data indicate that weight loss can reverse or arrest the harmful effects of obesity.
- In 2013 nearly 180,000 bariatric surgery procedures were performed in the U.S. Of these procedures 42% were laparoscopic sleeve gastrectomy, 34% were Roux-en-Y gastric bypass, and 15% were laparoscopic adjustable gastric banding.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Physical examination should assess the degree and distribution of body fat, signs of secondary causes of obesity, and obesity-related comorbidities.
- Increased waist circumference is apparent. Excess abdominal fat is clinically defined as a waist circumference >40 inches (>102 cm) in men and >35 inches (>88 cm) in women (in Asian men and women, >36 inches and >33 inches, respectively). Central obesity is a risk factor for mortality even among individuals with normal BMIs.
- Symptoms associated with hypertension, coronary artery disease (CAD), and diabetes (e.g., polyuria, polydipsia, acanthosis nigricans, retinopathy, and neuropathy) may be present.
- Obesity is associated with cardiac hypertrophy, diastolic dysfunction, and decreased aortic compliance, which are independent predictors of cardiovascular risk.
- Joint pain and swelling are associated with degenerative joint disease secondary to obesity.
- The physical exam and ECG often underestimate the presence and extent of cardiac dysfunction in obese patients. Jugular venous distention and hepatojugular reflux may not be seen and heart sounds are frequently distant.
- A large quantity of fluid is present in the interstitial space of adipose tissue, as the interstitial space is ~10% of the tissue wet weight. This excess fluid in this compartment, if redistributed into the circulation, can have negative repercussions in obese individuals with heart failure. Obese individuals have higher cardiac output and a lower total peripheral resistance than do lean individuals, and obesity is associated with persistence of elevated cardiac filling pressure during exercise.
- Obesity predisposes to heart failure through several different mechanisms: increased total blood volume, increased cardiac output, LVH, left ventricular diastolic dysfunction, and adipositas cordis (excessive epicardial fat and fatty infiltration of the myocardium).

ETIOLOGY

- The pathophysiology of obesity is complex and poorly understood, but includes social, nutritional, physiologic, psychological, and genetic factors.
- Environmental factors such as a sedentary lifestyle and chronic ingestion of excess calories can cause obesity.
- Obesity may be related to genetic factors, which are thought to be polygenic. Genetic studies with adopted children have demonstrated that they have similar BMIs to their biologic parents but not their adoptive parents. Twin studies also demonstrate a genetic influence on BMI.
- Secondary causes of obesity can result from medications (antipsychotics, steroids, and protease inhibitors being common ones) and neuroendocrine disorders (like Cushing syndrome and hypothyroidism).

DIAGNOSIS

- BMI will establish the diagnosis of obesity. BMI is defined as the adult's weight in kilograms divided by the square of his or her height—and is closely correlated with total body fat content.
- BMI values can categorize patients into three classes of obesity:
  1. Class I (mild): BMI of 30.0 to 34.9 kg/m^2
  2. Class II (moderate): BMI of 35.0 to 39.9 kg/m^2
  3. Class III (severe): BMI of ≥40 kg/m^2
- Although BMI is commonly used to define obesity, it is not a highly accurate indicator of body fat composition in children, who are undergoing rapid changes in height, or in bodybuilders or athletes who have large amounts of muscle tissue.
- Waist circumference or waist-hip ratio is indicative of visceral adipose tissue/intraabdominal fat, which may be more deleterious than overall overweight or obesity.

[1]Cunningham SA et al: Incidence of childhood obesity in the United States, *N Engl J Med,* 370:403-411, 2014.

DIFFERENTIAL DIAGNOSIS

It is important to evaluate obese patients for secondary medical causes of obesity. Hypothalamic disorders, hypothyroidism, Cushing syndrome, insulinoma, depression, and drugs (corticosteroids, antidepressants, second-generation antipsychotics, sulfonylureas, and HIV protease inhibitors) can cause obesity. In children, certain genetic conditions, such as Prader-Willi syndrome, are associated with obesity.

WORKUP

History should be obtained regarding weight change, family history of obesity, and eating and exercise behavior. Assessment for eating disorders and depression should be made. Attention should be directed to the use of nutritional supplements, over-the-counter medications, hormones, diuretics, and laxatives. The workup of an obese patient typically requires laboratory work to assess for risks and complications as well as to rule out underlying causative medical conditions. Fig. E1 describes the evaluation of patients with suspected endocrine cause of obesity.

LABORATORY TESTS

- Obese patients should be assessed for medical consequences of their obesity by screening for metabolic syndrome. This includes measurement of fasting lipid profile, blood pressure, and waist circumference and screening for diabetes or prediabetes (oral glucose tolerance test, fasting glucose, or hemoglobin A1C).
- Polycythemia might warrant screening for sleep apnea. Liver function tests should be obtained to screen for hepatic steatosis.
- In the proper clinical setting, thyroid function studies and dexamethasone suppression testing will exclude hypothyroidism and Cushing syndrome as underlying causes of obesity. If insulinoma is suspected, the patient will need to undergo a 72-hr fast to confirm hypoglycemia with inappropriate insulin secretion.
- Obesity is associated with changes in the ECG, including a reduction in voltage and nonspecific ST-T changes that may interfere with diagnosis of left ventricular hypertrophy (LVH) or CAD.

IMAGING STUDIES

- Several methods are available for determining or calculating total body fat but offer no significant advantage over the BMI. These include measurement of total body water, total body potassium, bioelectrical impedance, and dual-energy x-ray absorptiometry.
- Buoyancy testing is an accurate method for determining total body fat composition.

OTHER STUDIES

Obesity increases the risk of obstructive sleep apnea, which, in turn, increases the risks of hypertension, cardiac arrhythmias, CVD, stroke, and heart failure. Therefore, one should have a low threshold to screen obese patients for obstructive sleep apnea via sleep study/polysomnography.

TABLE 1 Weight-Loss Treatment Guidelines from the National Heart, Lung, and Blood Institute*

	BMI				
Treatment	**25.0-26.9**	**27.0-29.9**	**30.0-34.9**	**35.0-39.9**	**>40.0**
Diet, physical activity, behavioral therapy, or all three	Yes	Yes	Yes	Yes	Yes
Pharmacotherapy†		In patients with obesity-related diseases	Yes	Yes	Yes
Surgery‡				In patients with obesity-related diseases	Yes

*Data are from www.nhlbi.nih.gov/science/obesity-nutrition-and-physical-activity. These guidelines are generally consistent with those from the American Heart Association, the American Medical Association, the American Diabetic Association, the Obesity Society (Practical Guide), the American Diabetes Association, the American Academy of Family Physicians, the American College of Sports Medicine, and the American Cancer Society. *BMI* denotes body mass index, calculated as the weight in kilograms divided by the square of the height in meters.

†Pharmacotherapy should be considered only in patients who are not able to achieve adequate weight loss with available conventional lifestyle modifications and who have no absolute contraindications for drug therapy.

‡Bariatric surgery should be considered only in patients who are unable to lose weight with available conventional therapy and who have no absolute contraindications for surgery.

Rx TREATMENT

The National Heart, Lung, and Blood Institute (NHLBI) developed guidelines for selecting treatment strategies for overweight and obese patients based on BMI and comorbidities. They recommend a combination of dietary management, physical activity management, and behavior therapy for anyone with a BMI ≥25 or with a high-risk waist circumference and two or more obesity-associated comorbidities. Pharmacotherapy should be considered for patients with a BMI ≥30 or ≥27 with comorbidities.

Bariatric surgery is indicated for patients with a BMI ≥35 with comorbidities and for any patient with a BMI ≥40 (Table 1).

NONPHARMACOLOGIC THERAPY

- The cornerstones for weight management and reduction are calorie restriction, exercise, and behavioral modification. Assessment of patient's willingness to make changes must be evaluated, as treatment is more likely to succeed in motivated patients.
- The NHLBI guidelines recommend an initial diet to produce a calorie deficit of 500 to 1000 kcal/day. This has been shown to reduce total body weight by an average of 8% over 3 to 12 mo.
- These guidelines recommend the use of a food diary to focus on dietary substitutes.
- Thirty min of moderate-intensity activity on 5 or more days of the wk results in health benefits for obese individuals. Moreover, several studies indicate that 60 to 80 min of moderate to vigorous physical activity may provide additional benefit.
- Increased physical activity without caloric restriction (minimal or no weight loss) can reduce abdominal (visceral) adipose tissue and improve insulin resistance.
- The key features of the standard behavioral modification program include goal setting, self-monitoring, stimulus control (modification of one's environment to enhance behaviors that will support weight management), cognitive restructuring (increased awareness of perceptions of oneself and one's weight), and prevention of relapse (weight regain).
- Mammalian sleep is closely integrated with the regulation of energy balance. Trials have shown that the amount of human sleep contributes to the maintenance of fat-free body mass at times of decreased energy intake. Lack of sufficient sleep may compromise the efficacy of typical dietary interventions for weight loss and related metabolic risk reduction.

ACUTE GENERAL Rx

- According to the NHLBI *Guidelines on the Identification, Evaluation, and Treatment of Overweight and Obesity in Adults* and the U.S. Food and Drug Administration (FDA), pharmacotherapy is indicated for:
  1. Obese patients with a BMI ≥30
  2. Overweight patients with a BMI of ≥27 and concomitant obesity-related risk factors or diseases, such as hypertension, diabetes, or dyslipidemia
- Pharmacologic treatment options include:
  1. Gastrointestinal lipase inhibitors: Orlistat is the only drug available for long-term treatment of obesity. It blocks the digestion and absorption of ingested dietary fat. It is a reversible inhibitor of pancreatic, gastric, and carboxyl ester lipases and phospholipase A2, which are required for the hydrolysis of dietary fat in the gastrointestinal tract. Side effects include flatulence, fecal incontinence, cramps, and oily spotting. There can also be impairment of absorption of fat-soluble vitamins (A, D, E, K) and beta-carotene.

Oxalate-associated acute kidney injury and rare severe liver injury have also been reported.

2. C serotonin agonists: Lorcaserin is a selective serotonin agonist that acts centrally to reduce appetite, aiding weight loss. Adverse effects include headache, upper respiratory infections, dizziness, and nausea. While there is little evidence of serotonin-associated cardiac valvular disease or pulmonary hypertension (as seen with nonselective serotonergic agonists fenfluramine and dexfenfluramine), long-term data is currently limited.
3. Sympathomimetic medications: Phentermine and diethylpropion are currently approved for short-term treatment of obesity. They reduce food intake by causing early satiety. Side effects include increased blood pressure and increased pulse. They are Schedule IV drugs with a potential for abuse. Other sympathomimetic drugs that have been removed from the market due to concerns about cardiovascular safety are sibutramine, phenylpropanolamine, and ephedrine.
4. Antidepressants: While not FDA-approved for treatment of obesity alone, bupropion and fluoxetine are antidepressants that have been associated with modest weight loss. The FDA has recently approved a fixed-dose combination of bupropion with the opioid receptor antagonist naltrexone. It is called Contrave and approved for use as an adjunct to diet and exercise in patients with BMI ≥30 kg/m^2 or a BMI ≥27 kg/m^2 and one or more weight-related comorbidities (e.g., diabetes, hypertension, dyslipidemia).
5. Antiepileptic drugs: Zonisamide and topiramate (also used in migraine therapy) have been associated with weight loss in clinical trials but are not currently FDA-approved for treatment of obesity alone.
6. Diabetes drugs: While not FDA-approved for treatment of obesity alone, metformin, pramlintide (synthetic human amylin), and glucagon-like polypeptide-1 agonists (GLP-1) (exenatide) have been associated with weight loss in the treatment of individuals with diabetes. The GLP-1 receptor agonist liraglutide (Victoza) is now FDA approved at a higher dose as Saxenda for chronic weight management in adults with BMI ≥30 or a BMI ≥27 with a weight-related comorbidity such as hypertension, dyslipidemia, or diabetes.

CHRONIC Rx

- According to the NHLBI guidelines, surgical intervention is an option for selected patients with clinically severe obesity (a BMI ≥40 or a BMI ≥35 with comorbid conditions), when patients are at high risk for obesity-associated morbidity or death, and when less invasive methods of weight loss have failed. Box 1 summarizes patient requirements for bariatric surgery.

BOX 1 Patient Requirements for Bariatric Surgery

1. Patients with a BMI of 40 kg/m^2 or greater are potential candidates for bariatric surgery.
2. Patients with a BMI of 35 to 40 kg/m^2 with significant obesity-related comorbidity are also potential candidates for bariatric surgery.
3. Patients with a history of dieting.
4. Patients with no recent substance abuse.
5. Patients should be evaluated by a multidisciplinary team that includes a dietician and psychologic evaluation before surgery.

BMI, Body mass index.
From Cameron JL, Cameron AM: *Current surgical therapy,* ed 12, Philadelphia, 2017, Elsevier.

- Eligible patients should also be at an acceptable risk for surgery, well informed, and motivated.
- Restrictive surgeries limit the amount of food the stomach can hold and slow the rate of gastric emptying. These include vertical banded gastroplasty and laparoscopic adjustable silicone gastric banding (LAGB). Band slippage is the most common LAGB complication. Other potential complications include port or tubing malfunction, stomal obstruction, band erosion, pouch dilatation, and port infection. Gastric necrosis of the stomach wall is a rarer late complication that results from ischemia caused by a combination of gastric prolapse—the part of the stomach below the band herniates up through the device —and pressure from the band. Complications of bariatric surgery are summarized in Box 2.
- Gastric bypass has better outcomes than gastric band procedures for long-term weight loss, type 2 diabetes control and remission, hypertension, and hyperlipidemia. These procedures have benefits that include lower perioperative mortality rate, a quicker recovery period, and no malabsorption issues. However, they are not as effective as gastric bypass for weight reduction and comorbidity improvement.
  1. Malabsorptive surgeries reduce nutrient absorption by shortening the length of small intestine. These include jejunoileal bypass and the duodenal switch operation (DS).
  2. Restrictive malabsorptive bypass procedures combine the elements of gastric restriction and selective malabsorption. These include Roux-en-Y gastric bypass (considered the gold standard because of its high level of effectiveness and durability) and biliopancreatic diversion. These procedures have higher rates of comorbidity improvement than restrictive surgeries, but can be complicated by malabsorption and nutritional deficiencies.
- Compared with usual care, bariatric surgery is associated with reduced number of cardiovascular deaths and lower incidence of cardiovascular events in obese adults. A study on bariatric surgery patients demonstrated a significant reduction in long-term cardiovascular events. Ten-yr follow-up estimated relative risk reductions ranging from 18% to 79% according to the Framingham risk score, and 8% to 62% with the PROCAM risk score.
- A long-term observational study of obese patients with type 2 diabetes showed that bariatric surgery was associated with higher diabetes remission rates and fewer complications than usual care (Sjöström et al., 2014). Remission of type 2 DM occurs in 60% to 80% of patients 2 yr after surgery

BOX 2 Complications of Bariatric Surgery

Complications Common to All Bariatric Procedures
Early (Up to 30 Days After Surgery)
Venous thromboembolic disease
Bleeding
Anastomotic leaks
Wound infections
Persistent nausea/vomiting, dehydration
Regional abdominal organ trauma
Incisional and internal hernias
Bowel obstruction
Atelectasis
Pneumonia
Cardiac dysrhythmias
Urinary tract infection
Death

Late (Beyond 30 Days After Surgery)
Incisional and internal hernias
Bowel obstruction from adhesions
Nutritional deficiencies
Anastomotic strictures and marginal ulcers or erosions
Cholelithiasis
Anemia
Persistence or recurrence of obstructive sleep apnea
Need for body contouring
Regaining weight

Procedure-Unique Complications/ Adverse Effects
Roux-en-Y Gastric Bypass
Dumping syndrome

Laparoscopic Adjustable Gastric Banding
Band slippage or erosion
Port or device malfunction

Vertical Sleeve Gastrectomy
Refractory reflux

Biliopancreatic Diversion
Loose, foul-smelling stools
Protein-calorie malnutrition

From Kryger M et al: *Principles and practice of sleep medicine,* ed 6, Philadelphia, 2017, Elsevier

and persists in about 30% of patients 15 yr after Roux-en-Y gastric bypass.
- Liposuction is removal of fat by aspiration after injection of physiologic saline. This technique reduces the subcutaneous fat but has failed to improve insulin sensitivity or risk factors for CHD.
- The Maestro Rechargeable System is a subcutaneously implanted device recently FDA approved for weight loss in adults with a BMI of 40 to 45 or with a BMI of ≥35 and at least one obesity-related comorbidity. It utilizes high-frequency electrical pulses to block vagus nerve signals between the brain and stomach. It is less effective than bariatric surgery for weight loss. The list price for the Maestro system exceeds $15,000.
- The AspireAssist device is FDA approved for weight loss in adults ≥22 yr old with a BMI of 35 to 55. It requires the insertion of a PEG tube endoscopically and pulled through a percutaneous incision. Thirty min after a meal, the patient attaches a connector to it and drains a portion of their stomach content into a toilet. The tube is then flushed with potable water. The connector stops working after 115 cycles (6 wk) and is replaced at a follow-up appointment. Estimated cost for procedure and follow-ups are $13,000 for the first yr.

DISPOSITION

- The incidence of venous thromboembolism in the upper tertile of BMI was 2.42 times that of the lowest BMI tertile. Obese patients have a higher incidence of postoperative thromboembolic events when undergoing noncardiac surgery.
- Obesity may be associated with higher rates of postoperative pulmonary complications and poor wound healing.
- Weight-stable obese subjects have an increased risk of arrhythmias and sudden death even in the absence of cardiac dysfunction.
- Obesity and the cardiac autonomic nervous system are intrinsically related. A 10% increase in body weight is associated with a decline in parasympathetic tone accompanied by a rise in mean heart rate. Conversely, a 10% weight loss in severely obese patients is associated with significant improvement in autonomic nervous system cardiac modulation, including decreased heart rate and increased heart rate variability.
- Postmortem Determinants of Atherosclerosis in Youth (PDAY) study data provided convincing evidence that obesity in adolescents and young adults accelerates the progression of atherosclerosis decades before the appearance of clinical manifestations.
- Obesity accelerates the progression of native coronary atherosclerosis and after coronary artery bypass grafting.
- In older adults, obesity is associated with protection against hip fracture, but this protective effect on bone status does not offset the extensive array of potential adverse effects on conditions common in the older population.

REFERRAL

Obesity is commonly seen in the primary care setting. If pharmacologic therapy is considered, consultation with physicians specializing in obesity and experienced with the use of the drug is recommended. In addition, consultation with nutritionists and behavioral therapists is helpful. A consultation with general surgery is indicated in patients being considered for surgical intervention.

PEARLS & CONSIDERATIONS

COMMENTS

- Enhanced weight-loss counseling helps about one third of obese patients achieve long-term, clinically meaningful weight loss. Adults can lose 1 to 2 lb (0.45 to 0.9 kg per wk) by consuming 500 to 1000 fewer calories per day.
- The NHLBI launched the Obesity Education Initiative in January 1991. The overall purpose of the initiative is to help reduce the prevalence of overweight along with the prevalence of physical inactivity to reduce the risk of CHD and overall morbidity and mortality rates from CHD.
- A recent study on BMI and all-cause mortality in a large prospective study suggests that optimal BMI range is between 20 and 24.9 (Patel AV, 2014).
- Recent research indicates that brown adipose tissue represents a natural target for the modulation of energy expenditure. The presence of brown adipose tissue in humans may be quantified with the use of ^{18}F-FDG PET-CT. The amount of brown adipose tissue is inversely correlated with BMI, suggesting a potential role of brown adipose tissue in adult human metabolism.
- Obesity, glucose intolerance, and hypertension in childhood are strongly associated with increased rates of premature death from endogenous causes in this population.
- Recent trials have shown that among persons living in a controlled setting, calories alone account for the increase in fat. Protein affected energy expenditure and storage of lean body mass, but not body fat storage.
- There have been no evidence-based studies supporting combination medical therapy for weight loss.
- Data are lacking for the role of pharmacotherapy and bariatric surgery in the elderly population.

PREVENTION

- Prevention of overweight and obesity involves both increasing physical activity and dietary modification to reduce caloric intake.
- There is compelling evidence that prevention of weight regain in formerly obese individuals requires 60 to 90 min of moderate-intensity activity or lesser amounts of vigorous intensity activity.
- Moderate-intensity activity of approximately 45 to 60 min per day, or 1.7 physical activity level (PAL), is required to prevent the transition to overweight or obesity. For children, even more activity time is recommended.
- Clinicians can help guide patients to develop personalized eating plans and help them recognize the contributions of fat, concentrated carbohydrates, and large portion sizes.
- Clinicians must work with patients to modify other risk factors such as tobacco use, high glycemic intake, and elevated blood pressure to prevent the long-term chronic disease sequelae of obesity. Generally lower carbohydrate, moderate fat intake, with stable protein and energy intake results in higher energy expenditure during weight-loss maintenance.[3]
- Regular screening of body weight and BMI measurements at routine office visits can help identify early weight gain.
- Among obese adolescents, the most rapid weight gain occurs between 2 and 6 yr of age. Most children who are obese at that age are obese in adolescence.[2]

Obesity-Hypoventilation Syndrome ALG

BASIC INFORMATION

DEFINITION

The obesity-hypoventilation syndrome (OHS), also known as Pickwickian syndrome, is conventionally defined as a combination of obesity (body mass index [BMI] ≥30 kg/m^2) and daytime hypercapnia ($PaCO_2$ ≥45 mm Hg in arterial blood gas analysis) in the absence of other causes for hypoventilation. This syndrome is often accompanied by obstructive sleep apnea (apnea-hypopnea index [AHI] ≥5 events/hour) or nonobstructive sleep hypoventilation (AHI <5, $PaCO_2$ >55 mm of Hg for more than 10 min or an increase in the $PaCO_2$ >10 mm of Hg compared with daytime $PaCO_2$, to a value >50 mm of Hg for >10 min during sleep). The hypercapnia stems from low tidal volumes and from inappropriate central respiratory response to hypoxemia and elevated PCO_2 levels.

SYNONYMS

Pickwickian syndrome
OHS
Extreme obesity with alveolar hypoventilation
Obesity alveolar hypoventilation syndrome

ICD-10CM CODE

E66.2	Obesity hypoventilation syndrome (OHS)

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: The worldwide prevalence of obesity more than doubled in the last 30 yr and has become a global epidemic. In 2014, the World Health Organization estimated that more than 600 million adults were obese. A Centers for Disease Control report in 2015 estimated the prevalence of obesity among U.S. adults during 2011 to 2014 at 36.5%. The obesity epidemic is likely to increase the prevalence of myriad complications such as OHS. The prevalence of OHS in the general population is estimated to be 0.6%, and 8% to 20% in patients evaluated for sleep breathing disorders at sleep clinic centers.
PREDOMINANT SEX & AGE: Male gender and 50 to 60 yr of age
RISK FACTORS:

- Male gender
- 50 to 60 yr of age
- Morbidly obese (BMI ≥40 kg/m^2)
- Severe OSA (≥30 obstructive respiratory events/hour of sleep)
- Increased waist-hip ratio
- Neck circumference >45 cm

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Most of the OHS symptoms are similar to OSA:

- Excessive daytime somnolence
- Fatigue
- Disorientation
- Loss of concentration
- Change in mood
- Amnesia
- Morning headache

Symptoms and signs most common in OHS compared with OSA:

- Injected sclera (probably related to high PCO2 leading to cerebral vasodilation)
- Anasarca, dyspnea on exertion, signs of circulatory congestion, and cor pulmonale on cardiac and hepatic exam

ETIOLOGY

- Etiology of hypoventilation in obese patients depends on many factors.
- Three hypotheses for chronic hypoventilation are widely accepted (Fig. E1): the increase in mechanical load on respiratory muscles from obesity; leptin resistance inhibiting central respiratory drive causing worsening hypoventilation; and decreased response to elevated PCO_2 levels in OSA.
- Often subclinical OHS becomes clinical with external triggers such as sedative medications, overdiuresis, and other systemic disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anemia
- Heart failure with excessive diuresis
- Liver failure
- Stroke
- Central sleep apnea
- OSA
- Circadian rhythm disorder
- Drug or alcohol abuse
- Depression
- Hypothyroidism
- Sedative medication
- Metabolic abnormalities (e.g., hypo- or hypernatremia, hypercalcemia)
- Neuromuscular disease
- Pulmonary and lung disease
- Restless legs syndrome

WORKUP

- Detailed history and physical examination are helpful to identify patients who are at high risk for OHS. Fig. 2 illustrates a decision tree to screen for obesity-hypoventilation syndrome. Diagnostic features of obesity-hypoventilation syndrome are summarized in Box E1. Physiologic differences between eucapnic morbidly obese patients and those with obesity-hypoventilation syndrome are summarized in Box 2.
- Screen for OHS in men or women with BMI ≥30 or with sleep breathing disorder.
- The Epworth Sleepiness Scale (ESS) and the Stanford Sleepiness Scale (SSS) are the most commonly used scales for daytime sleepiness.
- If OSA is suspected, screen with STOP-BANG questionnaire (***s***noring, ***t***iredness, ***o***bserved apnea, blood ***p***ressure, ***B***MI, ***a***ge >50, ***n***eck circumference >16 inches, and ***g***ender).
- Overnight polysomnography to confirm whether AHI >5.
- Assess daytime oxygen saturation (SpO_2) levels to assess blood oxygenation level and serum bicarbonate level to assess carbon dioxide retention.
- If SpO_2 <90% on room air, serum bicarbonate >27 mEq/L, and BMI >30 with underlying sleep breathing disorder, consider obtaining an arterial blood gas to diagnose OHS.
- Consider forced vital capacity (FVC) and negative inspiratory force (NIF) if any suspicion of neuromuscular disease.
- ECG and echocardiogram are helpful to assess structural changes of the heart and pulmonary hypertension.

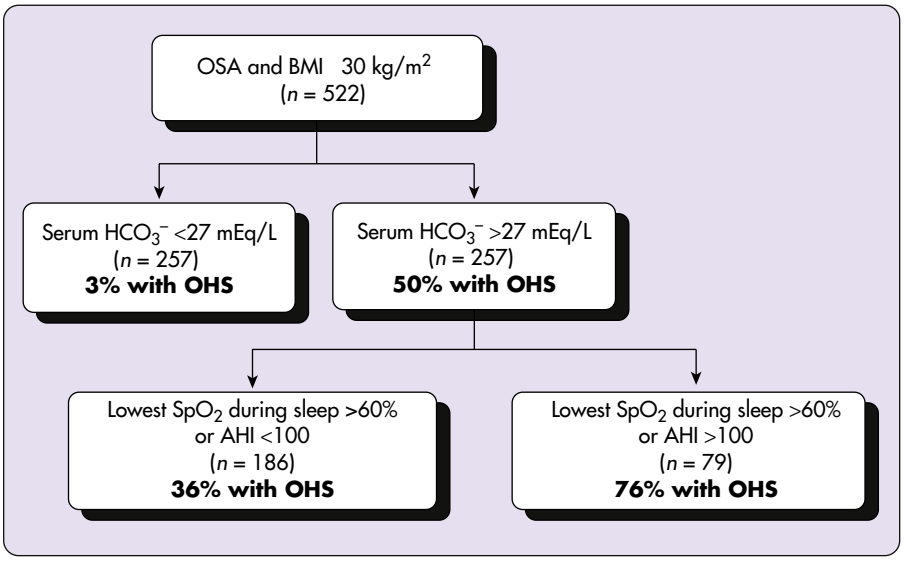

FIG. 2 Decision tree to screen for obesity-hypoventilation syndrome *(OHS)* based on observation in 522 obese patients with OSA (BMI ≥30 kg/m^2 and AHI ≥5). Among those with a venous serum bicarbonate level above 27 mEq/L, OHS was present in 50% of patients. Very severe OSA (AHI >100 events/hour or SpO_2 nadir during sleep <60%) increased the prevalence of OHS to 76%. *AHI,* Apnea-hypopnea index; *BMI,* body mass index; *OSA,* obstructive sleep apnea; *SpO_2,* the saturation of arterial blood with oxygen as measured by pulse oximetry. (From Kryger M et al: *Principles and practice of sleep medicine,* ed 6, Philadelphia, 2017, Elsevier.)

BOX 2 Physiologic Differences Between Eucapnic Morbidly Obese Patients and Those with Obesity-Hypoventilation Syndrome

	Eucapnic Morbid Obesity	Obesity-Hypoventilation Syndrome
Waist:hip ratio	↑	↑↑
FEV_1 /FVC	Normal	Normal/↓
Total lung capacity	Normal	Slight ↓
Functional residual capacity	↓	↓
Vital capacity	Normal or ↓	↓↓
Expiratory reserve volume	↓	↓↓
Work of breathing	↑	↑↑
Hypercapnic/hypoxic ventilatory drive	Normal	↓
Inspiratory muscle strength	Normal	↓

FEV1, Forced expiratory volume in first second; *FVC,* forced vital capacity.
From Kryger M et al: *Principles and practice of sleep medicine,* ed 6, Philadelphia, 2017, Elsevier.

- Polysomnography with continuous positive airway pressure (CPAP) titration can guide the physician to choose appropriate settings for positive airway pressure.
- Avoid medications that decrease respiratory drive and worsen ventilation.

LABORATORY TESTS

- Arterial blood gas (ABG) analysis on room air is the gold standard test to diagnose OHS in appropriate clinical setting.
- Venous blood gases (VBG), end-tidal carbon dioxide, arterialized capillary blood gases, and transcutaneous carbon dioxide monitoring can be used as alternatives to ABG to assess hypoventilation and carbon dioxide retention.
- Serum bicarbonate (>27 mEq/L) can be used as a great screening tool for OHS in an appropriate clinical setting. In a patient with normal kidney function, respiratory acidosis from OHS is usually compensated by retaining serum bicarbonate.
- Several studies showed serum bicarbonate level <27 mEq/L carries 97% negative predictive value for excluding a diagnosis of OHS in patients diagnosed as obese with OSA and normal renal function.
- Sleep hypoventilation can be measured by continuous end-tidal or transcutaneous carbon dioxide level measurement.

IMAGING STUDIES

- Echocardiogram will be helpful to assesses structural changes of the heart and pulmonary hypertension.
- Consider chest x-ray if any suspicion of pneumonia, COPD, or any lung disease.
- Consider CT chest or bronchoscopy if clinical condition warrants.

Rx TREATMENT

Four types of therapies available for both acute and chronic therapies for OHS: Positive airway (PAP) therapy, supplemental nasal oxygen, bariatric surgery, and oral respiratory stimulants.

NONPHARMACOLOGIC THERAPY

Positive airway therapy:

- Two types of PAP therapy available: CPAP and bilevel PAP (BiPAP). PAP therapy is considered first line for OHS.
- Short-term (≤3 weeks of PAP use) benefits of PAP: Improvement in $PaCO_2$ and PaO_2 levels and sleep breathing disorder.
- Long-term benefits of PAP (≥4 weeks of PAP use): Improvement in $PaCO_2$ and PaO_2 levels, lung volumes, central respiratory drive to carbon dioxide, and possible lowering of mortality.
- BiPAP recommend in patients who failed CPAP therapy (AHI ≥5 or a mean nocturnal oxygen saturation <90% on CPAP therapy) or who are intolerant to high PAP.

Oxygen therapy:

- Approximately 40% of patients with OHS on PAP therapy were at risk of hypoxemia during sleep. It can be controlled with supplemental oxygen as low as possible. However, inadvertent administration of excess oxygen might decrease minute ventilation significantly, which results in hypercapnia and respiratory acidosis.

Bariatric surgery:

- Bariatric surgery is indicated in all patients with a BMI ≥40 or with BMI ≥35 with obesity-related comorbid conditions. Recent studies showed significant improvement in PaO_2, $PaCO_2$, FEV_1, and FVC after bariatric surgery. After successful surgery, 14% of OHS patients may need PAP.

Tracheostomy:

- Reserved for patients who are not tolerant to PAP therapy

ACUTE GENERAL Rx

- Two respiratory stimulants currently available: Medroxyprogesterone acetate and acetazolamide.
- Medroxyprogesterone acetate stimulates respiratory center in hypothalamus. Clinical data showed neutral effect on $PaCO_2$ level.
- Acetazolamide increases bicarbonate excretion by the kidneys and causes metabolic acidosis, which increases respiratory drive. Acetazolamide has been shown to improve respiratory drive and decrease $PaCO_2$ level. However, clinical data are limited.

REFERRAL

Sleep specialist referral in case of diagnostic uncertainty and/or for patients not responding to positive airway therapy.

PEARLS & CONSIDERATIONS

- It is impossible to differentiate OHS from OSA based on clinical presentation alone.
- If SpO_2 <90% on room air, serum bicarbonate (>27 mEq/L), and BMI of >30 with underlying SBD, get an ABG to diagnose OHS.
- Positive airway therapy is a very effective treatment of choice for OHS.

PREVENTION

- Avoid sedative medications.
- Avoid overdiuresis in heart failure patients.
- Avoid alcohol intake.

PATIENT/FAMILY EDUCATION

- Weight loss
- Avoid sedative medication
- Avoid alcohol intake and recreational drug use
- Daily use of positive airway therapy for sleep

Chau EH et al: Obesity hypoventilation syndrome: a review of epidemiology, pathophysiology, and perioperative considerations, *Anesthesiology* 117(1):188-205, 2012.

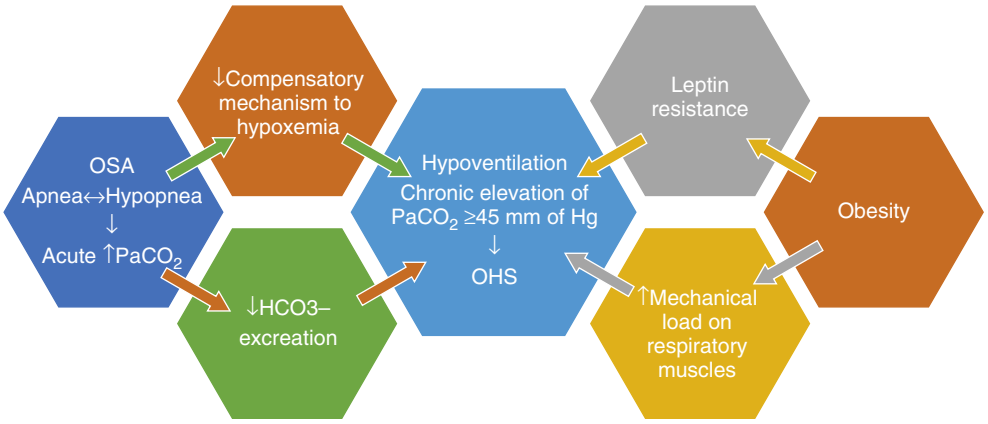

FIG. E1 Mechanism of obesity hypoventilation syndrome *(OHS).* *OSA,* Obstructive sleep apnea.

BOX E1 Diagnostic Features of Obesity-Hypoventilation Syndrome

Obesity
Body mass index ≥30 kg/m^2

Chronic Hypoventilation
Awake daytime hypercapnia (sea-level arterial PCO_2 ≥45 mm Hg)
Possible role of serum venous bicarbonate or calculated bicarbonate >27 mEq/L from capillary blood gas

Sleep Breathing Disorder
Obstructive sleep apnea (apnea-hypopnea index [AHI] ≥5 events/hour)
Nonobstructive sleep hypoventilation (AHI <5 events/hour, $PaCO_2$ above 55 mm Hg for more than 10 min, or an increase in the $PaCO_2$ [or surrogate] above 10 mm Hg [compared with awake supine $PaCO_2$] to a value >50 mm Hg for >10 min during sleep, or sustained hypoxemia with oxygen saturation ≤88% without obstructive respiratory events)

Exclusion of Other Causes of Hypoventilation
Severe obstructive airways disease (e.g., chronic obstructive pulmonary disease)
Severe interstitial lung disease
Severe chest wall disorders (e.g., kyphoscoliosis)
Severe hypothyroidism
Neuromuscular disease
Congenital hypoventilation syndromes

$PaCO_2$, Partial pressure of carbon dioxide in arterial blood; PCO_2, partial pressure of carbon dioxide.
From Kryger M et al: *Principles and practice of sleep medicine,* ed 6, Philadelphia, 2017, Elsevier.

Obsessive-Compulsive Disorder (OCD) PTG

BASIC INFORMATION

DEFINITION

Obsessive-compulsive disorder (OCD) is characterized by obsessions (recurrent and persistent thoughts, urges, or images experienced as intrusive and unwanted) and/or compulsions (repetitive behaviors or mental acts performed in response to obsessions, or according to rules that must be applied rigidly) that are time-consuming (e.g., >1 hr/day) or cause marked impairment or distress. The symptoms are usually, but not always, perceived as excessive and unreasonable.

SYNONYM

OCD

ICD-10CM CODES

F42 Obsessive-compulsive disorder
F60.5 Obsessive-compulsive personality disorder

DSM-5 CODES

300.3 Obsessive-compulsive disorder
301.4 Obsessive-compulsive personality disorder

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: Mean age at onset is 19.5 yr.
12-MO PREVALENCE: 1.2% of adults in the U.S., international prevalence estimates are similar (1.1% to 1.8%).
PREDOMINANT SEX: Slightly more common among females than males in adulthood, although males are more commonly affected in childhood.
PREDOMINANT AGE:

- Modal age of onset for females is between 20 and 29 yr.
- Modal age of onset for males is between 6 and 15 yr.

DISEASE COURSE:

- Condition is chronic with waxing and waning pattern.
- Symptoms typically worsen with stress.
- 15% show progressive deterioration, whereas 5% show an episodic course with little impairment between episodes.

GENETICS:

- OCD is a multifactorial familial condition that involves both polygenic and environmental risk factors.
- Rate of concordance is higher in monozygotic (57%) compared with dizygotic (27%) twins.
- Rate of disorder is also much higher in first-degree relatives of individuals with OCD and Tourette disorder (8.2%) than in the general population (2%).

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Persistent and recurrent intrusive and ego-dystonic obsessive ideas, thoughts, urges, or images that are perceived as alien and beyond one's control.
- Frequent experiencing of obsessions related to contamination (e.g., when using the telephone), excessive doubt (e.g., was the door locked?), organization (the need for a particular order), violent impulses (e.g., to yell obscenities in church), or intrusive sexual imagery.
- Compulsive behaviors (e.g., repeated hand washing, checking, rearranging) or mental rituals (e.g., counting, repeating phrases) meant to temporarily ameliorate anxiety caused by obsessions.
- Obsessions and compulsions are almost always accompanied by high anxiety and subjective distress. Both are usually, but not always, seen as excessive and unreasonable.

ETIOLOGY

- Strong evidence of cortico-striato-thalamo-cortical circuit dysfunction.
- OCD onset may be temporally associated with infectious illness of CNS (e.g., Von Economo encephalitis, Sydenham chorea).
- A condition called Pediatric Autoimmune Neuropsychiatric Disorders Associated with Streptococcal Infections (PANDAS) usually involves children under age 12. It is diagnosed when OCD and/or tic disorders suddenly appear following a streptococcal infection (e.g., strep throat or scarlet fever) or symptoms of OCD or tic symptoms worsen after a strep infection.
- OCD may follow head trauma or other premorbid neurologic condition, including birth hypoxia and Tourette syndrome.
- Intrusive, obsessive thinking may be part of the picture in patients with complex partial seizures.
- Serotonergic, dopaminergic, and glutamatergic systems believed important in some ritualistic instinctual behaviors, with dysfunction of these pathways possibly giving rise to OCD.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Obsessive-compulsive personality disorder (OCPD) is a maladaptive personality style defined by excessive rigidity, need for order and control, preoccupation with details, and excessive perfectionism. Unlike OCD, OCPD is ego-syntonic.
- Other psychiatric disorders in which obsessive or intrusive thoughts occur (e.g., body dysmorphic disorder, eating disorders, hypochondriasis, phobias, posttraumatic stress disorder).
- Impulse control disorders (e.g., trichotillomania [hair-pulling disorder], excoriation [skin-picking] disorder, pathologic gambling disorder, compulsive shopping, kleptomania, paraphilias/sexual compulsions).
- Neurologic disorders with repetitive behaviors (e.g., Tourette syndrome, Sydenham chorea, torticollis, autism).
- Delusions or psychosis, which may be mistaken for obsessive thoughts; unlike OCD, these individuals do not believe their obsessions are unreal and may likely meet criteria for another psychotic spectrum disorder that fully accounts for the obsessions (e.g., schizophrenia).

WORKUP

- Careful history leading to diagnosis
- In adolescents and children: Psychological testing to reveal learning disabilities
- Screen for presence of past or current tic disorder, and ascertain degree of insight (good or fair, poor, absent/delusional) into OCD beliefs

TREATMENT

NONPHARMACOLOGIC THERAPY

- Cognitive-behavioral therapy (CBT), comprising exposure/response prevention with or without cognitive reappraisal, is successful in up to 70% of patients. Best results are found for contamination obsessions and washing compulsions.
- Barriers to CBT include lack of availability/access, intense time requirements, and patient motivation to engage in treatment (e.g., anxiety resulting from exposure exercises).

ACUTE GENERAL Rx

- Antidepressants with serotonin reuptake blockade, including clomipramine, fluvoxamine, fluoxetine, paroxetine, sertraline, citalopram, and escitalopram; optimal dosages are typically at the high end of the prescription range. Risk/benefit/alternatives discussion is crucial (e.g., dose-related risk of QT interval prolongation with serotonin reuptake inhibitors in general and clomipramine, citalopram, and escitalopram in particular).
- Benzodiazepines (e.g., clonazepam) have limited efficacy in OCD.
- Most experience some symptom relief with treatment, but even after adequate treatment trials, 40% to 60% of patients endorse significant residual symptoms.
- Likely indefinite treatment. Relapse is common if medications are discontinued.
- Recent studies suggest that combination CBT and pharmacotherapy yields superior outcomes. More severe symptoms warrant combination therapy.
- Patients who do not respond to first-line treatments and those with comorbid psychosis and/or tic disorders may benefit from augmentation with a first- or second-generation antipsychotic medication (e.g., haloperidol, olanzapine, risperidone).
- Neurosurgical intervention (e.g., cingulotomy, deep brain stimulation) is reserved for the most severely symptomatic and treatment-resistant cases.

DISPOSITION

- Most mild to moderate cases can be managed on a regular outpatient basis. Treatment should typically start with SSRI monotherapy with regular follow-up to assess treatment response and side-effect management. Dose should be increased to maximum tolerated.
- Patient and family education may help improve medical adherence and support.

PEARLS & CONSIDERATIONS

Patients with OCD typically have insight regarding the irrationality of their obsessions and compulsions but lack the ability to control them. This may cause intense shame and avoidance of medical care unless patient education and support are provided. Screen for OCD, especially among patients who present with "depression" or "anxiety."

Ocular Foreign Body (PTG)

BASIC INFORMATION

DEFINITION

The term *ocular foreign body* refers to a foreign body on the surface of the corneal or conjunctival epithelium.

ICD-10CM CODES

T15	Foreign body on external eye
T15.0	Foreign body in cornea
T15.1	Foreign body in conjunctival sac
T15.8	Foreign body in other and multiple parts of external eye
T15.9	Foreign body on external eye, part unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Universal, with a predominance in active people. Common with industrial jobs and activities such as metal work, landscaping, and woodworking.

PREDOMINANT SEX: Perhaps slightly more common in men

PREDOMINANT AGE: Childhood through active adult yrs

PEAK INCIDENCE: Childhood through active adult yrs

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Pain with foreign body sensation is the most common symptom.
- Sudden onset: Patient may pinpoint the exact moment it occurred.
- Causes of most common foreign bodies:
  1. Grinding
  2. Drilling
  3. Auto repair
  4. Airborne particles, such as blown by fans
- Fig. E1 illustrates various ocular foreign bodies.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- History of corneal foreign body seen (small, white, superficial ring scars on cornea)
- Hemorrhage, loss of vision (with perforation of the globe)
- Distorted anterior chamber, soft eye
- Corneal abrasion
- Corneal ulceration (infection, bacterial or viral keratitis) or laceration
- Other keratitis
- Intraocular foreign body

WORKUP

- Fluorescein stain, slit-lamp examination if no foreign body is found
- Ultrasound examination
- Plain radiographs

LABORATORY TESTS

Intraocular pressure to make certain that eye has not been penetrated

IMAGING STUDIES

Occasionally, MRI of the orbits to identify foreign bodies not found by other means. Do not perform MRI if suspect metallic foreign body. Plain radiographs and ultrasound are sufficient.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Remove foreign body
- Treat infection
- Repair eye if ruptured
- Treat corneal abrasion or injury

ACUTE GENERAL Rx

- Saline irrigation
- Removal of foreign body with moist cotton-tipped applicator after instillation of topical anesthetic drops
- Use burr or more aggressive treatment if needed (often needed for deeper "rust ring" after metallic foreign body)
- Cycloplegics, antibiotics, and pressure dressing after removal of foreign body
- Repair corneal laceration or perforated eye (refer urgently to ophthalmologist)

DISPOSITION

If symptoms persist 24 hr after examination, refer to an ophthalmologist.

REFERRAL

To ophthalmology within 24 hr if patient not completely comfortable

PEARLS & CONSIDERATIONS

COMMENTS

- Make sure foreign body is not intraocular (inside eye).
- Alkaline or acidic chemical foreign bodies can be dangerous; pH test must be performed if either of these is suspected (for all chemical foreign bodies).

Opioid Overdose

BASIC INFORMATION

DEFINITION

Excessive use of an opioid, either derived from the opium poppy or semi- or fully synthetic, resulting in respiratory depression, central nervous system depression, and/or death

SYNONYMS

Opiate overdose
Heroin overdose
Narcotic overdose
Opioid poisoning

ICD-10CM CODES

T40.0X1	Poisoning by opium, accidental (unintentional)
T40.0X2	Poisoning by opium, intentional self-harm
T40.0X3	Poisoning by opium, assault
T40.0X4	Poisoning by opium, undetermined
T40.0X5	Adverse effect of opium
T40.1X	Poisoning by heroin
T40.4	Poisoning by other synthetic narcotics

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Drug overdose deaths and opioid-involved deaths continue to increase in the U.S. The majority of drug overdose deaths (more than six out of ten) involve an opioid. 91 Americans die every day from an opioid overdose.

PREVALENCE: From 1999 to 2017 more than 700,000 U.S. residents died from drug overdoses. From 2013 to 2017, the number of opioid-involved overdose deaths (opioid deaths) in the U.S. increased 90% from 25,052 to 47,600. This increase was primarily driven by substantial increases in deaths involving illicitly manufactured fentanyl (IMF) or fentanyl analogs mixed with heroin, sold as heroin, or pressed into counterfeit prescription pills.

PREDOMINANT SEX AND AGE: The "typical" heroin death involves experienced users in their 20s to 30s using coingestants, with a male predilection.

RISK FACTORS: The majority of drug-overdose deaths are unintentional or accidental (74%). The following increase risk for opioid overdose:

- Opioid dependence, in particular following reduced tolerance (following detoxification, release from incarceration, cessation of treatment)
- Injecting opioids
- Using prescription opioids, in particular taking higher doses
- Using opioids in combination with other sedating substances
- Using opioids and having comorbidities such as HIV, liver or lung disease, or suffering from depression
- Household members of people in possession of opioids (including prescription opioids)

The highest drug-induced mortality is associated with the following factors: 40 to 49 yr of age, male gender, non-Hispanic whites, and living in the South, all of which account for approximately 38.2% of drug-induced deaths in the U.S.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Patients with opioid overdose classically present with the triad of altered mental status, pinpoint pupils, and respiratory depression. Patients may be apneic or with low respiratory rate and tidal volumes. Respiratory depression becomes profound enough to cause anoxia, leading to death. Little to no response will be elicited from painful stimuli. Look for clinical clues, such as "track marks" or darkening along the length of veins from injection drug use that may suggest opioid overdose. The use of coingestants, which is exceedingly common in opioid overdose, can alter the classic exam findings one may expect. For example, use of sympathomimetics like cocaine can cause pupillary dilation. Respiratory rate <12 breaths/min is most sensitive for predicting response to naloxone. Once the patient is hemodynamically stable, examine for other sequelae of drug use, including pulmonary rales suggestive of aspiration pneumonia or murmurs and skin lesions associated with endocarditis in IV drug abusers.

ETIOLOGY

N/A

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypoglycemia
- Alcohol or sedative overdose
- Postictal state
- Infectious or metabolic encephalopathy
- Clonidine overdose
- Phenothiazine overdose
- Organophosphate exposure

WORKUP

Opioid overdose requires little workup if the patient's altered mental status can be completely attributed to the overdose (i.e., by full recovery with naloxone). However, if the patient remains altered or with significant respiratory compromise after adequate treatment, continue appropriate workup. Obtain an ECG in the following scenarios: use of methadone, oxycodone, loperamide or a coingestant tricyclic antidepressant to screen for QTc prolongation; coingestion of a sympathomimetic to rule out arrhythmias.

LABORATORY TESTS

- Serum glucose should be quickly obtained as with any resuscitation.
- Urine drug screen is not routinely required unless the history or physical exam raises suspicion for coingestants that would alter management.
- Tylenol and aspirin levels in intentional overdoses or when used in a combination formulation with an opioid.

IMAGING STUDIES

Not required unless guided by your physical exam and/or response to therapy:

- Computed tomography of the head and cervical spine for suspected trauma
- Chest x-ray if signs of aspiration
- Echocardiogram if concerned for endocarditis

TREATMENT

The principal goals of treatment for opioid overdose are support of ventilation and reversal of the drug.

NONPHARMACOLOGIC THERAPY

Support the airway and breathing. For apneic or bradypneic patients, use bag-valve-mask ventilation.

ACUTE GENERAL Rx

Administer naloxone, a short-acting opioid antagonist, as soon as possible. Intravenous is the preferred route; however, in November 2015, Narcan Nasal Spray became the first FDA-approved non-injectable naloxone product for the treatment of opioid overdose. Higher concentration intranasal naloxone 2 mg/ml seems to have efficacy similar to IM naloxone for reversal of opioid overdose. Via the IV route, onset of action is within 1 to 2 min. Dosing is as follows:

- For most adult patients, 0.4 to 1.2 mg should yield recovery of consciousness.
- For patients in cardiac arrest, 2 mg is the starting dose.
- Younger than 5 yr or body weight 20 kg or less: 0.1 mg/kg administered by IV push, intraosseous (IO) push, or by endotracheal tube (ETT).
- 5 yr and older or body weight more than 20 kg: 2 mg administered by IV push, IO, or ETT.

Prepare for adverse effects of acute withdrawal, including agitation, nausea, vomiting, piloerection, diarrhea, lacrimation, yawning, and rhinorrhea after naloxone administration to chronic opioid users, especially with higher doses. Naloxone continues to block binding of additional opioids to the receptor for 20 to 90 min.

CHRONIC Rx

- Naloxone autoinjectors and nasal sprays are available in some states and intended for buddy administration. Patients can buy these formulations over-the-counter in some states, whereas others require a prescription. Check your state's legislature for continual updates on this matter.
- A 2016 nonrandomized study demonstrated that patients prescribed opioids plus naloxone had 47% fewer opioid-related emergency department visits within 6 mo than those not prescribed naloxone.

REFERRAL

Patients can be offered referral to drug rehabilitation services. Otherwise, follow up with the primary care physician is appropriate.

BASIC INFORMATION

DEFINITION

- Opioid use disorder is defined as a cluster of cognitive, behavioral, and physiologic symptoms in which the individual continues use of opiates despite significant opiate-induced problems. Opiate use disorder is a chronic, relapsing disorder characterized by repeated self-administration that usually results in opiate tolerance, withdrawal, and compulsive drug use. Tolerance is the need to increase dose to achieve the same effect. Dependence may occur with or without the physiologic symptoms of tolerance and withdrawal.
- There are four stages of addiction:
  1. Stage I, acute drug effects: Rewarding effects of drug result from neurobiologic changes in response to the acute drug use. Duration varies from hours to days.
  2. Stage II, transformation to addiction: Associated with changes in neuronal function that accumulate with repeated administration and diminish over days or weeks after discontinuation of drug use.
  3. Stage III, relapse after extended periods of abstinence: Precipitated by an incubation of cue-induced craving (people, places, and things as triggers) and priming (relapse precipitated by drug exposure).
  4. Stage IV, end-stage addiction: Vulnerability to relapse endures for yr and results from prolonged changes at the cellular level.
- Pseudoaddiction: Undertreatment of pain resulting in "opiate-seeking" behaviors such as "doctor shopping" and multiple emergency department visits. These behaviors disappear with adequate treatment of pain.

SYNONYMS

Opioid dependence
OUD (opioid use disorder)
Opiate addiction
Opiate abuse
Narcotic addiction
Narcotic abuse
Substance use disorder

ICD-10CM CODES

F11.10	Opioid abuse, uncomplicated
F11.120	Opioid abuse with intoxication, uncomplicated
F11.121	Opioid abuse with intoxication delirium
F11.122	Opioid abuse with intoxication with perceptual disturbance
F11.129	Opioid abuse with intoxication, unspecified
F11.14	Opioid abuse with opioid-induced mood disorder
F11.150	Opioid abuse with opioid-induced psychotic disorder with delusions
F11.151	Opioid abuse with opioid-induced psychotic disorder with hallucinations
F11.159	Opioid abuse with opioid-induced psychotic disorder, unspecified
F11.181	Opioid abuse with opioid-induced sexual dysfunction
F11.182	Opioid abuse with opioid-induced sleep disorder
F11.188	Opioid abuse with other opioid-induced disorder
F11.19	Opioid abuse with unspecified opioid-induced disorder

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: It is estimated that more than 2.5 million Americans have an opioid use disorder.

PREVALENCE:

- In 2014, U.S. retail pharmacies dispensed 245 million prescriptions for opioid pain relievers.
- In 2014, 10.3 million persons reported using prescription opioids nonmedically.
- In the U.S., 400,000 persons have used heroin in the past mo, and 4 million have reported nonmedical use of prescription pain relievers.
- Emergency department visits involving misuse or abuse of prescription opioids increased 153% between 2004 and 2011.
- Admissions to substance-abuse treatment programs linked to prescription opioids more than quadrupled between 2002 and 2012.
- The percentage of eighth-, tenth-, and twelfth-graders who have used heroin has more than doubled since the late 1990s. This increase has largely been attributed to decreased price and increased purity in the last decade.
- In 2015, 33,000 Americans died of opioid-related overdose—quadrupling the rates from 1999.
- In March and October 2015, the Drug Enforcement Administration and Centers for Disease Control and Prevention issued nationwide alerts identifying fentanyl, particularly illicitly manufactured fentanyl, as a threat to public health and safety. Illicitly manufactured fentanyl is pharmacologically similar to pharmaceutical fentanyl but is unlawfully produced in clandestine laboratories and obtained via illicit drug markets; it also includes fentanyl analogs. Fentanyl is a synthetic opioid 50 to 100 times more potent than morphine and approved for the management of surgical/postoperative pain, severe chronic pain, and breakthrough cancer pain.
- In the U.S., approximately 10 million adults are prescribed long-term opioid therapy (LTOT) for chronic pain despite inadequate evidence of long-term benefit and growing evidence of harm.

PREDOMINANT SEX: Males abuse opioids more commonly than females, with a male:female ratio of 3:1 for heroin and 1.5:1 for prescription opiates.

PEAK INCIDENCE: The majority of new abusers of opiates are <26 yr.

RISK FACTORS:

- Family history
- Prior history of addiction
- Psychiatric disorders

GENETICS:

- Genetic epidemiologic studies suggest a high degree of heritable vulnerability for opioid dependence.
- Gene polymorphism for dopamine receptor/transporters, opioid receptors, serotonin receptors/transporters, proenkephalin, and catechol-*O*-methyltransferase all appear to be associated with vulnerability to opioid dependence. Future interventions for opiate dependence may include medications identified through genetic research.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Physical examination is often noncontributory.
- Small-sized pupils may be the only observable sign of use because only mild tolerance develops for miosis.
- Scars or tracks from chronic IV use may be visible over the veins of the arms, hands, ankles, neck, and breasts.
- Inflamed nasal mucosa or respiratory wheezing may be apparent in patients who are snorting heroin or OxyContin.
- Patients in withdrawal may have more dramatic findings such as tachycardia, hypertension, fever, piloerection (goose flesh), mydriasis, lacrimation, central nervous system (CNS) arousal, irritability, and repeated yawning. In patients with sympathetic overactivity and panic attacks, use of CNS stimulants, such as amphetamines or cocaine, should also be ruled out.
- Although gastrointestinal symptoms of nausea, vomiting, and abdominal pain are common in opioid withdrawal, other causes such as gastroenteritis, pancreatitis, peptic ulcer disease, and intestinal obstruction need to be ruled out.
- The history may provide relevant information in making the diagnosis. Significant findings may include:
  1. A long history of opioid self-administration, typically by the IV or intranasal route but sometimes through smoking as well.
  2. Polysubstance use. Intoxication by drugs other than narcotics (e.g., benzodiazepines, barbiturates) should be ruled out in unconscious patients.
  3. A high incidence of nonopioid-related psychiatric disorders (>80%).
  4. History of problems at work, school, or relationships associated with drug use.
  5. History of legal problems associated with drug use, such as arrest for possession, robbery, or prostitution.
  6. History of interpersonal violence (as perpetrator or victim).
  7. History of physical problems such as skin infections, phlebitis, endocarditis, or liver diseases attributable to acetaminophen toxicity (Vicodin/Percocet) or viral hepatitis. Hepatitis C is the most prevalent bloodborne pathogen. It is present in approximately 90% of opiate-dependent people and is often spread by sharing IV drug paraphernalia or snorting devices. There is also a higher incidence of HIV infection.

ETIOLOGY

Opioid use disorder is a biopsychosocial disorder. Pharmacologic, social, genetic, and psychodynamic factors interact to influence abusive

TABLE 1 CAGE-AID

1. Have you ever tried to **C**ut down on your alcohol or drug use?
2. Do you get **A**nnoyed when people comment about your drinking or drug use?
3. Do you feel **G**uilty about things you have done while drinking or using drugs?
4. Do you need an **E**ye-opener to get started in the morning?

Two or more questions answered in the affirmative require further assessment.
AID, adapted to include drugs.
From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

TABLE 2 Drug Abuse Screening Test (DAST-10)

1. Have you used drugs other than those required for medical reasons?
2. Do you abuse more than one drug at a time?
3. Are you unable to stop using drugs when you want to?
4. Have you ever had blackouts or flashbacks as a result of drug use?
5. Do you ever feel bad or guilty about your drug use?
6. Does your spouse (or parents) ever complain about your involvement with drugs?
7. Have you neglected your family because of your use of drugs?
8. Have you engaged in illegal activities in order to obtain drugs?
9. Have you ever experienced withdrawal symptoms (felt sick) when you stopped taking drugs?
10. Have you had medical problems as a result of your drug use (e.g., memory loss, hepatitis, convulsions, bleeding)?

Two or more questions answered in the affirmative require further assessment.
From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

behaviors. Pharmacologic factors are especially prominent in opiate addiction because these drugs are strong reinforcing agents due to their euphoric effects and their ability to reduce anxiety and increase self-esteem and the patient's subjective feelings of improved ability to cope with daily challenges.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Psychiatric disorders (e.g., anxiety, depression, bipolar disorder).
- Acute medical illness (e.g., hypoglycemia, seizure disorder, sepsis, renal or hepatic insufficiency) may mimic opiate withdrawal symptoms.

WORKUP

The history is the most important part of the workup. Useful screening tools are the CAGE-AID (Table 1), the DAST-10 (Table 2), and the CRAFFT (Table 3). The CAGE-AID has a sensitivity of 70% and a specificity of 85% when two questions are answered in the affirmative. The DAST-10 can discriminate between current users versus former users. The CRAFFT is a useful screening tool for adolescents. A CRAFFT score of 2 or higher is optimal for identifying any problem (sensitivity 76%, specificity 94%), any disorder (sensitivity 80%, specificity 86%), and drug dependence (sensitivity 92%, specificity 80%).

TABLE 3 CRAFFT Screening Tool for Adolescents

1. Have you ever ridden in a **C**ar driven by someone (including yourself) who was high or had been using alcohol or drugs?
2. Do you ever use alcohol or drugs to **R**elax, feel better about yourself, or fit in?
3. Do you ever use alcohol or drugs while you are by yourself **A**lone?
4. Do you ever **F**orget things you did while using alcohol or drugs?
5. Do your **F**amily or Friends ever tell you that you should cut down on your drinking or drug use?
6. Have you ever gotten into **T**rouble while you were using alcohol or drugs?

Two or more questions answered in the affirmative require further assessment.
From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

- Observation of opioid withdrawal is indicative of opioid addiction.
- Observation of purposeful behaviors such as complaints and manipulations directed at getting more drugs and anxiety during withdrawal is suggestive of opioid addiction.
- Screen blood and urine for opioid metabolites.
- Screen for communicable diseases: HIV, hepatitis B and hepatitis C, tuberculosis.
- Screen for endocarditis in patients with newly diagnosed murmurs.

LABORATORY TESTS

- Urine and serum toxicology screen
- Complete blood count
- Chemistries (alanine aminotransferase, aspartate aminotransferase, serum creatinine): Elevated liver function test (LFT) results may be from viral hepatitis or acetaminophen toxicity
- Hepatitis screen: If hepatitis C antibody positive, follow up with hepatitis C polymerase chain reaction (viral load) even in patients with normal LFTs
- HIV
- PPD

IMAGING STUDIES

Generally not helpful in routine diagnosis and treatment. Consider echocardiography in patients with heart murmurs and liver sonography or CT scan in patients with elevated LFTs or who are positive for hepatitis C or B (increased risk of hepatocellular carcinoma).

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Brief counseling interventions during a visit with their primary care physician or OB/GYN have proved efficacious in motivating patients for treatment.
- Therapeutic communities (residential).
- 12-step or other self-help groups (e.g., Alcoholics Anonymous, Narcotics Anonymous).
- Relapse prevention (counseling).
- Opioid prevention education (Table 4).

TABLE 4 Basic Components of Opioid Overdose Prevention Education Curriculum

1. Know the signs of an opioid overdose (e.g., unresponsive, limp, slow, shallow breathing, pale or clammy, finger nails or lips turning blue, gurgling).
2. Call 911.
3. Administer rescue breathing.
4. Administer naloxone if no response and Emergency Medical Services have not yet arrived
5. Stay with the person until help arrives.

From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

ACUTE GENERAL Rx

- Medical withdrawal (not overdosed). Opioid withdrawal alone is not recommended for treatment of opioid use disorder in most patients because of increased risk of overdose death and infectious disease (e.g., HIV through IV drug use) following detoxification.
- Short- (30 days) or long-term (30 to 180 days) protocols.
- Buprenorphine (opioid partial agonist) or methadone (opioid agonist) is initiated in tapering doses.
- Clonidine 0.1 mg bid to tid can be used to minimize autonomic symptoms (sweating) and craving.
- Nonsteroidal antiinflammatory drugs for body and muscle aches.
- The anticholinergic dicyclomine can be used to minimize gastrointestinal hyperactivity.
- Nonbenzodiazepine hypnotics, low-dose atypical antipsychotics (e.g., quetiapine), or low-dose tricyclic antidepressants are effective for promoting adequate sleep.
- Psychosocial supports tailored to patient needs should be offered as an adjunct to medical treatment.

CHRONIC Rx

Opioid antagonist treatment:

- Buprenorphine/naloxone is the preferred first-line treatment. Methadone is an alternative in certain populations.
- Naltrexone: Does not stabilize neuronal circuitry like partial or full opioid agonists and generally results in poor outcomes, much like Antabuse for alcohol.
- Opioid partial agonist therapy: Buprenorphine (Suboxone, Bunavail).
- Opioid agonist therapy: Methadone.

NOTE: Buprenorphine and methadone are both metabolized by the cytochrome P450 3a4 and 2d6 I isoenzyme pathways. Prescribers should be aware of multiple possible drug interactions.

Methadone and buprenorphine produce similar improvements during opioid withdrawal, although buprenorphine is associated with less sedation and respiratory depression. To avoid precipitating more intense withdrawal, buprenorphine should be initiated 12 to 18 hours after the last administration of opioids in patients who misuse shorter-acting opioids (48 hours in patients who are receiving long-acting drugs such as methadone), with initial doses of 4 to 8 mg.[1]

PATIENT SELECTION FOR BUPRENORPHINE OR METHADONE

- Appropriate patients for buprenorphine office-based treatment:
  1. Patients interested (highly motivated) in treatment
  2. Have no major contraindications (see following)
  3. Can be expected to be reasonably compliant with treatment
  4. Understand the benefits and risks of buprenorphine treatment
  5. Willing to follow safety precautions
- Less likely to be appropriate for office-based treatment:
  1. Have comorbid dependence on benzodiazepines or other CNS depressants (including ethylene alcohol)
  2. Have significant untreated psychiatric comorbidities
  3. Have active or chronic suicidal or homicidal ideation or attempts
  4. Have multiple previous treatments with frequent relapses
  5. Have poor response to previous treatment with buprenorphine
  6. Have significant medical complications (e.g., hepatic insufficiency, bacterial endocarditis, active tuberculosis)
- Methadone maintenance: Narcotic treatment program (clinic setting) indications:
  1. Evidence of opiate addiction >1 yr
  2. Two failed previous treatment attempts
  3. Patients not appropriate for office-based treatment
  4. Eligible without active "use" if prior methadone maintenance patient within previous 2 mo
  5. Pregnancy

DISPOSITION

- Opioid addiction is a chronic, relapsing disease
- High rate of relapse after "detox."
- Relapse potential after medically supervised withdrawal from methadone:
  1. 90% after 1 yr stable in treatment
  2. 80% after 3 yr stable in treatment
  3. 70% after 5 yr stable in treatment
- Postmarketing surveillance indicates that the diversion and abuse of prescription opioid medications increased between 2002 and 2010 and plateaued or decreased between 2011 and 2013. These findings suggest that the U.S. may be making some progress in controlling the abuse of opioid analgesics[2]

From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

REFERRAL

Refer to addiction medicine specialist or narcotic treatment program when the neurobiologic disease of opioid addiction is identified.

PEARLS & CONSIDERATIONS

COMMENTS

- Methadone maintenance is the gold standard for the pregnant opioid-addicted patient regardless of the duration of the addiction or prior treatment attempts. Detoxification is contraindicated during pregnancy.
- Breastfeeding is encouraged in mothers on methadone maintenance. The American Academy of Pediatrics statement regarding "Transfer of Drugs and Other Chemicals into Human Milk" has placed methadone into the "usually compatible with breastfeeding" group based on the assumption that maternal urine is monitored to detect use of illicit drugs. The U.S. Department of Health and Human Services also recommends that mothers on methadone be encouraged to breastfeed.
- When a physician identifies a patient as a "drug seeker," it is imperative that the physician avoid abruptly stopping the opioid prescription because this will often result in the patient's buying the drugs illegally. These patients should be counseled and referred for treatment.
- Patients on methadone or buprenorphine who have pain resulting from an acute injury will need pain medication in addition to their daily dose of methadone or buprenorphine. They will require higher than usual doses of pain medications because of opioid receptor blockade attributable to their methadone or buprenorphine use.
- Opioid-dependent patients have a lower pain threshold resulting from hyperalgesia caused by the long-term use of opioids.

[2]Dart RC et al: Trends in opioid analgesic abuse and mortality in the United States, *N Engl J Med* 372:241-248, 2015.

PREVENTION

Education is the hallmark of prevention:

- School drug prevention education programs.
- Educate children about their family medical history, including diseases of addiction.
- Address childhood psychiatric disorders to prevent self-medicating.

Opioid overdose:

- Naloxone (Narcan) is a competitive mu-opioid receptor antagonist in the brain and is effective for opioid overdose. It is available for IM/IV and intranasal administration. It begins to reverse respiratory depression, sedation, and hypotension 2 to 5 min after IM administration and 1 to 2 min after IV administration.

PATIENT & FAMILY EDUCATION

- Stigma of addictions and treatment often interferes with good treatment.
- Family needs to be educated so they can support the patient's efforts.
- Encourage family meeting with addiction specialist, counselor.
- Recommend support groups for family members. Table 5 identifies organizations providing referral information for patients. Recommendations for integrating risk reduction strategies for addressing opioid misuse in the primary care setting are summarized in Table E6.

TABLE E6 Recommendations for Integrating Risk Reduction Strategies for Addressing Opioid Misuse in the Primary Care Setting

Risk Reduction Tools	Type of Client	Delivery Recommendations
Brief substance abuse screening	All clients, particularly those individuals prescribed opioid medications or with a history of substance abuse problems	Administer CAGE-AID* or similar screening tool as part of routine treatment.
Motivational interviewing	Clients who have identified opioid use or abuse	Standard procedure may be delivered by primary care provider or other clinic staff.
Comprehensive tools for safer injections, including safer injection education	Clients who have reported or are suspected of injection drug use; tools should be available to all patients, not just those identified as drug users.	Resources including educational materials, syringes, alcohol wipes, etc. distributed and discussed by the primary care provider or other clinic staff.
Naloxone prescription and distribution	Targeting individuals using illicit or prescribed opioids, including individuals prescribed opioids	Discussion, prescription of naloxone by the primary care provider; additional education may be delivered by other clinic staff.
Buprenorphine prescription	Targeting individuals using illicit or prescribed opioids, seeking medication assisted treatment	Discussion and prescription by the primary care provider

*For a full definition of CAGE-AID, see Table 1.

From Bowman S et al: Reducing the health consequences of opioid addiction in primary care, *Am J Med* 126, 565-571, 2013.

Oppositional Defiant Disorder (ODD) PTG

BASIC INFORMATION

DEFINITION

Oppositional defiant disorder (ODD) is an ongoing pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness, that is not developmentally appropriate, lasts more than 6 mo, and leads to impairment in social, academic, or occupational functioning for a child or adolescent.

SYNONYM

ODD

ICD-10CM CODE
F91.3 Oppositional defiant disorder
DSM-5 CODE
313.81 Oppositional defiant disorder

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: Usually diagnosed in school-aged children (roughly ages 6-12)
PREVALENCE: Ranges from 1% to 16% based on source (community prevalence)
PREDOMINANT SEX AND AGE:
- Males more than females
- Highest diagnosis in prepubertal children
- Usually present by age 8

GENETICS: Some evidence for genetic factors, but studies are not usually specific to ODD (e.g., studies also include conduct disorder or more generally refer to aggressive or delinquent behaviors) and include potential confounding factors (e.g., difficult to distinguish between genetic and environmental contribution)
RISK FACTORS:
- Male gender, low socioeconomic status
- The following risk factors have been identified more generally for development of disruptive behavior disorders or aggression:
  1. Family history (especially parental) of aggressive or criminal behaviors
  2. Parental substance abuse (e.g., fetal alcohol syndrome)
  3. Prenatal or early childhood exposure to toxins (e.g., lead)
  4. Perinatal complications
  5. Head injuries
  6. Cognitive impairment
  7. Learning disabilities
  8. History of abuse or witnessed domestic violence
  9. Overall family instability

PHYSICAL FINDINGS & CLINICAL PRESENTATION

DSM-5 criteria are met when there is a pattern of angry/irritable mood, argumentative/defiant behavior, or vindictiveness for at least 6 mo, and four or more symptoms from any category are present
- Angry/irritable mood:
  1. Often loses temper
  2. Is touchy or easily annoyed
  3. Is often angry and resentful
- Argumentative/defiant behavior:
  1. Often argues with adults
  2. Often actively defies or refuses to comply with requests from authority figures or with rules
  3. Often deliberately annoys others
  4. Often blames others for his or her mistakes/misbehavior
- Vindictiveness:
  1. Has been spiteful/vindictive at least twice within the past 6 mo

Symptoms are associated with distress in the individual or others, or they negatively impact social, educational, occupational, or other important areas of functioning. Symptoms may not occur only during the course of a psychotic, mood, or substance use disorder. Also, criterion must not be met for disruptive mood dysregulation disorder and, if 18 yr or older, for antisocial personality disorder. Symptoms are classified in terms of severity based on whether they are confined to only one setting, e.g., at home or at school (mild), to at least two settings (moderate), and three or more settings (severe). Finally, the DSM-5 specifies that symptoms may not occur only in the context of a sibling relationship.

ETIOLOGY

Multiple hypothetical models have been developed for disruptive behavior disorders and antisocial behaviors in general, including a few focused specifically on ODD that address the complex interaction between various predisposing and protective factors. These models identify some biologic factors (including genetic, structural, toxin exposure, etc.), some child functional factors (including cognitive, social, and neuropsychological deficits), and broad psychosocial factors that focus on parenting styles (including history of physical abuse), peer involvement, and other environmental factors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Child abuse or neglect
- Learning disorder or other deficits in executive functioning
- Intellectual disability (intellectual developmental disorder)
- Communication disorders (including language disorder, speech sound disorder, childhood-onset fluency disorder, and social communication disorder)
- Attention deficit hyperactivity disorder
- Intermittent explosive disorder
- Conduct disorder
- Antisocial personality disorder
- Mood disorder (bipolar disorder or depression)
- Psychotic disorders
- Substance use disorders
- Parent-child relational problem

WORKUP

Diagnosis is made based on history, including individual and family interviews as well as collateral data from additional sources (parents, teachers, other medical providers, therapist, etc).

LABORATORY TESTS

None indicated

IMAGING STUDIES

None indicated

TREATMENT

Initial treatment of ODD should include psychosocial interventions aimed at changing the maladaptive patterns of interaction between the child or adolescent and his or her family and environment.

If the interventions listed here are not effective, or if serious concerns exist regarding safety or impairment in functioning, pharmacologic interventions targeting specific symptoms (such as aggression) or comorbid disorders (such as ADHD, anxiety disorders, or mood disorders) may help.

There are currently no medications approved by the FDA for the treatment of ODD.

NONPHARMACOLOGIC THERAPY

- Parent management training
- Cognitive problem-solving skills training
- Social skills training
- Individual psychotherapy
- Family psychotherapy

ACUTE GENERAL Rx

- Medication may be considered as an adjunct to behavioral treatment or in cases where comorbidity is a factor. There is some evidence for symptom improvement with trials of stimulants, mood stabilizers, or atypical antipsychotics, but medication should never be used alone or as first-line treatment for ODD.
- Higher levels of care such as a hospital or acute residential setting may be required for stabilization if acute safety concerns develop in the context of ODD, such as severe aggression.

COMPLEMENTARY & ALTERNATIVE MEDICINE

No evidence-based treatments are available.

DISPOSITION

- Most patients with ODD can be managed in an outpatient setting with either standard or intensive, home-based support; treatment should always be provided in the least restrictive setting possible.
- Hospitalization is sometimes necessary for crisis management only; consideration of different levels of care, including day treatment, therapeutic school settings, or residential facilities, may be appropriate for more severe cases or in situations where the family is not willing or able to participate adequately in the outpatient regimen.

REFERRAL

Consider referral to a mental health provider specializing in the treatment of children, adolescents, and families (including potentially a

child and adolescent psychiatrist) if the patient and family are not responding to basic parenting interventions or are demonstrating significant safety concerns or other evidence of impairment in functioning at home, in school, or in the community.

PEARLS & CONSIDERATIONS

COMMENTS

- Involvement of the family and school is crucial in the management of patients with this disorder.
- Polypharmacy (the prescribing of multiple medications simultaneously) to target the more complicated symptoms of this disorder should be implemented with great caution and only after discrete trials of therapeutic interventions and single medication agents have failed.
- Standardized assessment tools used to identify ADHD, disruptive behavior disorders, and general child and adolescent psychopathology may be helpful in confirming the diagnosis of ODD and/or monitoring progress throughout treatment.
- ODD symptoms are independently associated with increased externalizing symptoms, internalizing symptoms, delinquent behaviors, and social and academic functioning.
- One-time, intensive interventions are not considered effective treatment options (including boot camps, shock incarceration) and may carry additional risks.
- When ODD coexists with attention deficit hyperactivity disorder, stimulant therapy can reduce the symptoms of both disorders.

PREVENTION

Most effective prevention strategies include both individualized treatment and universal interventions that incorporate a parent-directed component as one of the primary elements. They also may incorporate social-cognitive skills training, academic skills training, proactive classroom management and teacher training, and group therapy. These may take place in schools, clinics, and other community-based settings in addition to targeted clinical work.

Optic Atrophy

BASIC INFORMATION

DEFINITION

- *Optic atrophy* refers to the degeneration of axons of the optic nerve.
- It is a sign indicative of optic nerve insult rather than a distinct disease entity.

SYNONYM

Unilateral/bilateral optic atrophy

ICD-10CM CODE
H47.2 Optic atrophy

EPIDEMIOLOGY & DEMOGRAPHICS

PREDOMINANT SEX: Depends on etiology
PREDOMINANT AGE: Variable
PEAK INCIDENCE: Varies depending on cause

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Optic atrophy is identified weeks to months after an initial insult such as optic neuritis, trauma, or ischemia. Frequently, it is noted by the physician during a routine eye exam.
- Asymmetry of disc color is often first subtle finding.
- Temporal part of optic disc is pale initially; later, the entire disc becomes pale/white.
- Optic disc pallor (Fig. E1) occurs 4 to 6 wk after optic nerve insult.
- Unilateral lesion produces a relative afferent pupillary defect (RAPD): Swing flashlight eye to eye; abnormal pupil dilates to direct light.
- Decreased visual acuity, blurred vision, visual field deficits (e.g., central scotoma), abnormal color vision (e.g., red desaturation).

ETIOLOGY

- Inflammatory optic neuritis: MS, sarcoidosis, neuromyelitis spectrum disorder, infections (syphilis, CMV, HIV, Lyme disease, cat-scratch disease)
- Vascular: Ischemic optic neuropathy, central retinal artery occlusion, temporal arteritis
- Compression: Pituitary tumor, meningioma, thyroid eye disease
- Hereditary: Leber hereditary optic neuropathy, dominant optic atrophy
- Nutritional, toxic, and metabolic: Amiodarone, isoniazid, B_{12} deficiency, tobacco, alcohol
- Trauma
- Glaucoma (end-stage disease)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Optic disc anomalies such as myelinated nerve fibers, "blonde" fundus

WORKUP

- A detailed history to identify onset and course, exposure to risk factors such as toxic/nutritional factors, detailed family history, and associated findings such as headache, eye pain, proptosis, or neurologic deficits.
- Ophthalmic examination to document deficits of visual acuity, color vision, contrast sensitivity, and visual fields must be performed. Relative afferent pupillary defect (RAPD) on swinging flashlight examination is sine qua non for unilateral optic nerve disease and must be documented. Absence indicates retinal disease or bilateral lesions.
- General examination and neurologic examination can provide clues to an underlying cause.
- Pertinent laboratory testing as noted below; genetic studies with a genetic consultation can be obtained in cases with a suggestive history.
- In the absence of an obvious cause, contrasted MRI of brain and orbits should be obtained to evaluate for demyelinating lesions and compressive lesions of the anterior visual pathways. Lumbar puncture should be obtained in patients with unexplained optic atrophy, especially with neurologic deficits.

LABORATORY TESTS

- Depends on suspected cause: None for trauma, tumor, or MS
- Serum B_{12}, RPR, HIV
- Autoimmune diseases: ESR, ANA, ACE, aquaporin-4 antibodies (NMO IgG)

IMAGING STUDIES

- MRI of the brain and orbits with contrast , fat suppression, and special (thin) cuts through orbits is necessary to identify compressive lesions in all patients with unexplained optic atrophy; especially important in patients with positive predictive factors for abnormal imaging (e.g., young age, progression, bilateral findings).
- If sarcoid is suspected, order chest x-ray and/or chest CT.

TREATMENT

ACUTE GENERAL Rx

Treat the underlying cause—discontinue identifiable toxins, use B_{12} replacement, neurosurgical intervention is necessary if tumor is found; consider IV steroids if there is evidence for active demyelinating disease.

CHRONIC Rx

The optic nerve does not regenerate, although symptoms often improve.

DISPOSITION

- Visual loss usually occurs over weeks to months
- Appointment with neurologist or ophthalmologist

REFERRAL

Depends on the underlying disease process

PEARLS & CONSIDERATIONS

COMMENTS

- An experienced clinician should be able to identify pale optic discs and a RAPD.
- Pupillary dilation with mydriatic agents (e.g., tropicamide) may be necessary to optimize funduscopic examination.
- Patient education material can be obtained from the National Eye Institute, Department of Health and Human Services, 9000 Rockville Pike, Bethesda, MD 20814.

AUTHOR: **Sachin Kedar, MBBS, MD**

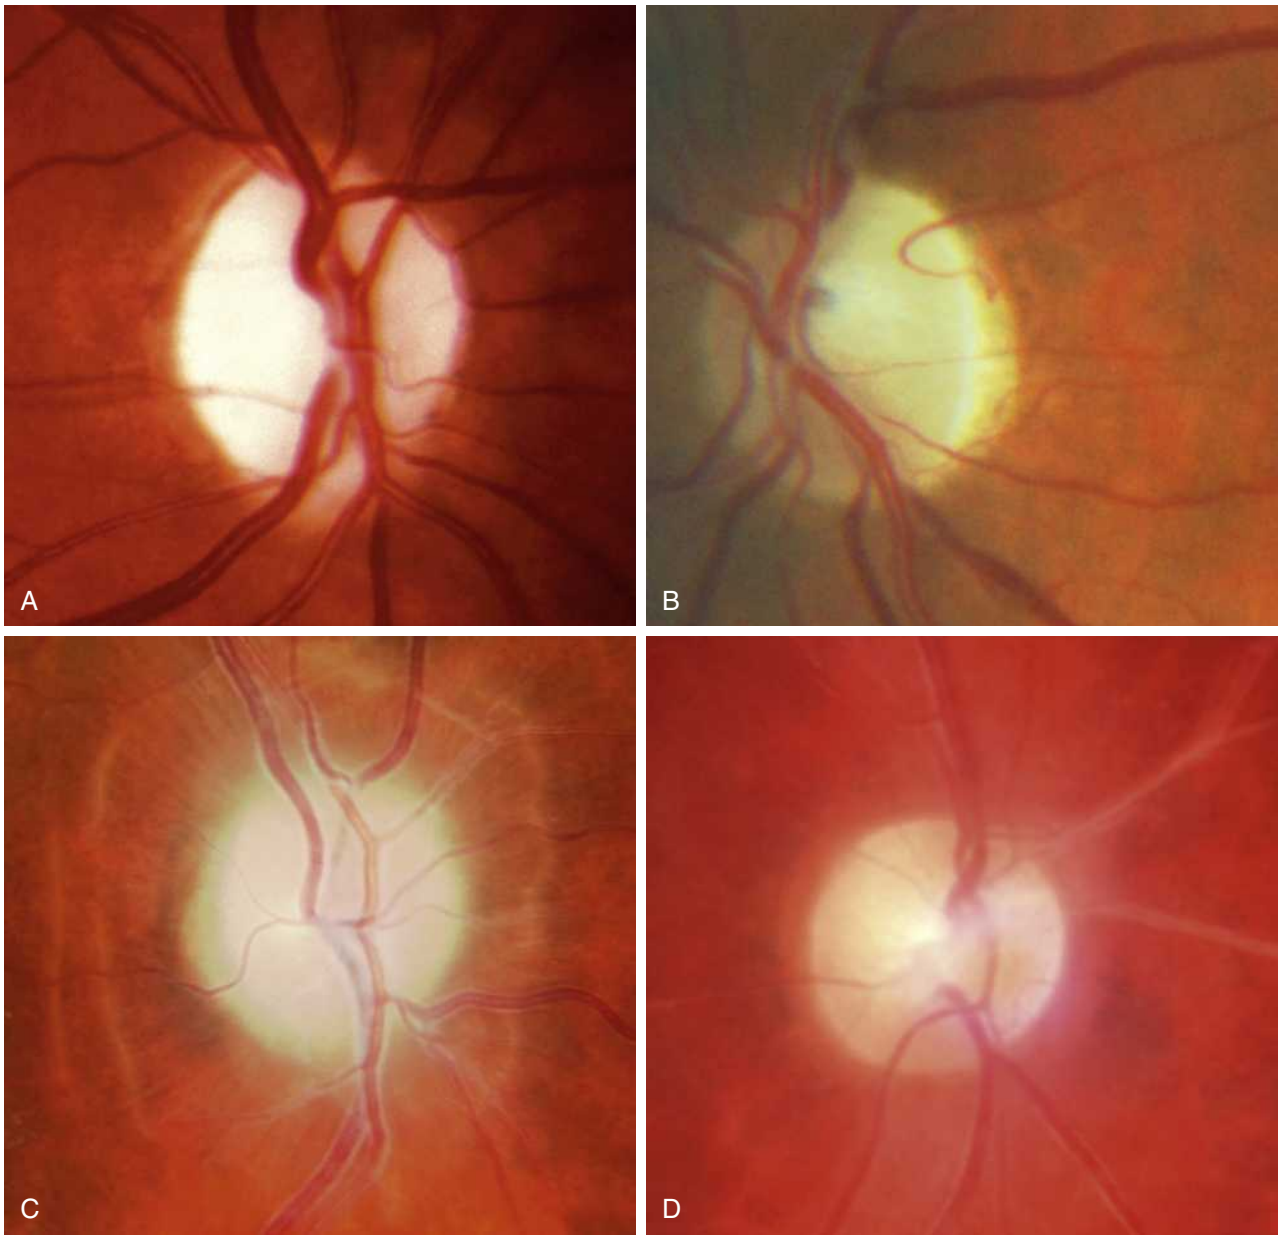

FIG. E1 Optic atrophy. A, Primary due to compression. **B,** Primary due to nutritional neuropathy—note predominantly temporal pallor. **C**, Secondary due to chronic papilloedema—note prominent Paton lines (see text). **D,** Consecutive due to vasculitis. Optic Neuritis

BASIC INFORMATION

DEFINITION

Optic neuritis is an inflammation of the optic nerve resulting in impaired visual function.

SYNONYMS

Optic papillitis
Retrobulbar neuritis

ICD-10CM CODES
H46.8 Other optic neuritis
H46.9 Unspecified optic neuritis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 1 to 5/100,000 person(s) per yr; rates vary according to incidence of multiple sclerosis (MS). Optic neuritis affects 1% to 5% of patients with neurosarcoid.
PREVALENCE (IN U.S.): Common in patients with MS
PREDOMINANT SEX: Female:male ratio: 1.8:1
PEAK INCIDENCE: 20 to 49 yr, mean 30
GENETICS: Unknown. If due to MS, it is more common in patients with certain human lymphocyte antigen (HLA) blood types and in monozygotic twins of affected siblings.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Presentation with acute or subacute (days) visual loss, often accompanied by periocular tenderness that worsens with eye movements.
- **Marcus Gunn pupil** (relative afferent pupillary defect [RAPD]): Direct and consensual response is normal; however, when flashlight is swung from eye to eye, the affected eye's pupil dilates to direct light.
- Decreased visual acuity.
- Unilateral visual field abnormalities—often a central scotoma (Fig. E1).
- Color desaturation; red is most often affected.
- Normal fundus examination in 66% cases; disc edema is noted in 33%. Other abnormalities include uveitis or periphlebitis. In neurosarcoid, the optic nerve head may exhibit a lumpy appearance suggestive of granulomatous infiltration, and there may be associated vitritis (Fig. E2).
- May have movement or light-induced phosphenes (flashes of light lasting 1 to 2 sec).
- Uhthoff phenomenon (benign exercise- or heat-induced deterioration of vision) is seen in some. Vision may also worsen in bright sunlight.
- Over time the optic disc may atrophy and become pale.

ETIOLOGY

An inflammatory response associated with an infection or autoimmune disease (such as collagen vascular disease, granulomatous disease, MS, or neuromyelitis optica).

DIAGNOSIS

Diagnosis is clinically established in a young patient with acute onset of monocular vision loss associated with retroorbital pain associated with eye movements and presence of RAPD lasting more than 24 hr. Absence of other orbital or ocular pathology is based on clinical examination.

DIFFERENTIAL DIAGNOSIS

For optic neuritis:
- Inflammatory: MS, neuromyelitis optica spectrum disorder (NMOSD), sarcoidosis, lupus, Sjögren, Behçet, postinfectious, postvaccination, neuroretinitis, acute disseminated encephalomyelitis, paraneoplastic, autoimmune optic neuropathy
- Infectious: Syphilis, TB, Lyme disease, *Bartonella,* HIV, cytomegalovirus (CMV), herpes, helminths, chickenpox, Q fever, periorbital infections, *Toxocara* sp.
- Ischemic: Anterior and posterior ischemic optic neuropathies, diabetic papillopathy, branch or central retinal artery or vein occlusion
- Drugs and toxins: Arsenic, methanol, ethambutol, cyclosporine, etc.
- Mitochondrial: Leber hereditary optic neuropathy, other mitochondrial

WORKUP

A thorough neurologic examination; dilated ophthalmoscopy

LABORATORY TESTS

Acute optic neuritis is a clinical diagnosis based on presentation with classical features: acute, painful unilateral loss of vision associated with RAPD in a young person with no other apparent causes such as trauma. In atypical cases additional studies may be considered.
- CBC, antinuclear antibody (ANA), ACE, erythrocyte sedimentation rate (ESR)
- Consider HIV Ab, Lyme titer, rapid plasma reagin (RPR), other autoimmune or infectious causes
- Bilateral or recurrent optic neuritis (ON): neuromyelitis optica (NMO) immunoglobulin (IgG), myelin oligodendrocyte glycoprotein (MOG IgG), paraneoplastic CRMP-5-IgG

IMAGING STUDIES

- Contrast-enhanced MRI of the brain is performed to assess the risk of developing MS. Often enhancement of the optic nerve is seen. MRI orbits with thin sections of fat suppressed sequences may be needed if the patient demonstrates atypical features (Fig. E3).
- Consider using optical coherence tomography to follow optic nerve atrophy objectively longitudinally.

TREATMENT

NONPHARMACOLOGIC THERAPY

Assure patient that in most cases of typical optic neuritis, there is near complete recovery of vision.

ACUTE Rx

Treat if the visual loss is significant, atypical features, or if there is an abnormal MRI (higher risk of MS). Treatment is with methylprednisolone (MP) 250 mg IV every 6 hr (or 1 g IV daily) for 3 days followed by an oral prednisone taper of 11 days. Optic neuritis from NMOSD is often more severe and has a worse prognosis; therefore plasma exchange can be considered.

CHRONIC Rx

Depends on underlying cause. Disease-modifying treatment when increased risk of developing MS or neuromyelitis optica spectrum disorder. See topic "Multiple Sclerosis."

DISPOSITION

Most often vision is worst at the end of wk 1, followed by recovery over months. In the Optic Neuritis Treatment Trial (ONTT), 90% had 20/40 or better vision at 1 yr and 3% had 20/200 or worse. Of initial 20/200 or worse cases, only 5% remained in that group at 6 mo.

REFERRAL

- To neurologist for other neurologic signs and to assess risk of developing MS. In ONTT (Optic Neuritis Treatment Trial), risk of MS >15 yr was 72% with ≥1 lesion(s) on MRI, and 25% with a normal MRI.
- To ophthalmologist when atypical features or slowly progressive; urgently when other ocular pathology is present or if vision worsens or does not improve after several wk, or pain is severe.

PEARLS & CONSIDERATIONS

- Bilateral optic neuritis suggests a systemic inflammatory disorder, infection, NMOSD, or paraneoplastic, but can also occur in MS.
- Acute bilateral loss of vision with a severe headache or diplopia should raise concern for pituitary apoplexy and/or giant cell arteritis.

BASIC INFORMATION

DEFINITION

Oral cancers refer to malignant transformation of the oral tissues usually preceded by a process of sequential dysplastic changes leading to the development of squamous carcinoma. Oral squamous cell cancers (OSCC) include oral cavity cancers (lip, floor of mouth, buccal mucosa, anterior tongue, gingivae, hard palate, retromolar trigone), oropharynx cancers (base of tongue, tonsils, soft palate, pharyngeal walls), and hypopharynx cancers (pyriform sinus, postcricoid area, posterior pharyngeal wall).

SYNONYMS

Head and neck cancer
Oral malignant neoplasm
OSCC

ICD-10CM CODES

C01	Malignant neoplasm of base of tongue
C03	Malignant neoplasm of gum
C04	Malignant neoplasm of floor of mouth
C05	Malignant neoplasm of palate
C06	Malignant neoplasm of other and unspecified parts of mouth
C09	Malignant neoplasm of tonsil
C10	Malignant neoplasm of oropharynx
C11	Malignant neoplasm of nasopharynx
C12	Malignant neoplasm of piriform sinus
C13	Malignant neoplasm of hypopharynx
C14	Malignant neoplasm of other and ill-defined sites of lip, oral cavity and larynx
C14.0	Malignant neoplasm of pharynx, unspecified
C14.2	Malignant neoplasm of Waldeyer ring
C14.8	Malignant neoplasm of overlapping sites of lip, oral cavity and pharynx

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE & PREVALENCE: OSCC comprise the sixth most common cancer in the world. An estimated 530,000 cases are diagnosed annually around the globe, and the rates have been rising, particularly in young people and among minorities. It was estimated that in 2019, approximately 53,000 new cases and 10,860 deaths would occur in the U.S. The incidence of oral cancers linked to alcohol and tobacco use has been declining in the U.S., whereas those linked to human papillomavirus (HPV), primarily HPV type 16, are on the rise, especially for cancers located in the tonsils and base of tongue. In developed countries across the world, HPV is increasingly implicated in the growing incidence of oral cancer. In Asian countries where chewing betel nut is customary, oral cancer accounts for up to 40% of cancers in some regions. Squamous cell carcinoma is the most common malignancy that occurs in the oral cavity.

PREDOMINANT SEX & AGE: The ratio of oral cancer in males: females is 2.5:1 in the U.S. Black males have a higher early incidence in the 50- to 60-yr age group, but with increasing age, white men predominate.

GENETICS: The genes that are critically altered in OSCC include *TP53,* the retinoblastoma family, *p16* and cyclin *D1*. The *TP53, CCND1,* and *CDKN2A* genes are established cancer genes in HPV-negative cancers. *TP53* and the genes encoding the Rb family are established cancer genes in HPV-positive cancers. Signaling pathways that are involved in the pathogenesis of oral cancers include that of the human epidermal receptor (HER) family, vascular endothelial growth factor (VEGF) receptor, and signal transducer and activator of transcription 3 (STAT 3). The tumor suppressor gene *TP53* is frequently mutated in HPV-negative tumors.

RISK FACTORS (Fig. 1): The following factors are implicated in the development of oral cancer:

- Tobacco use
- HPV infection (primarily types 16 and 18)
- Alcohol
- Immune deficiency
- Radiation
- Betel nut consumption
- Solar radiation

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Specific patient complaints may include the following: oral ulcers or mass, choking, difficulty breathing, dysphagia, odynophagia, voice hoarseness, globus sensation, otalgia, ear or nose stuffiness, hemoptysis, trismus, neck mass, and pain in the head/neck region.
- Generalized symptoms and signs may include weight loss, fatigue, anorexia, altered mood, and sleep.

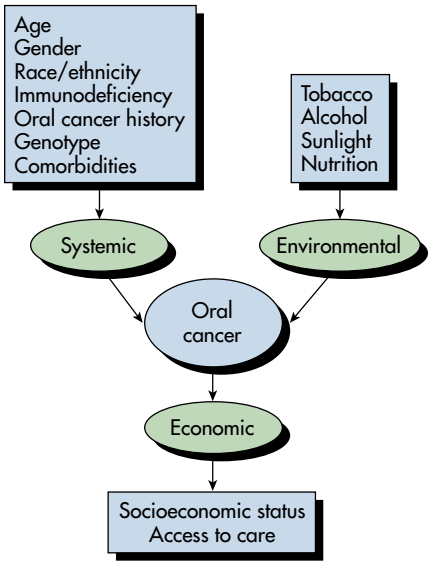

FIG. 1 Risk model for oral cancer. Oral cancer is a multifactorial disease process that includes systemic, environmental, and economic effects. The interplay of these variables ultimately leads to the incidence of this disease. The multifactorial nature of oral cancer should be addressed in the assessment of a patient's risk. (From Jones DL, Rankin KV: Oral cancer and associated risk factors. In Cappelli D, Mobley C [eds]: *Prevention in clinical oral health care,* St Louis, 2008, Elsevier, pp 68-77.)

- Clinically, oral cancers can present as:
  1. Erythroplakia (flat red patch); can mimic inflammatory or traumatic lesions
  2. Leukoplakia (white patch; Fig. E2)
  3. Raised lesion
  4. Ulcerated lesion
  5. Warty lesion or growth

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Oral leukoplakia
- Invasive fungal infections
- Chancre of early syphilis and gumma of tertiary syphilis
- Chronic ulcer
- Metastatic or locally invading cancers from sinuses or other sites of the body

PATIENT WORKUP

- Primary workup includes either biopsy or fine-needle aspiration (FNA) of the presenting lesion or suspected neck lymph node for histopathologic analysis. HPV assessment with p16 immunohistochemical staining and confirmatory in situ hybridization (ISH) testing is performed when indicated for oropharynx primary tumors.
- Detailed examination of the oral cavity, pharynx, larynx, neck, ears, nose, and cranial nerves should be performed.
- Laryngoscopy and examination under anesthesia are commonly performed.
- Pretreatment evaluation of tumor size, the extent of invasion, and the presence or absence of regional lymph node metastases is critical for planning treatment.
- Laboratory workup can include complete blood count, complete chemistry panel, and thyroid function.
- Staging workup includes CT or MRI imaging of the head and neck and a chest x-ray. If locoregional or advanced disease is a consideration, a PET scan is typically completed.
- The TNM system is used for staging of OSCC and is subdivided according to primary tumor sites: (1) lip and oral cavity, (2) pharynx.

TREATMENT

- Surgery, radiation therapy, and chemotherapy are treatment modalities involved in the treatment plan for OSCC.
- The use of supportive and special therapeutic modalities such as nutritional therapy including feeding gastrostomy, speech and swallowing therapy, reconstructive surgery, and speech prosthesis is required often.
- For treatment purposes OSCC are classified as early (T1 or T2 lesions), locoregional (T3-4 or any N), or metastatic (M1) stages. Site-specific TNM staging is done as per the primary tumor site (e.g., oral cavity, oropharynx, hypopharynx, etc.).
- After staging completion, the initial treatment considerations include:
  1. Determination of primary tumor resectability (resectable vs. unresectable)
  2. Management of neck nodes

3. Intent of radiation therapy (curative vs. palliative)
4. Need for organ preservation
5. Need for reconstructive surgery
6. Need for chemotherapy
7. HPV status of tumor

- Localized tumors (stage I or II) can be approached by initial surgical resection or definitive radiotherapy. Loco-regionally advanced tumors (stage III and localized IV) that are resectable are typically approached by upfront surgery followed by adjuvant radiation and/or chemotherapy. Unresectable patients are typically treated with definitive chemotherapy and radiotherapy. Patients with distant metastatic disease are treated with systemic chemotherapy, while locally recurrent tumors can be approached with either surgery or chemotherapy or both.
- Surgery is typically associated with less long-term morbidity than radiation therapy. Surgical therapy traditionally involved wide-exposure approaches (mandibulotomy, transpharyngeal access). Newer surgical techniques allow tumor resection through the mouth. Recently, transoral robotic surgery (TORS) has been developed to improve access to oropharyngeal squamous cell carcinomas with excellent oncologic outcomes.
  1. Acute surgical complications can include infection, bleeding, aspiration, wound breakdown, fistula, and flap loss.
  2. Surgical procedures can cause functional deficits in speech and swallowing, but these adverse effects can be minimized by appropriate reconstruction and prostheses.
- Definitive radiation therapy is reserved for patients who cannot tolerate surgery or for whom surgical resection would result in particularly severe functional impairment.
  1. Radiation therapy can include external beam radiation and brachytherapy.
  2. Radiation therapy side effects include mucositis, radiation dermatitis, loss of taste, dysphagia, dental caries and decay, and xerostomia.
  3. Late complications can include skin/soft tissue atrophy and fibrosis, osteoradionecrosis, and trismus.
- Systemic chemotherapy can be administered alone or in combination with radiotherapy, depending on the disease stage. Agents typically used include cisplatin, carboplatin, 5-fluorouracil, taxanes, and the epidermal growth factor receptor (EGFR) antibody cetuximab.
- For locally advanced OSCC, the combination of cisplatin and radiotherapy is the regimen of choice. In selected patients with large primary tumors or bulky nodal disease, neoadjuvant chemotherapy may be utilized prior to chemoradiotherapy administration.
- Patients who have metastatic cancers or unresectable locoregional recurrences usually are treated with systemic chemotherapy.
- Standard doublet chemotherapy regimens (platinum plus either 5-fluorouracil or a taxane) can be combined with the epidermal growth factor receptor (EGFR)–targeting antibody cetuximab. A recent study has demonstrated the superiority of frontline therapy with platinum plus 5-fluorouracil chemotherapy in combination with the checkpoint inhibitor pembrolizumab.
- In patients who have not received checkpoint inhibitor therapy previously, nivolumab and pembrolizumab have been shown to improve survival outcomes after failure of first-line chemotherapy.
- The negative predictive value of post-treatment PET imaging in patients with locally advanced cancer who have been treated with chemoradiotherapy is 98% to 99%.

DISPOSITION

- Prognosis depends on the staging and resectability of the primary tumor as well as on patient performance status.
- Tumor HPV status is a strong and independent prognostic factor for survival among patients with base of tongue and oropharyngeal cancer.

REFERRAL

Referral to multidisciplinary head and neck cancer team consisting of ENT or head/neck surgeon, radiation oncologist, and medical oncologist

PEARLS & CONSIDERATIONS

COMMENTS

- Oral and pharyngeal cancer is the sixth most common cancer globally.
- Biopsy with HPV-status assessment is the key for accurate diagnosis.
- Posttreatment rehabilitation and surveillance is important.

PREVENTION

- Encourage patients to stop using any type of tobacco and drinking alcohol.
- Examine oral cavities at annual checkups and work up suspicious lesions.

BASIC INFORMATION

DEFINITION

Oral hairy leukoplakia (OHL) is a painless, white, nonremovable, plaquelike lesion typically located on the lateral aspect of the tongue.

SYNONYMS

Oral hairy leukoplakia
OHL

ICD-10CM CODE
K13.3 Hairy leukoplakia

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE AND PREVALENCE: Epstein-Barr virus (EBV) is implicated in the etiology of OHL, and the incidence of EBV seroprevalence is high in individuals who are HIV seropositive. However, OHL occurs in only 25% of these cases but may also occur in other immunosuppressed individuals, for example, organ transplant recipients.
RISK FACTORS: OHL is usually found in HIV-seropositive individuals (median CD4 count is 468/ml) but may also be identified in smokers and other immunocompromised patients such as transplant recipients (particularly renal) and patients taking steroids. Diagnosing OHL is an indication to institute a workup to evaluate and manage HIV disease.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Varying morphology and appearance, which may change daily.
- May be unilateral or bilateral.
- White plaques can be small with fine, vertical corrugations on the lateral margin of the tongue (Fig. 1). The plaques from OHL are adherent to the tongue surface (in contrast to candidal plaques, which may be easily scraped off).
- Irregular surface; may have prominent folds or projection, occasionally markedly resembling hairs.
- May spread to cover the entire dorsal surface or spread onto the ventral surface of the tongue where the lesions usually appear flat.
- Rarely, lesions can manifest on the soft palate, buccal mucosa, or posterior oropharynx.
- Usually asymptomatic, but some patients have mouth pain, soreness, or a burning sensation; impaired taste, or difficulty eating; others complain of its unsightly appearance.
- OHL may rarely progress to oral squamous cell carcinoma, particularly in smokers, which has a poor prognosis.

ETIOLOGY

EBV is implicated in its etiology, and OHL is a result of unchecked lytic replication of EBV in the epithelium of keratinized cells. OHL differs from most EBV-related diseases in that infection is predominantly lytic rather than latent, with abundant virus production resulting in cell lysis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Oral homogenous/non-homogenous leukoplakia
- *Candida albicans*
- Lichen planus
- Idiopathic leukoplakia
- White sponge nevus
- Dysplasia
- Squamous cell carcinoma

WORKUP

Requires physical examination and evaluation of HIV disease

LABORATORY TESTS

The *provisional* diagnosis is clinical and based on:
- Visual inspection
- Inability to scrape the lesion off the tongue with a blade
- Failure to respond to antifungal therapy

The *presumptive* diagnosis requires biopsy and histologic demonstration of:
- Epithelial hyperplasia with hairs
- Absence of inflammatory cell infiltrate

The *definitive* diagnosis requires:
- In situ hybridization of histologic or cytologic specimens revealing EBV DNA *or*
- Electron microscopy of specimens revealing herpes-like particles
- Measurement of the DNA content in cells of oral leukoplakia may be used to predict the risk of oral carcinoma

NOTE: Specimens obtained from lesions may demonstrate hyphae of *Candida albicans,* which may coexist and potentiate EBV-induced OHL.

TREATMENT

NONPHARMACOLOGIC THERAPY

OHL is usually asymptomatic and requires no specific therapy. It may resolve spontaneously and is generally benign in HIV-seropositive patients.

ACUTE GENERAL Rx

- Antiretroviral therapy (ART) has considerably changed the frequency of oral lesions caused by opportunistic infections in HIV-seropositive individuals.
- Topical retinoids (0.1% vitamin A) may improve the appearance of OHL-affected oral surfaces through their dekeratinizing and immunomodulation effects; however, they are expensive, and prolonged use may result in a burning sensation over the treated area.
- Topical podophyllin resin 25% solution has been reported to induce resolution.
- Surgical excision and cryotherapy may help, but the lesions may recur.
- High-dose acyclovir 800 mg five times per day, valacyclovir 1000 mg tid, famciclovir 500 mg tid, ganciclovir 1000 mg tid, or foscarnet 40 mg/kg IV tid will cause lesions to resolve but only temporarily.

REFERRAL

Referral to ENT or oral surgeon for biopsy of tongue to confirm diagnosis

PEARLS & CONSIDERATIONS

- OHL may be the presenting sign of patients infected with HIV who are unaware of their status.
- The incidence has decreased significantly in the era of antiretroviral therapy.

BASIC INFORMATION

DEFINITION

Orchitis is an inflammatory process (usually infectious) involving the testicles. Infection may be viral or bacterial and can be associated with infection of other male sex organs (prostate, epididymis, or bladder) or lower urogenital tract or sexually transmitted diseases often via hematogenous spread. Common causes are:

- Viral: Mumps—20% postpubertal; Coxsackie B virus
- Bacterial: Pyogenic via spread from involving epididymis; bacteria include *Escherichia coli, Klebsiella pneumoniae, P. aeruginosa, Staphylococcus, Streptococcus* or *Rickettsia, Brucella* spp.
- Other:
  1. Viral—HIV-associated, CMV
  2. Fungi
     a. Cryptococcosis
     b. Histoplasmosis
     c. *Candida*
     d. Blastomycosis
     e. Syphilis
  3. *Mycobacterium tuberculosis* and *M. leprae*
  4. Parasitic causes: Toxoplasmosis, filariasis, schistosomiasis
- Table 1 describes a classification of epididymitis and orchitis based on etiology.

SYNONYMS

Epididymo-orchitis
Testicular infection
Testicular inflammation

ICD-10CM CODES

N45.9	Orchitis, epididymitis, and epididymo-orchitis without abscess
A54.1	Gonococcal orchitis
A56.1	Chlamydial orchitis
N51.1	Mumps orchitis

EPIDEMIOLOGY & DEMOGRAPHICS

PREDOMINANT SEX: Male
PREDOMINANT ORGANISM: The leading cause of viral orchitis is mumps. The mumps virus rarely causes orchitis in prepubertal males but involves one or both testicles in nearly 30% of postpubertal males.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Testicular pain, unilateral or bilateral swelling
- May have associated epididymitis, prostatitis, fever, scrotal edema, erythema, cellulitis
- Inguinal lymphadenopathy
- Acute hydrocele (bacterial)
- Rare development: Abscess formation, pyocele of scrotum, testicular infarction
- Spermatic cord tenderness may be present
- Granulomatous

DIAGNOSIS

Clinical presentation as described previously with possible history of acute viral illness or concomitant epididymitis

DIFFERENTIAL DIAGNOSIS

- Epididymo-orchitis-gonococcal
- Autoimmune disease
- Vasculitis
- Epididymitis
- Mumps, with or without parotitis
- Neoplasm
- Hematoma
- Spermatic cord torsion

LABORATORY TESTS

- CBC with differential
- Urinalysis
- Viral titer—mumps. Mumps IgM will be detectable after 5 days of onset of clinical mumps and remain positive for up to 4 wk. A reverse-transcriptase PCR (RT-PCR) on serum or buccal or oral swab is another option.
- Urine culture for mumps virus
- Ultrasound of testicle to rule out abscess

IMAGING STUDIES

Ultrasound if abscess suspected

TREATMENT

- Dependent on cause
- Viral (mumps): Observation; bed rest, ice packs, analgesics, and a scrotal sling for support may provide some relief of discomfort that accompanies mumps orchitis
- Bacterial: Empiric antibiotic treatment with parenteral antibiotic treatment until pathogen identified: Ceftriaxone (250 mg IM once) plus doxycycline (100 mg PO bid for 10 days), in men <35 yr old to cover *Neisseria gonorrhoeae* and *Chlamydia trachomatis.* In men who have sex with men or men >35 yr old: Levofloxacin 500 to 750 mg IV/PO qd for 10 to 14 days *or* ampicillin-sulbactam *or* third-generation cephalosporin or piperacillin/tazobactam
- Surgery for abscess, pyogenic process

DISPOSITION

Follow-up for evidence of recurrence, hypogonadism, and infertility may be needed with bilateral orchitis.

REFERRAL

- To a urologist if surgical drainage is needed
- To an endocrinologist if hypogonadism develops
- To a fertility specialist if infertility develops

PEARLS & CONSIDERATIONS

Consider tuberculous orchitis if symptoms fail to respond to standard antibacterial therapy, even in the absence of chest radiographic evidence of pulmonary tuberculosis.

BASIC INFORMATION

DEFINITION

Orthostatic hypotension (OH) is defined as the presence of at least one of the following:

- Decrease in systolic blood pressure by ≥20 mm Hg or
- Decrease in diastolic blood pressure by ≥10 mm Hg, within 3 min of standing.

It is a physical sign that requires further investigation to discern its underlying etiology.

Recent studies have shown that blood pressure measurements within 1 min might be more useful in predicting fractures, falls, and other adverse events and for most patients, assessment within 1 min of standing rather than waiting for 3 min may be sufficient.[1]

SYNONYMS

Postural hypotension
OH

ICD-10CM CODE
I95.1 Orthostatic hypotension

EPIDEMIOLOGY & DEMOGRAPHICS

- The incidence of OH is increased in older people. Surveys have shown OH to be present in approximately 20% of adults over 65 yr of age.
- Also, higher incidence noted in those with diseases associated with autonomic dysfunction (e.g., Parkinson disease, diabetes mellitus).
- OH may cause up to 30% of all syncopal events in the elderly, and OH is associated with an increased risk of heart failure among those aged 45 to 55 yr and an increased risk of cardiovascular disease and all-cause mortality among those aged 55 yr and older.
- There is an association between orthostatic hypotension and cognitive dysfunction among older adults.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Symptoms may include dizziness, lightheadedness, syncope, visual and auditory disturbances, weakness, diaphoresis, pallor, and nausea.
- OH may be asymptomatic, especially in older hypertensive patients with autonomic dysfunction. These patients tend to have systolic hypertension when seated or supine.
- Associated with increased autonomic activity during meals (from increased splanchnic blood flow), exercise, prolonged standing, and hot weather.
- Supine and nocturnal hypertension in patients with OH may indicate an underlying autonomic dysfunction.

[1]Juraschek SP et al: Associated of history of dizziness and long-term adverse outcomes with early vs. later orthostatic hypotension assessment times in middle-aged adults, *JAMA Intern Med* 2017.

ETIOLOGY

- There are two main mechanisms for OH: autonomic dysfunction and volume depletion.
- Normal response: Assumption of an upright posture results in the pooling of approximately 500 ml of blood in the lower extremities due to gravity and decreased venous return, decreased cardiac output, and decreased arterial pressure. The consequent increase in sympathetic tone due to increased carotid baroreceptor activity causes arterial and venous constriction as well as positive inotropic and chronotropic effects, thereby limiting the fall in upright blood pressure. Peripheral vasoconstriction is also mediated by increased activity of the renin-angiotensin system and decreased activity of atrial natriuretic factor.
- Autonomic Dysfunction: Impairment of the baroreceptor reflex, as in central (such as Parkinson disease) or peripheral autonomic dysfunction (such as diabetes) and aging, may cause OH because decreased blood pressure cannot be counteracted by the aforementioned regulatory mechanisms.
- Volume depletion: May be caused by diuretics, vomiting, hemorrhage, and hyperglycemia. Mechanism of OH in these patients is similar to what is described earlier, with failure of the regulatory mechanisms kicking in.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Common:

- Medications: Antihypertensives, antidepressants (tricyclics), antipsychotics (phenothiazines), alcohol, narcotics, barbiturates, insulin, nitrates, PDE-5 inhibitors, alpha-adrenergic antagonists
- Reduced intravascular volume (hemorrhage, dehydration, hyperglycemia, hypoalbuminemia)
- Postprandial effect (especially in the elderly)
- Vasovagal syncope
- Deconditioning
- Central autonomic dysfunction (Parkinson disease)
- Peripheral autonomic dysfunction (diabetes mellitus, Guillain-Barré syndrome)

Uncommon:

- Central autonomic dysfunction (Shy-Drager syndrome)
- Postganglionic autonomic dysfunction: Impaired norepinephrine release
- Autoimmune autonomic dysfunction: Nicotinic acetylcholine receptor autoantibodies
- Paraneoplastic autonomic dysfunction: Anti-Hu antibodies (in small-cell lung cancer)
- Postural tachycardia syndrome (POTS): Usually occurs in young women; an abnormally large increase in heart rate is observed in the upright position, caused by increased venous pooling from autonomic dysfunction of the lower extremities, but blood pressure is not affected because of an excess of plasma norepinephrine
- Impaired cardiac output (myocardial infarction, aortic stenosis, arrhythmias)
- Cerebrovascular accident
- Adrenal insufficiency
- Deconditioning
- Carotid sinus hypersensitivity
- Anxiety, panic attacks
- Seizures
- Sepsis
- Idiopathic

WORKUP

- Obtain a detailed history including medication list, recent history of potential volume loss, medical history of congestive heart failure, malignancy, diabetes and alcoholism, evidence on history and physical examination of parkinsonism, ataxia, peripheral neuropathy, or dysautonomia.
- Measure supine blood pressure after the patient has been resting comfortably. The duration of time that the patient should spend supine and standing when measuring orthostatic hypotension is controversial. Limited evidence supports having the patient remain supine for 5 to 10 min before obtaining the supine blood pressure, followed by blood pressure measurement within 1 min of standing and again after 3 min of standing. The blood pressure cuff must be held at the level of the right atrium; holding the cuff below this level will result in a 5 to 10 mm Hg underestimation of blood pressure.
- Thorough neurologic examination should be performed.

LABORATORY TESTS

- Hemoglobin and hematocrit
- Consider BUN/Creatinine if suspecting dehydration as the cause
- EKG if suspecting underlying cardiac cause
- Consider when treatable causes of OH have been ruled out:
  1. Blood pressure and heart rate monitoring with a tilt table test
  2. Plasma norepinephrine measurements (to distinguish postganglionic from preganglionic autonomic dysfunction)
  3. Other methods, which use the Valsalva maneuver or measure sweating as indirect means of evaluating the autonomic nervous system

IMAGING STUDIES

None

TREATMENT

NONPHARMACOLOGIC THERAPY

- Patient education (leg crossing, prolonged sitting before first standing in the morning, avoid excessive straining and hot baths)
- High-salt diet (e.g., bouillon cubes); caution if history of heart failure
- Liberal fluid intake
- Take needed antihypertensive medications at different times of the day
- Raise the head of the bed at night

TABLE 1 Management of Orthostatic Hypotension in Older Adults

Identify and treat correctable causes.

Reduce or eliminate drugs causing orthostatic hypotension.

Avoid situations that may exacerbate orthostatic hypotension.

- Standing motionless
- Prolonged recumbency
- Large meals
- Hot weather
- Hot showers
- Straining at stool or with voiding
- Isometric exercise
- Ingesting alcohol
- Hyperventilation
- Dehydration

Raise the head of the bed to a 5- to 20-degree angle.

Wear waist-high, custom-fitted, elastic stockings and an abdominal binder.

Participate in physical conditioning exercises.

Participate in controlled postural exercises using the tilt table.

Avoid diuretics and eat salt-containing fluids (unless congestive heart failure is present).

Drug therapy:

- Caffeine
- Fludrocortisone
- Midodrine
- Desmopressin
- Erythropoietin

From Fillit HM: *Brocklehurst's textbook of geriatric medicine and gerontology,* ed 8, Philadelphia, 2017, Elsevier.

- Compression stockings (to include splanchnic circulation)
- Multiple low-carbohydrate meals to avoid postprandial OH
- Avoid large carbohydrate loads and excess alcohol consumption

ACUTE GENERAL Rx

- Correction of volume status and impairment of cerebral perfusion.
- Review medication list and attempt to eliminate those potentially contributing to OH.

CHRONIC Rx

- Fludrocortisone: 0.1 mg/day (may combine with an alpha-1 agonist to lower the dose of each); monitor for electrolyte disturbances and supine hypertension
- Midodrine (alpha-1 agonist): 10 mg three times a day; monitor for supine hypertension
- Erythropoietin (consider if anemic)
- Caffeine (for postprandial hypotension)

Table 1 summarizes management of orthostatic hypotension in older adults.

OTHER TREATMENTS

- Pyridostigmine (enhances renal sodium reabsorption): 0.2 to 0.6 mg/day (not FDA-approved for this indication)
- Octreotide: 300 to 600 mg/day (not FDA-approved for this indication)
- Indomethacin (prostaglandin inhibitor)
- DDAVP (experimental)
- Droxidopa (used for patients with autonomic dysfunction to increase the availability of norepinephrine) has been FDA approved for treatment of adults with symptomatic neurogenic orthostatic hypotension caused by primary autonomic failure or nondiabetic autonomic neuropathy

PEARLS & CONSIDERATIONS

COMMENTS

- The presence of OH should always trigger a search for an underlying etiology.
- OH is diagnosed by observing changes in blood pressure, not heart rate.
- Volume depletion should cause an increased heart rate on standing; a lack of heart rate response in this setting suggests autonomic dysfunction.
- Pharmacotherapy with mineralocorticoids may require concomitant potassium replenishment and monitoring for hypertension.
- Evidence to support the efficacy of pharmacologic interventions to treat OH, including midodrine, is limited.
- The etiology of OH is often multifactorial in older patients, but increased susceptibility to volume depletion due to decreased baroreceptor reflexes frequently contributes. Chronic vitamin D deficiency is associated with the development of OH.
- Intensive blood pressure control did not increase injurious falls compared with controls among community-dwelling older adults participating in the Systolic Blood Pressure Intervention Trial (SPRINT).
- The physical examination of patients with dizziness, gait disturbance, and/or falls should include an assessment for OH. OH is an independent predictor of unexplained falls in older adults.
- Because OH may be asymptomatic, physical examination of those at risk must include assessment of blood pressure in both the supine and upright positions.

Osgood-Schlatter Disease (PTG)

BASIC INFORMATION

DEFINITION

Osgood-Schlatter disease is painful swelling of the growing tibial tuberosity in adolescents.

SYNONYMS

Juvenile osteochondrosis
Tibial tubercle apophysitis

ICD-10CM CODE

M92.40 Juvenile osteochondrosis of patella, unspecified knee

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: 4 cases/100 adolescents.
PREDOMINANT SEX: Male:female ratio of 3:1.
PREDOMINANT AGE: Males: Ages 13 to 15 yr, females: Ages 11 to 13 yr

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Gradual onset of pain and swelling of the tibial tubercle
- Worsening of pain with athletic activity
- Dull ache exacerbated by jumping or climbing stairs
- Tenderness to touch over tibial tubercle, particularly with resisted knee extension

ETIOLOGY

- Repetitive microtrauma and avulsion of the developing ossification center of the tibial tuberosity
- Anatomic variants such as patella alta
- Baseline muscle tightness (quadriceps, gastrocnemius, soleus)
- Lower strain in the patellar tendon leads to faster force transmission

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Stress fracture of the proximal tibia
- Hoffa disease
- Sinding-Larsen-Johansson syndrome
- Patellar tendinitis

WORKUP

- The diagnosis of Osgood-Schlatter disease is made with history and physical examination.
- Imaging may be indicated to exclude fracture or bony tumors.

IMAGING STUDIES

- Lateral x-rays may show separation and fragmentation of the upper tibial epiphysis (Fig. E1).
- Musculoskeletal ultrasound (Fig. E2) can also be used and may show shorter patellar tendon excursion per force applied compared with normal tendons.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Activity modification with increased periods of rest
- Physical therapy

ACUTE GENERAL Rx

- Ice, especially after exercise
- Nonsteroidal antiinflammatory drugs
- Quadriceps stretching exercises and cross-training with low-impact sports
- Injections of local anesthetic mixed with dextrose have shown efficacy in randomized controlled trials
- Surgical (open or arthroscopic) debridement indicated in refractory cases, although this is controversial
- Newer arthroscopic techniques have been developed in order to minimize patient morbidity

DISPOSITION

- Condition usually heals when the epiphysis closes.
- 90% of patients respond to conservative treatment.
- Recent studies have shown promising results with the use of hyperosmolar dextrose injections in recalcitrant disease.
- Surgery is rarely needed in the treatment of Osgood-Schlatter disease but can be used for relief of persistent symptoms in patients that have separated ossicles or an abnormally ossified tibial tuberosity.

REFERRAL

Orthopedic consultation is recommended when symptoms persist >6 to 8 wk. with conservative treatment.

PEARLS & CONSIDERATIONS

COMMENTS

Larsen-Johansson disease is a similar disorder. While the diagnosis of Osgood-Schlatter disease is clinical, imaging may be needed to rule out infection, fracture, and malignancy.

BASIC INFORMATION

DEFINITION

Osteoarthritis (OA) is a progressive disease of the joint representing failed repair of joint damage. It is a complex disorder involving the articular cartilage, the subchondral bone, ligaments, menisci, periarticular muscles, peripheral nerves, and synovium. The process often starts with "micro-cracks" in the articular cartilage with resultant inflammatory cascade perpetuated by the cartilage, synovium, and other joint structures. It results in pain, stiffness, and functional disability often leading to reduced health-related quality of life. It also has a significant economic burden (up to 2.5% of the GDP in the U.S.) and is the leading cause of analgesic consumption and joint replacement surgeries. The American College of Rheumatology Classification criteria for osteoarthritis is described in Table 1.

SYNONYMS

Degenerative joint disease (DJD)
DJD
Arthrosis
OA

ICD-10CM CODES

M15.1	Heberden nodes (with arthropathy)
M15.2	Bouchard nodes (with arthropathy)
M15.3	Secondary multiple arthritis
M15.4	Erosive OA
M15.8	Other polyosteoarthritis
M15.9	Polyarthrosis, unspecified
M17	Gonarthrosis (arthrosis of knee)
M18	Arthrosis of first metacarpal joint
M19	Other arthrosis
M19.8	Other specified arthrosis
M19.9	Arthrosis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Affects more than 30 million individuals in the U.S. Approximately 10% of men and 18% of women over the age of 60 yr are affected.

PREDOMINANT SEX: Prior to age 50, there is almost no gender discrepancy. After age 50, there is increased incidence of OA in females compared to males.

PREDOMINANT AGE: Occurs more frequently after 50 yr of age, but it is increasingly being recognized that OA may occur as early as 30 yr of age.

GENETICS: 39% to 65% heritability rate in twin studies of women who have generalized OA, concordance rate of 0.64 in monozygotic twins. In genome-wide association studies, 11 candidate loci have been identified, but all with a very small effect size.

RISK FACTORS: Osteoarthritis is considered predominantly a mechanical noninflammatory form of arthritis (Fig. 1). OA is thought to be the result of hostile biomechanics on an already susceptible joint (Fig. E2). Risk factors may be classified as either local or systemic. Local or biomechanical factors include obesity leading to increased load on the articular cartilage, mechanical environment of the joint (includes deformities like pes planus, genu varus and valgus, proprioception at the joint), local joint activity/occupation (textile worker leading to hand OA, high-impact runners leading to knee OA), and muscle weakness (quadriceps weakness leading to knee OA). Other deformities, such as femoro-acetabular impingement and limb length inequality, can confer significant risk of developing end-stage OA Systemic risk factors include nutritional factors such as antioxidant and vitamin D deficiency, hormonal status, high bone mineral density, and genetics (candidate genes being evaluated include IGF-1 gene, cartilage oligomeric protein gene, vitamin D receptor gene). That said, there is no concrete evidence showing that preventing the disease or reducing disease progression can be achieved by supplemental vitamin D, antioxidants, or estrogen. Obesity also increases the susceptibility of developing osteoarthritis via systemic adipokines.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Similar symptoms in most forms: Pain generally with activity, stiffness, or gelling (generally short-lived and morning stiffness lasting less than 30 min), crepitus

TABLE 1 American College of Rheumatology Classification Criteria for Osteoarthritis

Hip	Knee (Clinical Criteria)	Hand
Pain in the hip and two of the following: ESR <20 mm/hr Radiographic joint space narrowing Radiographic osteophytes	Pain in the knee and five of the following: Age >50 <30 min morning stiffness Crepitus Bony enlargement Bony tenderness No synovial warmth	Pain, aching, and stiffness in the hand and three of the following: Fewer than three MCP joints swollen Hard tissue enlargement of two or more DIP joints Hard tissue enlargement of two or more of the following joints: Second and third DIP, second and third PIP, both CMC joints Deformity of at least one of the following joints: Second and third DIP, second and third PIP, both CMC joints

CMC, Carpometacarpal; *DIP,* distal interphalangeal; *ESR,* erythrocyte sedimentation rate; *MCP,* metacarpophalangeal joint; *PIP,* proximal interphalangeal.

TABLE 2 Risk Factors for Osteoarthritis

Host Factors		Environmental Factors	
Genetic factors	Familial clustering has also been found at the hip and knee	Biomechanics	Repetitive ergonomic and biomechanical demands may create joint stresses leading to OA Hemiparesis associated with reduction of expression of OA in the affected limb and overexpression in the remaining functional limb Chopstick use associated with OA of the IP joint of the thumb, second and third MCP, and PIP joints
Age	The strongest identifiable risk factor	Trauma	Injuries to the joint, such as dislocations, fractures, ligament ruptures, and meniscal tears
Gender	The age association is strongest in women: Possibly a hormonal influence Hand OA has a peak incidence in menopausal women		
Hormones	Controversial Hand OA has a peak in menopausal women; however, the Chingford and Framingham studies suggested estrogen has protective effect		
Bone mineral density	Negative relationship between bone mineral density and OA at some sites		
BMI	Obesity is strongly associated with the incidence of knee OA Hand OA likely to be related to biomechanical factors		
Joint alignment	Varus deformity of the knee is associated with progressive OA, as is varus/valgus ligamentous instability at the knee joint Developmental problems leading to altered joint biomechanics such as congenital dysplasias		

BMI, Body mass index; *IP,* interphalangeal; *MCP,* metacarpophalangeal joint; *OA,* osteoarthritis; *PIP,* proximal interphalangeal.
Modified from Fillit HM: *Brocklehurst's textbook of geriatric medicine and gerontology,* ed 8, Philadelphia, 2017, Elsevier.

- Loss of function in joints (e.g., loss of dexterity in patients with hand osteoarthritis, with or without significant pain)
- Joint tenderness (Fig. E3), swelling
- Crepitus with motion, pain with range of motion
- Bouchard and Heberden nodes (bony enlargement of the proximal interphalangeal [PIP] and distal interphalangeal [DIP] joints of the hand, respectively) (Fig. E4)

ETIOLOGY

Osteoarthritis is most often primary or idiopathic and can be monoarticular, oligoarticular, or polyarticular. Secondary OA is due to an identifiable condition such as trauma, mechanical abnormalities, or congenital disorders. Risk factors for osteoarthritis are summarized in Table 2. Inflammatory arthritis, crystal deposition diseases, metabolic disorders, Paget disease of bone, and osteonecrosis may also contribute to the development of secondary OA.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bursitis, tendinitis
- Crystal arthropathies like calcium pyrophosphate arthropathy
- Inflammatory arthritis such as rheumatoid arthritis (Fig. E5), seronegative arthritis

WORKUP

- No specific laboratory test exists for osteoarthritis, and investigations are not always needed for the diagnosis of osteoarthritis.
- Rheumatoid factor, ESR, CBC, and antinuclear antibody tests may be required if inflammatory component is suggested by history and are normal in patients with OA.
- Arthrocentesis of swollen joints: Synovial fluid examination is noninflammatory (clear, viscous fluid with normal white cell count).

IMAGING STUDIES

- Plain x-ray of the involved joints is the first step and usually of high diagnostic value
- Radiographic evaluation (Fig. E6) reveals:
  1. Joint space narrowing (Fig. E7)
  2. Subchondral sclerosis
  3. New bone formation in the form of osteophytes
- MRI (Fig. E8) can detect early OA changes and other sources of pain such as synovial thickening, effusions, bone marrow edema, bony attrition, and periarticular lesions
- Musculoskeletal ultrasound (MSKUS) is emerging as an alternative modality to identify joint damage, osteophytes, effusions, and synovial proliferation

Rx TREATMENT

- Optimal use of both pharmacologic and nonpharmacologic measures (Fig. 9) yields best outcome
- Education and reassurance

NONPHARMACOLOGIC THERAPY

HAND OA:

- Joint protection techniques
- Assistive devices
- Thermal modalities
- Trapeziometacarpal splints

HIP AND KNEE OA:

- Weight loss for overweight patients is probably the most crucial recommendation
- Pedometer step-count of more than 10,000 steps per day has been shown to prevent osteoarthritis; a dose-response curve has been noted for this modality with benefits seen at step counts as low as 6000 per day
- Physical therapy includes closed-chain quadriceps strengthening, aerobics, aquatics, and resistance exercises
- Medial wedge insoles for knee valgus, subtalar strapped lateral insoles for varus knees
- Patellar taping
- Hinged and unhinged knee braces, off-loader knee braces
- Assistive devices such as canes or walkers
- Thermal agents
- Tai chi

ACUTE GENERAL Rx/ PHARMACOLOGIC Rx

- Hot or cold fomentation.
- Topical applications of capsaicin or topical application of NSAIDs (diclofenac gel).
- Oral acetaminophen is no longer recommended by American College of Rheumatology or European League against Rheumatism as a first-line analgesic. However, it can be tried for low-grade pain given its relative safety.
- Oral NSAIDs are the first-line analgesics for OA pain. One must consider side effects of NSAIDs, including GI bleeding, cardiovascular toxicity, and renal toxicity. All NSAIDs can increase myocardial infarction risk. Topical NSAIDs are safer than oral NSAIDs.
- Duloxetine if previous initial treatment fails.
- Opioid analgesics including tramadol are recommended only for severe pain that is unresponsive to other treatment modalities.
- Arthrocentesis of the involved joint, followed by intraarticular steroid injection, has

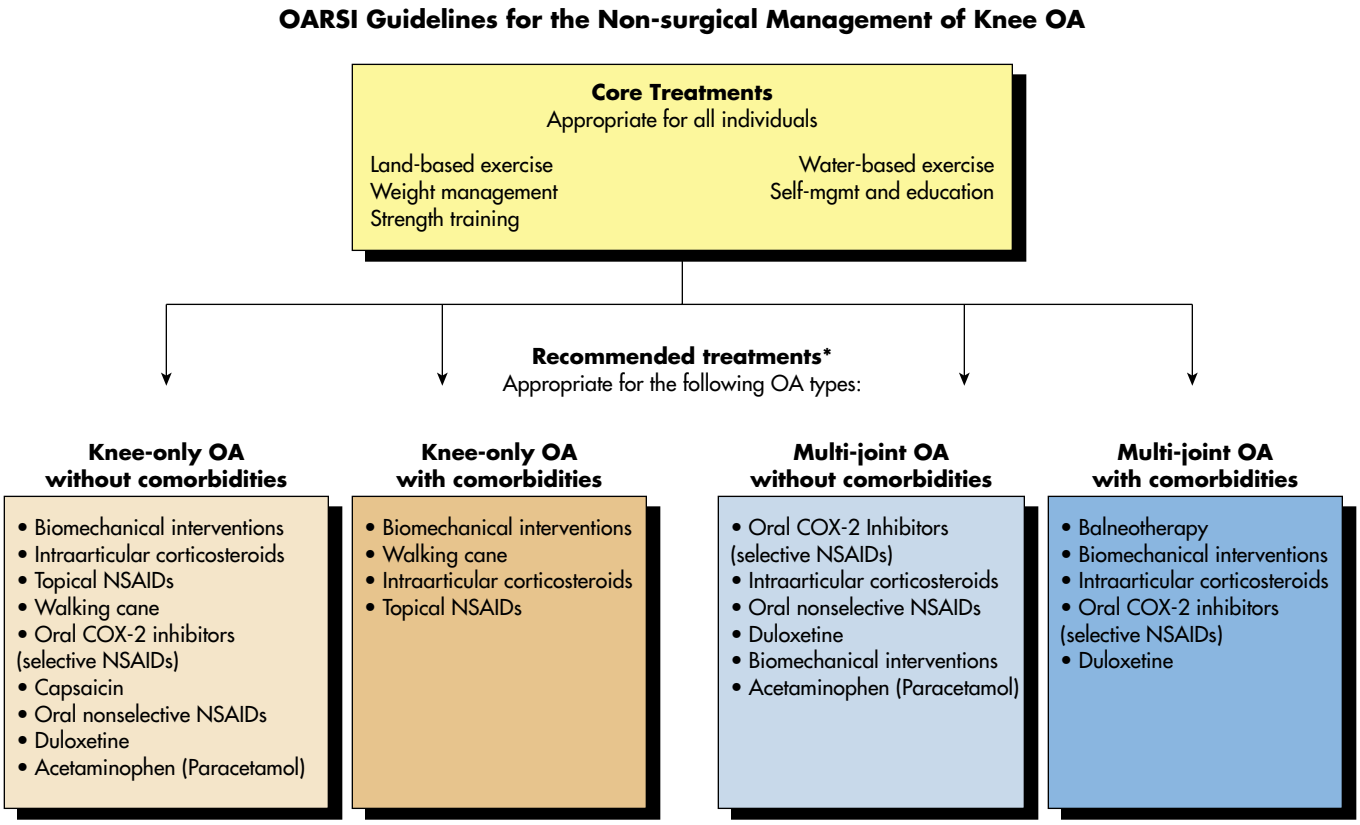

FIG. 9 Appropriate treatments summary. *COX-2,* Cyclooxygenase-2; *NSAID,* nonsteroidal antiinflammatory drug; *OA,* osteoarthritis; *OARSI,* Osteoarthritis Research Society International. (From McAlindon TE et al: OARSI guidelines for the non-surgical management of knee osteoarthritis, *Osteoarthritis Cartilage* 22:363-388, 2014.)

been shown to provide short-term relief of symptoms.

- Nutritional supplements such as glucosamine and chondroitin are unproven. Most trials indicate that neither glucosamine sulfate nor glucosamine hydrochloride reduces pain compared with placebo in knee or hip osteoarthritis. A recent trial did however show modest long-term benefit for physical function with glucosamine sulfate.[1]
- Use of intraarticular hyaluronan injection is controversial. Most trials have shown that hyaluronic acid injections are only minimally better than sham injections in improving pain and function in patients with knee DJD. Positive trials could possibly be influenced by the pharmaceutical industry.

[1]Gregori D et al: Association of pharmacological treatments with long-term pain control in patients with knee osteoarthritis: a systematic review and meta-analysis, *JAMA* 320:2564-2579, 2018.

DISPOSITION

Progression of OA is not always inevitable, and the prognosis is variable depending on the site and extent of disease. Research is currently very active to find other targets to treat OA pain.

REFERRAL

Orthopedic surgical consultation for patients not responding to nonpharmacologic and pharmacologic management. Rheumatology referral could be sought for local injections.

PEARLS & CONSIDERATIONS

COMMENTS

Surgical intervention is generally helpful in degenerative joint disease. Arthroplasty, arthrodesis, and realignment osteotomy are the most common procedures performed. Arthroscopic debridement of the knee appears to be of questionable value. In patients needing hip arthroplasty, resurfacing hip arthroplasty (in which the femoral head is resurfaced with a cap and the neck is preserved) is increasingly popular among younger patients because it results in more hip movement and allows total hip arthroplasty later in the patient's life if necessary.

BASIC INFORMATION

DEFINITION

Osteochondritis dissecans (OCD) is a relatively common cause of joint pain and dysfunction in the pediatric and young adult population. This pathology results from a localized area of subchondral bone destruction with resultant risk for disruption of the overlying cartilage. OCD is subclassified further into the juvenile form (skeletally immature) and the adult form (skeletally mature). If left untreated, OCD may lead to loose bodies in the joint space and predispose the patient to the early development of osteoarthritis.

SYNONYM

Osteochondrosis

ICD-10CM CODES

M93.20	Osteochondritis dissecans of unspecified site
M93.211	Osteochondritis dissecans, right shoulder
M93.212	Osteochondritis dissecans, left shoulder

M93.279	Osteochondritis dissecans, unspecified ankle and joints of foot
M93.28	Osteochondritis dissecans other site
M93.29	Osteochondritis dissecans multiple sites

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: Adolescent Age Group
PREVALENCE: 15 to 29/100,000 persons
PREDOMINANT SEX: Male/female ratio of 2-4:1
PREDOMINANT AGE: Typically between 10 and 20 years of age
GENETICS: While there is emerging evidence that OCD has a genetic component, the genetic basis is still largely unknown.
RISK FACTORS: Repetitive microtrauma, young athletes

CLINICAL PRESENTATION & PHYSICAL FINDINGS

- OCD most commonly affects the knee (75%) followed by the elbow (6%) and the ankle (4%); other joints are affected in 15% of cases.
- Common lesion locations are the medial femoral condyle (see Fig. E2), capitellum of the humerus, and talus.
- Clinical symptoms are variable and nonspecific; early lesions cause poorly localized pain with activity.
- As the disease progresses, stiffness and intermittent swelling may occur.
- In the knees, range of motion typically remains intact.
- If a loose fragment becomes detached, it can cause locking or catching.
- Physical exam reveals tenderness at the site of the lesion; crepitus may also be present.
- When the knee is involved, a positive Wilson sign can sometimes be elicited (pain with knee extension and internal rotation). Antalgic gait and limp can occur in chronic cases.
- Rarely, cases may be asymptomatic.

ETIOLOGY & PATHOPHYSIOLOGY

- While the exact cause of OCD remains unknown, proposed etiologies include mechanical, inflammatory, genetic, and vascular causes. Repetitive microtrauma has gained attention as a leading theory of the most common cause of OCD. The disease process is thought to start with bony injury resulting in hypovascularization, with subsequent defective repair causing necrosis of the bone with structural collapse and detachment of the overlying subchondral bone and cartilage. Given the various proposed theories, the likely etiology of OCD is multifactorial.
- OCD is seen more frequently in children and adolescents and is more commonly associated with repetitive trauma and athletic participation.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Knee: Meniscal tear, patellofemoral syndrome, medial plica syndrome, stress fracture
- Elbow: Panner disease, Little League elbow, epicondyle avulsion fracture, epicondylitis
- Ankle: Ankle sprain, os trigonum, tarsal coalition

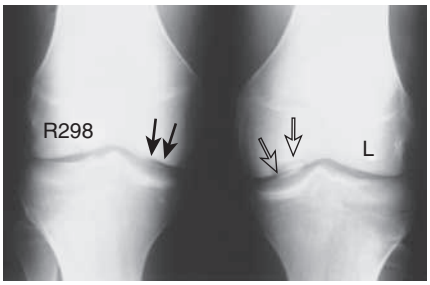

FIG. E1 Bilateral, asymmetrical osteochondritis dissecans with a healed right lesion *(black arrows)* and an unhealed, unstable left lesion (*open arrows*) in a 17-yr-old tennis player. (From DeLee D, Drez D [eds]: *DeLee and Drez's orthopaedic sports medicine,* ed 2, Philadelphia, 2003, Saunders.)

FIG. E2 Osteochondritis dissecans (OCD). A coronal MRI of an OCD lesion of the medial femoral condyle. (From Frontera WR: *Clinical sports medicine: medical management and rehabilitation,* Philadelphia, 2006, Saunders.)

IMAGING STUDIES

- X-rays including weight-bearing films and "tunnel views," where the knee is flexed between 30 and 50 degrees, are the initial test of choice.
- Early small lesions can look normal or can demonstrate subtle increased subchondral bone density.
- The defining lesion of OCD is seen on x-ray as a subchondral bone fragment surrounded by a radiolucent, crescent-shaped line (Fig. E1). Sclerosis on plain radiographs is a sign of a poor prognosis.
- MRI (Fig. E2) is the most sensitive test (91% to 96%) and is useful to identify OCD in symptomatic patients with normal x-rays.
- Contrast is used to evaluate blood supply to the affected fragment and to evaluate stability of the lesion.

TREATMENT

ACUTE GENERAL Rx

- Conservative management: Typically indicated in juvenile OCD without an intraarticular foreign body and in adult patients who have a small, stable fragment or asymptomatic lesion.

- Non–weight-bearing and immobilization for 4 to 6 wk; physical therapy may be initiated once healing starts.
- Surgery: Indicated for juvenile OCD with a loose body and in cases that fail to improve after 4 to 6 mo of conservative management; also indicated in adults with symptomatic OCD.

DISPOSITION & PROGNOSIS

- Office follow-ups are initially frequent, every 2 wk.
- X-ray changes should be monitored every 6 wk while immobilized.
- Return to activity can be attempted once the patient is pain-free and has full, active range of motion; this usually takes 3 to 6 mo.
- Once complete healing occurs, joint function typically returns to normal.
- Complete healing is frequent in skeletally immature children with small lesions (95%), but in adults with larger lesions, complete healing is less common (50%).

REFERRAL

- Orthopedic consultation for most symptomatic children and adults with OCD for staging and management options.
- Surgical options include arthroscopic subchondral drilling, fixation of the unstable fragment with Kirschner wires, osteochondral allograft resurfacing, autologous chondrocyte implantation, or in severe cases, arthroplasty.

PEARLS & CONSIDERATIONS

COMMENTS

- Although inflammation is suggested by the name, ischemia and subchondral bony trauma rather than inflammation have been implicated as the most likely causes of OCD. *Osteochondral lesion* or *osteochondrosis dissecans* may be more appropriate terms to describe these disorders.
- The condition is often bilateral, especially in the knee, which could suggest the possibility of an endocrine or genetic cause.
- The prognosis of OCD in younger patients is better, and an open physis is a predictor of success with nonoperative management.
- This condition should always be considered in the patient whose "sprained" ankle does not improve over the usual course of treatment.

BASIC INFORMATION

DEFINITION

Rickets is a result of deficient mineralization of osteoid matrix before closure of the epiphyseal plate causing softening and weakening of bones in infants and children. The mineralization impairment may be secondary to abnormal calcium, phosphorus, or vitamin D metabolism leading to accumulation of osteoid before epiphyseal closure, compromising bone stability at sites of rapid bone growth. When this occurs in adulthood after epiphyseal closure, it is referred to as osteomalacia. Renal osteodystrophy is a term used to describe a similar condition in patients with chronic kidney disease. Certain forms of the disorder may respond only to high doses of vitamin D and are referred to as vitamin D–resistant rickets (VDRR).

ICD-10CM CODES	
E55.0	Rickets, active
E83.30	Disorder of phosphorus metabolism, unspecified
M83.9	Adult osteomalacia, unspecified
N25.0	Renal osteodystrophy

RISK FACTORS

- Children ages 6 to 24 mo
- Premature infants
- Residents of northern latitudes with inadequate sunlight exposure
- Solely breastfed infants
- Darker skin pigmentation
- Use of anticonvulsants

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The classic clinical presentation of children with rickets includes the following:

- Apathy, muscle weakness, muscle cramps, delayed growth, short stature
- Skeletal pain and swollen joints (Figs. E1 and E2)
- Protuberant abdomen due to muscle hypotonia
- Widened sutures, delayed closure of fontanelles, and frontal bossing of head
- Craniotabes (softening of skull bones)
- Delayed eruption of teeth and poorly mineralized teeth
- Bowing deformity of lower extremities, specifically femur and tibia (Fig. E3)
- Table E1 summarizes clinical features of rickets
- Rachitic rosary (enlargement and prominence of the rib head at the costochondral junctions)
- Harrison groove (indentation of the lower ribs)
- Breastbone that is pushed forward (pigeon chest)
- Pathologic fractures
- Scoliosis or kyphosis

The less pronounced clinical presentation of adults with osteomalacia includes the following:

- Skeletal pain and bone tenderness
- Muscle hypotonia and proximal muscle weakness
- Pathologic fractures and decreased bone density
- Gait disturbances

ETIOLOGY

The most common cause of rickets and osteomalacia is vitamin D deficiency. Not having enough calcium and phosphorus intake can also lead to rickets. Vitamin D and PTH play an important role in calcium homeostasis. Vitamin D is required for adequate calcium absorption in the gastrointestinal tract. Low vitamin D leads to a reduced intestinal absorption of calcium, causing a compensatory increase in PTH and resorption of bone, leading to increased alkaline phosphatase levels. This may arise from various conditions, including inadequate dietary intake, malabsorption, chronic parenteral nutrition, and the additional risk factors listed previously. Malabsorption that causes inefficient mineral-

FIG. E1 Rachitic "rosary" in a child with rickets. (Courtesy of Dr. Thomas D. Thacher, Rochester, MN. In Kliegman, RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.)

FIG. E2 Hands and forearms of a young child with rickets show prominence above the wrist, resulting from flaring and poor mineralization of the lower end of the radius and ulna. (From Bullough PG: *Orthopaedic pathology,* ed 5, St Louis, 2010, Mosby, Fig 8-31. In Kliegman, RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.)

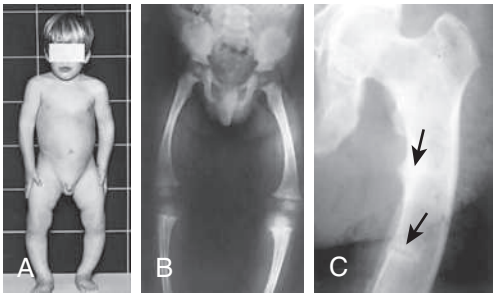

FIG. E3 A, A typical example of rickets. Note the bowing of the femurs and tibiae, which may result from vitamin D deficiency, phosphate deficiency, or other causes. **B,** A skeletal radiograph of a child with rickets. Note that the weight-bearing bones of the lower extremities are bowed and that the epiphyses are open, mottled, and overgrown. **C,** Looser zones or pseudofractures that are characteristic of osteomalacia or rickets. Because the epiphyses are closed, the patient is an adult. This radiograph is diagnostic of osteomalacia. (From Stewart A: Metabolic bone diseases. In Andreoli TE et al [eds]: *Cecil essentials of medicine,* ed 8, Philadelphia, 2010, WB Saunders.)

TABLE E1 Clinical Features of Rickets

General
Failure to thrive (malnutrition)
Listlessness
Protruding abdomen
Muscle weakness (especially proximal)
Hypocalcemic dilated cardiomyopathy
Fractures (pathologic, minimal trauma)
Increased intracranial pressure

Head
Craniotabes
Frontal bossing
Delayed fontanel closure (usually closed by 2 yr)
Delayed dentition
No incisors by age 10 mo
No molars by age 18 mo
Caries
Craniosynostosis

Chest
Rachitic rosary
Harrison groove
Respiratory infections and atelectasis*

Back
Scoliosis
Kyphosis
Lordosis

Extremities
Enlargement of wrists and ankles
Valgus or varus deformities
Windswept deformity (valgus deformity of one leg with varus deformity of other leg)
Anterior bowing of tibia and femur
Coxa vara
Leg pain

Hypocalcemic Symptoms†
Tetany
Seizures
Stridor caused by laryngeal spasm

*These features are associated most frequently with vitamin D deficiency disorders.
†These symptoms develop only in children with disorders that produce hypocalcemia (see Table E3).
From Kliegman RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.

ization is observed in diseases such as cystic fibrosis, in intestinal disorders such as celiac disease, and in many chronic illnesses, including severe liver disease. The biochemistry of osteomalacia and rickets is summarized in Table E2. Chronic renal failure can produce bone mineralization deficiency due to electrolyte abnormalities causing hypocalcemia and renal osteodystrophy (renal rickets). This results in decreased excretion of phosphate, therefore elevating serum phosphorus, along with elevated parathyroid hormone (PTH) and low levels of 1,25-OH vitamin D.

Other causes specifically include vitamin D–dependent rickets (VDDR - type I & II) and VDRR, also known as hereditary hypophosphatemic rickets.

- VDDR type I (VDDR-1) results from abnormalities in the vitamin D 1-alpha hydroxylase enzyme that converts to the active metabolite of $1,25(OH)_2D$.
- VDDR type II (VDDR-II), also known as hereditary vitamin-D resistant rickets (HVDRR), results from defective vitamin D receptors due to a mutation in the gene that encodes the vitamin D receptor.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Osteoporosis
- Hyperparathyroidism
- Hyperthyroidism
- Hypophosphatasia
- Skeletal dysplasia

WORKUP

- Rickets is a clinical diagnosis. It is often challenging to determine the exact etiology; however, clinical, biochemical, and radiologic findings can be useful.
- A thorough dietary and medication history for children is important. Bone biopsy is generally not performed; however, it is the diagnostic gold standard.

LABORATORY TESTS

Blood testing should include serum calcium, inorganic phosphorus (Pi), alkaline phosphate, PTH, 25-OH vitamin D, creatinine, and liver enzymes. Table E3 summarizes laboratory findings in various disorders that cause rickets. Children may present solely with an elevated alkaline phosphatase level and characteristic physical findings.

IMAGING STUDIES

- In rickets, characteristic radiologic findings include irregular epiphyseal-metaphyseal junctions with widening and flaring of the epiphyses of long bones, causing bowing.
- Pseudofractures (Looser zones) and narrow radiolucent lines may be seen as a result of microfractures at high stress points or at the location of entry of blood vessels into the bone and are observed in severe rickets and osteomalacia.

Rx TREATMENT

- Treatment is dependent on the underlying etiology; however, high doses of vitamin D resolve most deficiencies. Nutritional deficiency of vitamin D is rare with the amount of vitamin D currently present in milk and dairy products; however, if a deficiency is detected, initial treatment with 2000 IU vitamin D_2 or D_3 daily is recommended, with periodic monitoring of vitamin D levels and dose adjustment as needed to maintain normal levels.
- VDDR type I is treated with both vitamin D and phosphate replacement. The earliest biochemical change after initiation of treatment is an increase in the level of phosphorus followed by a rise in calcium level. Serum calcium, phosphorus, alkaline phosphatase, calcidiol levels, and urine calcium and phosphorus levels should be obtained within 2 wk of initiation of therapy and at periodic intervals thereafter. The treatment of type II VDDR is more complex and requires the expertise of an endocrinologist and/or nephrologist.
- Familial hypophosphatemic rickets is treated with calcitriol and oral phosphorus.
- Oral phosphorus alone is the treatment of choice for hereditary hypophosphatemic rickets with hypercalciuria.

REFERRAL

- Because of the complex nature of many of these disorders, a qualified endocrinologist and nephrologist should be consulted for treatment.
- Orthopedic consultation may be required for some cases of bowlegs or spinal deformities, which may require specific bracing for long-term growth of the bones. Corrective surgery may be necessary if the deformity is very severe.
- Surgical care is also indicated for slipped capital femoral epiphysis, which is fairly common in renal rickets.

BASIC INFORMATION

DEFINITION

Osteomyelitis is an acute or chronic infection of the bone secondary to the hematogenous or contiguous source of infection or direct traumatic inoculation, which is usually bacterial.

SYNONYM

Bone infection

ICD-10CM CODES

M86	Osteomyelitis
M86.0	Acute hematogenous osteomyelitis
M86.1	Other acute osteomyelitis
M86.2	Subacute osteomyelitis
M86.3	Chronic multifocal osteomyelitis
M86.6	Other chronic osteomyelitis
M86.9	Osteomyelitis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

PREDOMINANT SEX: Male > female
PREDOMINANT AGE: All ages

PHYSICAL FINDINGS & CLINICAL PRESENTATION

HEMATOGENOUS OSTEOMYELITIS:

- Usually occurs in tibia/fibula (children)
- Localized inflammation: Often secondary to trauma with accompanying hematoma or cellulitis
- Abrupt fever
- Lethargy
- Irritability
- Pain in involved bone

VERTEBRAL OSTEOMYELITIS:

- Usually hematogenous
- Fever: 50%
- Localized pain/tenderness. Back pain is the most common initial symptom (86% of cases)
- Neurologic defects: Motor/sensory (sensory loss, weakness, radiculopathy)

CONTIGUOUS OSTEOMYELITIS:

- Direct inoculation
- Associated with trauma, fractures, surgical fixation
- Chronic infection of skin/soft tissue
- Fever, drainage from surgical site

CHRONIC OSTEOMYELITIS:

- Bone pain
- Sinus tract drainage, nonhealing ulcer
- Chronic low-grade fever
- Chronic localized pain

ETIOLOGY

- *Staphylococcus aureus*
- MRSA: Methicillin-resistant S. *aureus*
- *Pseudomonas aeruginosa*
- Enterobacteriaceae
- *Streptococcus pyogenes*
- Enterococcus
- Mycobacteria
- Fungi
- Coagulase-negative staphylococci
- *Salmonella* (in sickle cell disease)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Gaucher disease
- Bone infarction
- Charcot joint
- Fracture

WORKUP

- ESR, C-reactive protein: Nondiagnostic but if significantly elevated they increase the pretest probability of osteomyelitis and can be useful in monitoring therapeutic response
- Blood culturing, CRC with differential
- Bone culture. A culture of a biopsy specimen has a significantly higher overall diagnostic yield than does a blood culture. Bone samples should be cultured for aerobic and anaerobic bacteria and for fungi
- Pathologic evaluation of bone biopsy for acute/chronic changes consistent with necrosis or acute inflammation
- PCR analysis of specimens obtained by means of biopsy or puncture may be useful for organisms that are difficult to identify (anaerobic bacteria, *Bartonella* sp., *Kingella kingae*); however, broad-range PCR has suboptimal sensitivity and specificity due to contamination and may not provide sufficient information on the susceptibility of the microorganisms to antibiotics

IMAGING STUDIES

- Bone radiograph examination (Fig. E1): Initial study but not sensitive in early osteomyelitis as may not show changes for as much as 2 wks
- MRI with and without contrast (Fig. E2): Most accurate imaging study. CT only if patient has contraindication to MRI
- Triple-phase technetium-99m bone scan (Fig. E3) when MRI is unavailable or contraindicated. Typically positive within a few days after onset of symptoms but accuracy is lower than that of MRI
- Gallium scan (Ga-67) scintigraphy with single-photon emission CT (SPECT) has higher accuracy than bone scan but is less sensitive for detection of epidural abscess in vertebral osteomyelitis
- Indium-111–labeled leukocyte scintigraphy scan; low sensitivity (<20%) for vertebral osteomyelitis
- Positron emission tomography (PET) scanning with ^{18}F-fluorodeoxyglucose has high accuracy (similar to MRI) and is useful in patients with metallic implants
- Table 1 summarizes imaging findings in osteomyelitis

TREATMENT

- Surgical debridement in biopsy-positive cases will guide direction for antibiotic therapy. This will vary with type of osteomyelitis. Duration of therapy is usually 4 to 6 wk for acute osteomyelitis; chronic osteomyelitis may need a longer course of medication
- Orthopedic hardware should be removed if possible
- *S. aureus:* Cefazolin IV, nafcillin IV, vancomycin IV (in patient allergic to penicillin)
- *S. aureus* (methicillin resistant): Vancomycin IV, linezolid, daptomycin
- *Streptococcus* spp.: Ceftriaxone, IV penicillin G in sensitive species
- *P. aeruginosa:* Cefepime, imipenem/cilastatin, or meropenem
- Enterobacteriaceae: Ceftriaxone or ertapenem
- Anaerobes: Clindamycin, ticarcillin clavulanate, cefotetan, or metronidazole
- Table 2 summarizes antimicrobial therapy for selected microorganisms in osteomyelitis
- Hyperbaric oxygen therapy: May be useful in chronic osteomyelitis
- Wound-assisted vacuum device may help closure of wound
- Surgical debridement of all devitalized bone and tissue
- Immobilization of affected bone (plaster, traction) if bone is unstable

DISPOSITION

Acute hematogenous osteomyelitis usually resolves without recurrence or long-term complications, but contiguous focus osteomyelitis, bone infections from open fractures, or osteomyelitis frequently recurs.

REFERRAL

- To an orthopedic surgeon if chronic osteomyelitis with need for bone debridement, bone grafting, or stabilization of infected tissue adjacent to a bone fracture
- To an infectious disease specialist for appropriate treatment for difficult-to-treat or recalcitrant infections
- To a hyperbaric oxygen chamber service for nonhealing, chronic osteomyelitis

PEARLS & CONSIDERATIONS

- Chronic osteomyelitis is one of the most challenging infections to treat; the high failure rate is a consequence of poor vascular supply, nondistensible bone tissue, and limited penetration of bone tissue.
- Parenteral antibiotics are usually chosen initially, but oral fluoroquinolones have good bone penetration and may be used in stable patients. A recent trial comparing oral versus IV antibiotics for bone and joint infections found that oral antibiotic therapy is not inferior to IV antibiotic therapy when used during the first 6 wk for complex orthopedic infections.[1]

[1]Li HK, et al: Oral versus intravenous antibiotics for bone and joint infection, *N Engl J Med* 380(5): 425-436, 2019.

TABLE 1 Imaging Findings in Osteomyelitis

	Plain Radiograph	CT	MRI	NM
Acute	Minimal findings Soft-tissue swelling may be seen	Not useful	Bone marrow edema can occur as early as 24-48 h, seen as low T1, and high T2 signal	May show increased uptake, but takes a few days
Subacute	Lucent or sclerotic lesion, periosteal reaction, soft-tissue swelling	Cortical and marrow abnormalities including abscess, periosteal reaction, soft-tissue edema, and abscess	Bone marrow changes, cortical abnormalities seen as thickening, bone abscess, periosteal reaction, increased T2 signal in soft tissues, abscess formation. Postgadolinium T1W sequences outline abscess cavities clearly	Three-phase bone scintigram, indium-111 WBC scan and combined studies are useful, especially to assess multifocal involvement. PET-CT generally not used in this context, but may be useful in exceptional circumstances
Chronic	Bone sclerosis, cortical thickening, sequestrum and cloaca, bone destruction, resorption, and deformities	Much better than plain radiographs to demonstrate cloaca and sequestrum, periosteal new bone formation, and abscess	Better soft-tissue and bone marrow resolution to demonstrate medullary and cortical changes, sequestra and cloaca well demonstrated, useful to outline soft-tissue abscess, and sinus tracts	Generally useful if there is a problem with diagnosis. Combined WBC and bone marrow scintigram is useful. May highlight multiple sites of involvement

CT, Computed tomography; *MRI,* magnetic resonance imaging; *NM,* nuclear medicine; *PET,* positron emission tomography; *WBC,* white blood cell.
From Grant, LA: *Grainger & Allison's Diagnostic Radiology Essentials*, ed 2, 2019, Elsevier.

TABLE 2 Antimicrobial Therapy for Selected Microorganisms in Chronic Osteomyelitis in Adults

Microorganism	First Choice*	Alternative Choice
Methicillin/oxacillin/nafcillin-sensitive staphylococci	Nafcillin sodium or oxacillin sodium 1.5-2 g IV q4- for 4-6 wk *or* cefazolin 1-2 g IV q8h for 4-6 wk	Vancomycin 15 mg/kg IV q12h for 4-6 wk
Methicillin/oxacillin/nafcillin-resistant staphylococci (MRSA)	Vancomycin† 15 mg/kg IV q12h for 4-6 wk *or* daptomycin 6 mg/kg IV q24h	Linezolid 600 mg PO/IV q12h *or* levofloxacin† 500-750 mg PO/IV daily, plus rifampin 600-900 mg PO for 6 wk if susceptible to both drugs
Penicillin-sensitive streptococci	Aqueous penicillin G 20 × 10^6 U/24 hr IV either continuously or in six equally divided daily doses *or* ceftriaxone 1-2 g IV q24h *or* cefazolin 1-2 g IV q8h for 4-6 wk	Vancomycin 15 mg/kg IV q12h for 4-6 wk
Enterococci	Aqueous crystalline penicillin G 20 × 10^6 U/24 hr IV either continuously or in six equally divided daily doses *or* ampicillin sodium 12 g/24 hr IV either continuously or in six equally divided daily doses; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional*	Vancomycin† 15 mg/kg IV q12h; the addition of gentamicin sulfate 1 mg/kg IV or IM q8h for 1-2 wk is *optional*
Enterobacteriaceae	Ceftriaxone 1-2 g IV q24h for 4-6 wk or ertapenem 1 g IV q24h	Ciprofloxacin 500-750 mg PO q12h for 4-6 wk or levofloxacin 500-750 mg PO q24h
Pseudomonas aeruginosa	Cefepime 2 g IV q12h, meropenem 1 g IV q8h, or imipenem 500 mg IV q6h for 4-6 wk	Ciprofloxacin 750 mg PO q12h for 4-6 wk or ceftazidime 2 g IV q8h

IM, Intramuscular; *IV,* intravenous; *MRSA*, methicillin-resistant *Staphylococcus aureus; PO,* by mouth.
*Antimicrobial selection should be based on in vitro sensitivity data, as well as allergies, intolerances, and drug interactions in individual patients.
†Doses shown are based on normal renal and hepatic function and may need to be adjusted or serum levels monitored (vancomycin).

- The optimal duration of therapy for vertebral osteomyelitis is unclear. Trials comparing 6 wk to 12 wk of antibiotic treatment in pyogenic vertebral osteomyelitis showed similar cure rates (91%) in both groups.

BASIC INFORMATION

DEFINITION

Osteonecrosis, also known as avascular necrosis (AVN), is ischemic death of bone due to insufficient blood supply. It is not a specific disease entity but a final common pathway to several disorders that impair blood supply to the femoral head and other locations.

SYNONYMS

AVN
Avascular necrosis
Aseptic necrosis

ICD-10CM CODES

M87	Idiopathic aseptic necrosis of bone
M87.1	Osteonecrosis due to drugs
M87.2	Osteonecrosis due to previous trauma
M87.3	Other secondary osteonecrosis
M87.9	Osteonecrosis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- 15,000 new cases per yr in the U.S. It is most commonly associated with the hip and accounts for 10% of total hip replacements in the U.S.
- Usually occurs in middle age and is more frequent in males than females
- Associated conditions:
  1. Corticosteroid treatment: 35%
  2. Alcohol abuse: 22%
  3. Idiopathic and other: 43%
  4. Hemoglobinopathies, pancreatitis, chronic renal failure, SLE, chemotherapy, decompression sickness
- Common sites involved
  1. Femoral head
  2. Femoral condyle
  3. Humeral head
  4. Navicular and lunate wrist bones
  5. Talus

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- May be asymptomatic in early stages
- Pain in the involved area exacerbated by movement or weight bearing in later stages
- Decreased range of motion as the disease progresses
- Functional limitation

ETIOLOGY

Final common pathway of conditions that lead to impairment of the blood supply to the involved bone. Trauma disrupting the blood supply is the most common cause of osteonecrosis. Arterial factors are considered the most common cause of osteonecrosis. Table 1 describes proposed mechanism of disease of common conditions associated with osteonecrosis.

STAGING

Tables 2 and 3 and Box 1 illustrate various staging systems for osteonecrosis.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- None in late stages
- Early: Any condition causing focal musculoskeletal pain, including arthritis, bursitis, tendinitis, myopathy, neoplastic bone and joint diseases, traumatic injuries, pathologic fractures

WORKUP

Fig. 1 describes a diagnostic algorithm for osteonecrosis.

IMAGING STUDIES (FIG. 2)

- MRI: The most sensitive technology to diagnose early aseptic necrosis. The first sign is a margin of low signal. An inner border of high signal associated with a low-signal line is specific for aseptic necrosis ("double line sign"). Sensitivity is 75% to 100%.
- Radiography: Insensitive early in the course. The earliest changes include diffuse osteopenia, areas of radiolucency with sclerotic border, and linear sclerosis. Later, a subchondral lucency (crescent sign) indicates subchondral fracture. More advanced cases reveal flattening, collapsed bone, and abnormal bone contour. In late disease, osteoarthritic changes are seen.
- Bone scan:
  1. Early: "Cold" area
  2. Later: Increased radionuclide uptake as a result of remodeling
  3. Sensitivity in early disease is only 70% and specificity is poor
- CT scan: May reveal central necrosis and area of collapse before those are visible on radiographs.

TREATMENT

PREVENTION

- Manage etiologic conditions
- Minimize corticosteroid use

NONPHARMACOLOGIC THERAPY

- Core decompression: Effectiveness 35% to 95% in early phases
- Bone grafting
- Osteotomies
- Joint replacement

ACUTE GENERAL Rx

- Decrease weight bearing of affected area.
- Pulsing electromagnetic fields applied externally (still experimental).
- Peripheral vasodilators (e.g., dihydroergotamine) (unproven).
- Late-stage AVN is most often treated by total joint arthroplasty.

PROGNOSIS

- When diagnosed at an early stage treatment is appropriate in all cases because 85% to 90% can be expected to progress to a more advanced stage.
- Contralateral joint involvement is common (30% to 70%).

TABLE 2 Ficat Staging System

Stage	Description
I	Normal radiographic findings
II	Sclerotic or cystic lesions
III	Subchondral collapse
IV	Osteoarthritis with articular collapse

From Hochberg MC: *Rheumatology*, ed 7, Philadelphia, 2019, Elsevier.

TABLE 3 Steinberg Staging System

Stage	Description
I	Normal radiographic findings; abnormal bone scan and/or magnetic resonance imaging findings • Mild (<15% of head affected) • Moderate (15%-30% of head affected) • Severe (>30% of head affected)
II	Lucent and sclerotic changes in the femoral head • Mild (<15% of head affected) • Moderate (15%-30% of head affected) • Severe (>30% of head affected)
III	Subchondral collapse without flattening • Mild (<15% of head affected) • Moderate (15%-30% of head affected) • Severe (>30% of head affected)
IV	Flattening of the femoral head • Mild (<15% of head affected) • Moderate (15%-30% of head affected) • Severe (>30% of head affected)
V	Joint narrowing and/or acetabular changes • Mild • Moderate • Severe
VI	Advanced degenerative changes

From Hochberg MC: *Rheumatology*, ed 7, Philadelphia, 2019, Elsevier.

BOX 1 International Classification of Osteonecrosis of the Femoral Head (Association Research Circulation Osseous)

- Stage 0: Bone biopsy results consistent with osteonecrosis; other test results normal
- Stage I: Positive findings on bone scan, magnetic resonance imaging (MRI), or both
  - A: <15% involvement of the femoral head (MRI)
  - B: 15% to 30% involvement
  - C: >30% involvement
- Stage II: Mottled appearance of femoral head, osteosclerosis, cyst formation, and osteopenia on radiographs; no signs of collapse of femoral head on radiographic or computed tomographic study; positive findings on bone scan and MRI; no changes in acetabulum
  - A: <15% involvement of the femoral head (MRI)
  - B: 15% to 30% involvement
  - C: >30% involvement
- Stage III: Presence of crescent sign lesions classified on basis of appearance on anteroposterior and lateral radiographs
  - A: <15% crescent sign or <2-mm depression of femoral head
  - B: 15% to 30% crescent sign or 2- to 4-mm depression
  - C: >30% crescent sign or >4-mm depression
- Stage IV: Articular surface flattened; joint space shows narrowing; changes in acetabulum with evidence of osteosclerosis, cyst formation, and marginal osteophytes

From Hochberg MC: *Rheumatology*, ed 7, Philadelphia, 2019, Elsevier.

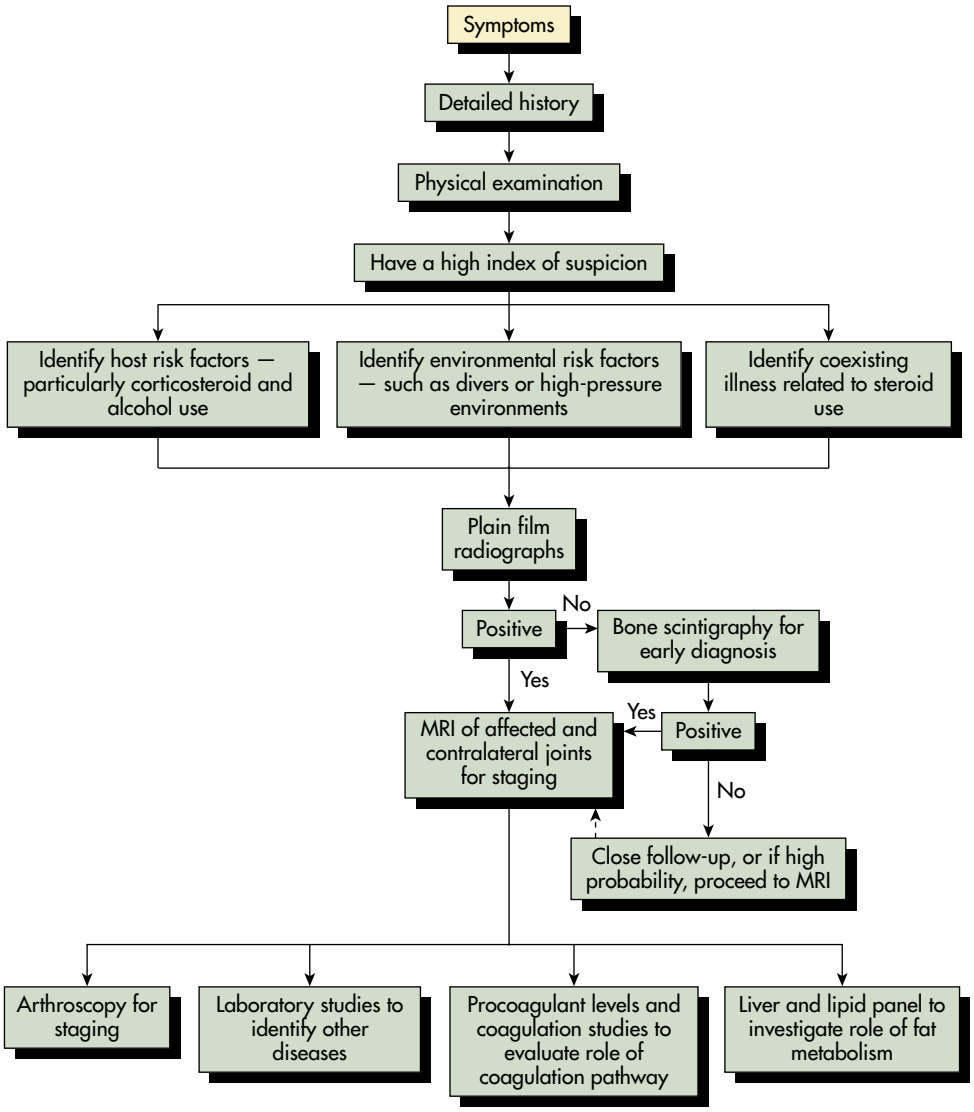

FIG. 1 Diagnostic algorithm for osteonecrosis. *MRI*, Magnetic resonance image. (From Firestein GS et al: *Kelley's textbook of rheumatology*, ed 9, Philadelphia, 2013, Saunders.)

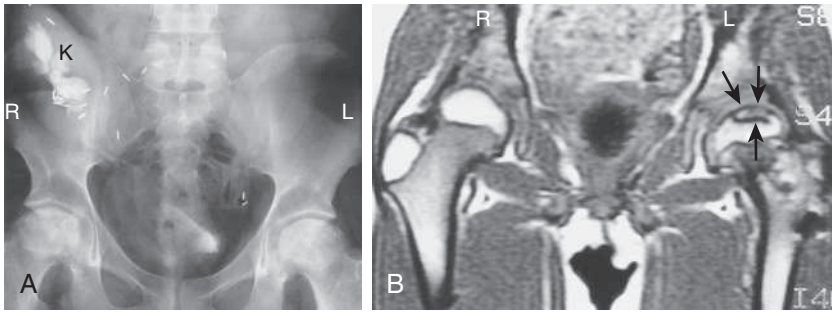

FIG. 2 Aseptic necrosis of the hips. A, Aseptic necrosis can occur from a number of causes, including trauma and steroid use. In this patient, an anteroposterior view of the pelvis shows a transplanted kidney *(K)* in the right iliac fossa. Use of steroids has caused this patient to have bilateral aseptic necrosis. The femoral heads are somewhat flattened, irregular, and increased in density. **B,** Aseptic necrosis in a different patient is demonstrated on an MRI scan as an area of decreased signal *(arrows)* in the left femoral head. This is the most sensitive method for detection of early aseptic necrosis. (From Mettler FA [ed]: *Primary care radiology,* Philadelphia, 2000, Saunders.)

BASIC INFORMATION

DEFINITION

Osteoporosis is a skeletal disorder characterized by a progressive loss of bone mass and a decline in bone quality that results in increased bone fragility and a higher fracture risk. Poor bone mass acquisition during adolescence and bone loss during the sixth decade of life are the main processes responsible for osteoporosis. The various types are as follows:

PRIMARY OSTEOPOROSIS: Primary osteoporosis is the loss of bone mass due to aging and decreased gonadal function, not to any other chronic illness.

- Idiopathic osteoporosis: Unknown pathogenesis; may occur in children and young adults.
- Type I osteoporosis (postmenopausal women): Occurs after menopause due to an abrupt decline in estrogen production. It is characterized by accelerated and disproportionate trabecular bone loss and is associated with fractures of the spine, hip, and wrist.
- Type II osteoporosis (involutional): Occurs in both men and women aged >70 yr due to the progressively negative balance between bone formation and resorption. It is characterized by both trabecular and cortical bone loss and associated with fractures of the spine, long bones, and hip.

SECONDARY OSTEOPOROSIS: Secondary osteoporosis is bone loss due to another chronic condition such as thyroxine excess, hyperparathyroidism, malignancies, gastrointestinal disease, medications, renal failure, and connective tissue diseases (see "Differential Diagnosis").

ICD-10CM CODES

M81.0	Age-related osteoporosis without current pathological fracture
M81.4	Drug-induced osteoporosis
M81.5	Idiopathic osteoporosis
M81.6	Localized osteoporosis

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE (IN U.S.):

- Affects more than 10 million people in the U.S.
- Annual incidence of osteoporotic fractures exceeds 1.5 million in the U.S. (70% women)
- Twice as common in women
- Results: Institutionalization, death, and costs in excess of $17 billion annually

RISK FACTORS:

- Female sex
- Postmenopausal state
- Advanced age
- Petite body frame, low body weight (<58 kg)
- White or Asian ancestry
- Sedentary lifestyle
- Nulliparity
- Calcium deficiency
- Previous low-trauma fracture
- Parental history of hip fracture
- Tobacco use
- Excess alcohol or caffeine use
- Long-term glucocorticoid use
- Chronic disease states; e.g., primary ovarian insufficiency, diabetes mellitus, androgen deficiency, inflammatory bowel disease, hyperthyroidism, hypercortisolism

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most commonly silent with no signs and symptoms.
- Insidious and progressive development of dorsal kyphosis ***(dowager's hump),*** loss of height, and skeletal pain typically associated with fracture; reduced gait speed or grip strength; other physical findings related to other conditions with associated increased risk for osteoporosis such as nodular thyroid, hepatic enlargement, jaundice, cushingoid features (see "Risk Factors" and Boxes 1 and 2).

ETIOLOGY

Normal bone turnover involves balance between process of bone resorption and bone formation. Osteoclasts resorb bone, and osteoblasts secrete bone matrix for building bone. In postmenopausal women, rate of bone turnover increases after loss of ovarian function, leading to progressive bone loss.

Several fracture risk calculation tools have been developed. FRAX is the leading tool among them. Clinical risk factors used in the World Health Organization Fracture Risk Assessment Tool (WHO FRAX) 10-yr fracture risk calculator are summarized in Box 3.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Malignancy (multiple myeloma, lymphoma, leukemia, metastatic carcinoma)
- Primary hyperparathyroidism
- Osteomalacia
- Paget's disease
- Osteogenesis imperfecta: Types I, III, and IV

WORKUP

- History and physical examination, with appropriate evaluation for identified risk factors and secondary causes. Medications associated with osteoporosis are summarized in

BOX 1 Major Clinical Risk Factors for Osteoporotic Fracture

- Age
- Gender
- Previous fragility fracture
- Glucocorticoid therapy
- History of falls
- Family history of hip fracture
- Other causes of secondary osteoporosis
- Low body mass index
- Smoking
- High alcohol intake

From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

BOX 2 Causes of Secondary Osteoporosis

- Endocrine
  1. Hypogonadism in either sex, including untreated, premature menopause and treatment with aromatase inhibitors or androgen deprivation therapy
  2. Hyperthyroidism
  3. Hyperprolactinemia
  4. Cushing disease
  5. Diabetes
- Gastrointestinal
  1. Celiac disease
  2. Inflammatory bowel disease
  3. Chronic liver disease
  4. Chronic pancreatitis
  5. Other causes of malabsorption
- Rheumatologic
  1. Rheumatoid arthritis
  2. Other inflammatory arthropathies
- Hematologic
  1. Multiple myeloma
  2. Hemoglobinopathies
  3. Systemic mastocytosis
  4. Chronic heparin treatment
- Respiratory
  1. Cystic fibrosis
  2. Chronic obstructive pulmonary disease
- Metabolic
  1. Homocystinuria
- Chronic renal disease
- Immobility

From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

BOX 3 Clinical Risk Factors Included in the FRAX Case-Finding Algorithm

- Age (50 to 90 yr)
- Sex
- Weight (in kilograms) and height (in centimeters). Body mass index is automatically computed from height and weight
- Previous fragility fracture (yes/no)
- Parental history of hip fracture (yes/no)
- Current tobacco smoking (yes/no)
- Long-term use of oral glucocorticoids (over 3 mo) (yes/no)
- Rheumatoid arthritis (yes/no)
- Alcohol consumption of 3 or more units daily (yes/no)
- Other causes of secondary osteoporosis (yes/no): Includes type I diabetes, osteogenesis imperfecta, longstanding untreated hyperthyroidism, hypogonadism or premature menopause (<45 yr), chronic malnutrition, malabsorption, chronic liver disease.

From World Health Organization. WHO risk fracture assessment tool. www.shef.ac.uk/FRAX.
From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

TABLE 1 Medications Associated with Osteoporosis

System	Medication
Endocrine	Aromatase inhibitors (e.g., anastrozole) Excess thyroxine replacement Glucocorticoids Gonadotropin-releasing hormone agonists Ovarian-suppressing drugs (e.g., medroxyprogesterone acetate) Thiazolidinediones SGLT2 inhibitors
Gastrointestinal	Proton pump inhibitors
Hematologic	Heparin Warfarin
Infectious disease	Antiretroviral therapy
Immunosuppressant	Cyclosporine Cytotoxic drugs Tacrolimus
Neurologic	Anticonvulsants—phenytoin, phenobarbital, carbamazepine
Psychiatric	Selective serotonin reuptake inhibitors
Renal	Loop diuretics (e.g., furosemide)

SGLT2, Sodium-glucose transport protein 2.
From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

Table 1. Investigations for secondary osteoporosis are summarized in Box E4.

- WHO guidelines for the diagnosis of osteoporosis are based on bone mineral density (BMD) measurements of the hip or spine in g/cm^2 and are reported as a T score.
  1. Dual-energy x-ray absorptiometry (DEXA) is the gold standard for screening and monitoring changes in BMD due to excellent precision, widespread availability, low cost, and minimal radiation exposure.
  2. DEXA (Fig. 1) is indicated in all women 65 yr and older and in postmenopausal women younger than 65 yr of age who are at risk for fracture (e.g., weight <127 lbs, parental history of hip fracture, use of medications that cause bone loss, current smoking, excessive alcohol use (>2 drinks per day), rheumatoid arthritis, or presence of diseases that cause bone loss). Causes of erroneous bone mineral density measures by DEXA in the lumbar spine are summarized in Table 2.
  3. FRAX questionnaire (Fig. 2): Use of FRAX calculator (https://shelf.ac.uk/FRAX/) is proposed by the U.S. Preventive Services Task Force (USPSTF) to determine the need for screening in women between the ages of 50 and 64. If the FRAX 10-yr major osteoporotic risk is greater than or equal to 9.3%, the USPSTF recommends screening with DEXA scan.
  4. Currently, routine testing in men for osteoporosis is not recommended unless there are clinical manifestations of low bone mass.
  5. Quantitative ultrasound can be used as an adjunctive tool to predict risk of fracture in both men and women. It is cheaper than DEXA and has no radiation. However, at this point, additional research and trials are needed to establish its utility in diagnosis and management of osteoporosis.
- Recommendations as to when to repeat bone density testing should be based on initial T scores (Fig. 3). Data from the Study of Osteoporotic Fractures indicates that in women with normal bone density or mild osteopenia, repeat testing might not be necessary for another 10 to 15 yr. For women with moderate osteopenia, a screening interval of 3 to 5 yr may be appropriate. For women with advanced bone loss/osteoporosis, testing every 1-2 yr is recommended.

LABORATORY TESTS (BOX 5)

- Biochemical profile to evaluate renal and hepatic function, primary hyperparathyroidism, and malnutrition.
- CBC: For nutritional status and myeloma.
- TSH to rule out the presence of hyperthyroidism.
- 24-hour urinary calcium levels and 26-hydroxyvitamin D level may be helpful in evaluating for secondary causes of osteoporosis.
- May consider celiac panel and serum protein electrophoresis. Biochemical markers of bone remodeling may be useful to predict rate of bone loss and/or follow therapy response. Specific biochemical markers are followed (e.g., 3-mo interval) to document normalization as a response to therapy.
  1. High-turnover osteoporosis: High levels of resorption markers (lysyl pyridinoline, deoxy lysyl pyridinoline, n-telopeptide of collagen cross-links, C-telopeptide of collagen cross-links) and formation markers (osteocalcin and bone-specific alkaline phosphatase); accelerated bone loss responding best to antiresorptive therapy.
  2. Low-normal-turnover osteoporosis: Normal or low levels of the markers of resorption and formation (see "high-turnover osteoporosis" listed previously); no accelerated bone loss; responds best to drugs that enhance bone formation.

IMAGING STUDIES

- BMD determination (see "Workup") should be performed on all women with determined risk factors and/or associated secondary causes; criteria for diagnosis of osteoporosis based on measurement of bone density and T score equivalent cut points are summarized in Table 3.
  1. Normal: BMD <1 SD of the young adult reference mean
  2. Osteopenia: BMD 1 to 2.5 SD below the young adult reference mean
  3. Osteoporosis: BMD >2.5 SD below the young adult reference mean
- For patient undergoing treatment: The frequency of BMD monitoring is controversial and many experts recommend that clinicians should not monitor BMD during the initial 5-yr drug treatment period because no studies have proven that such monitoring improves fracture outcomes.
- X-ray exam of appropriate part of skeleton (Figs. E4 and E5) to evaluate clinical osteoporotic fracture only.

Rx TREATMENT

When to treat:

- Osteoporosis based on DEXA measurements of BMD
- History of hip and vertebral fracture
- Osteopenia on DEXA + 10-yr FRAX score of greater than or equal to 3% at hip or greater than or equal to 20% of major osteoporotic fracture

NONPHARMACOLOGIC THERAPY

Prevention:

- Identification and minimization of risk factors
- Appropriate diagnosis and treatment of secondary causes
- Behavioral modification: Proper nutrition, physical activity, fracture prevention strategies

ACUTE GENERAL Rx

- Vitamin D supplement: 600 IU/day for persons 19 to 70 yr of age and 800 IU/day for persons 71 yr and older. Recommended supplementation of calcium and vitamin D is summarized in Table 4.
- Calcium supplement: The recommended dietary intake of calcium for women 19 to 50 yr of age and men 19 to 70 yr of age is 1000 mg/day; women older than age 50 and men older than age 70 require 1200 mg/day. Calcium intake above 2500 mg/day (2000 mg/day in persons >50 yr of age) should be avoided. Consumption of calcium-rich foods and beverages is the preferred approach to ensuring adequate calcium intake.[1]
- Oral bisphosphonates (alendronate, risedronate): Decrease bone resorption by attenuating osteoclast activity. They are first-line therapy for the treatment of most patients with osteoporosis, with proven efficacy to reduce fracture risk. The bisphosphonates

[1]Bauer DC: Calcium supplements and fracture prevention, *N Engl J Med* 369:1537-1543, 2013.

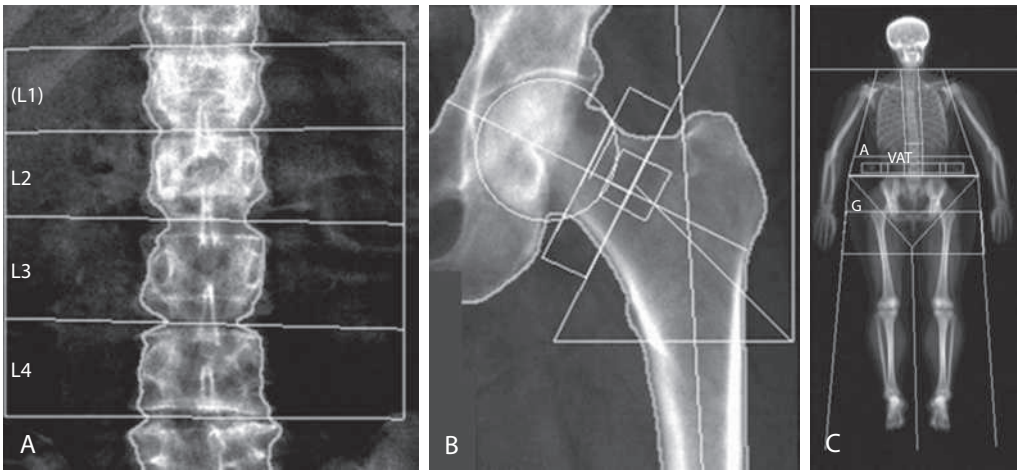

FIG. 1 Dual-energy x-ray absorptiometry (DEXA) provides "areal" bone mineral density (BMD) (g/cm^2) and is currently the gold standard for diagnosis of osteoporosis by bone densitometry (World Health Organization definition T score –2.5 or below) in **(A)** posteroanterior lumbar spine *(L1 through L4)* or **(B)** hip (femoral neck or total). **C,** DEXA of the whole body can provide information on total and regional BMD and body composition (fat and muscle mass). Recent additional parameters measured are android *A*/gynoid *G* ratio and visceral adipose tissue *(VAT).* (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2014, WB Saunders.)

TABLE 2 Causes of Erroneous Bone Mineral Density Measures by DEXA in the Lumbar Spine

Overestimation of Bone Mineral Density
Extraneous calcification (lymph nodes, aorta)
Degenerative disk and spine disease (osteophytes)
Ankylosing spondylitis
Vertebral fracture
Sclerotic metastases
Vertebral hemangioma
Overlying metal artifacts (navel rings)
Surgical interventions (metallic rods, spinal fusion)
Vertebroplasty
Paget disease
Treatment with strontium ranelate
Underestimation of Bone Mineral Density
Laminectomy

DEXA, Dual-energy x-ray absorptiometry.
From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2014, WB Saunders.

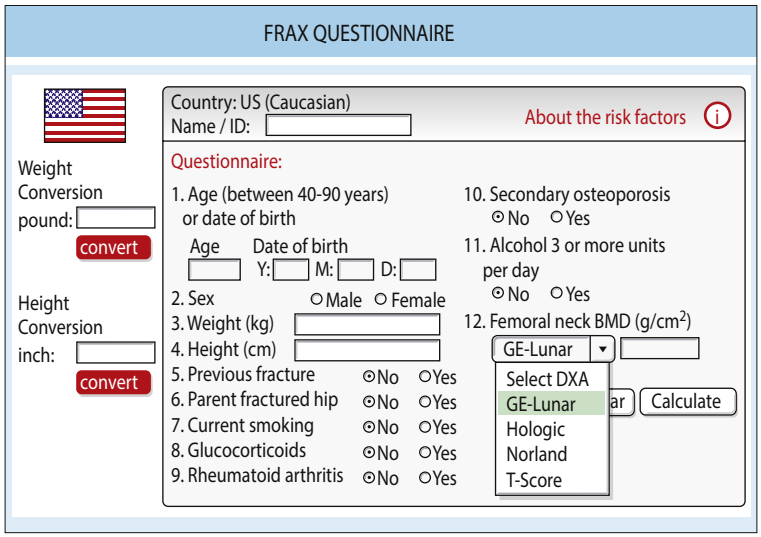

FIG. 2 FRAX questionnaire. (From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.)

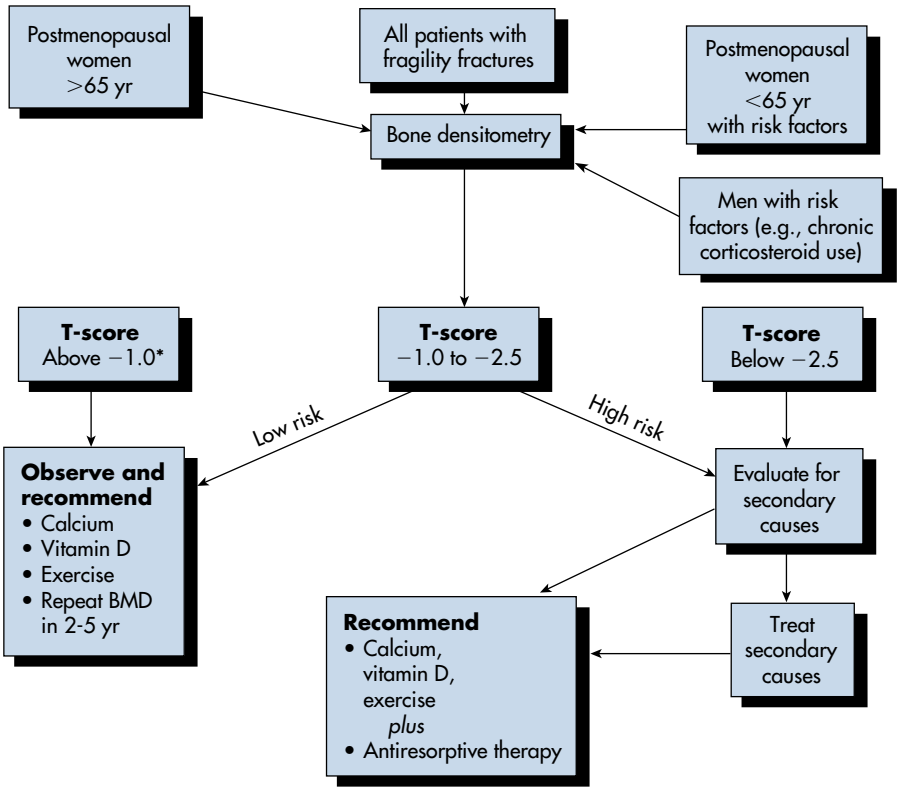
differ in binding affinity, dose frequency, and route of administration. To facilitate absorption, most oral bisphosphonates are taken on an empty stomach with a full glass of water. Patients are instructed to remain in a sitting or standing position for 30 to 60 min. Contraindications include esophageal disorders, inability to remain standing for 30 to 60 min after taking the medication, chronic kidney disease, and Roux-en-Y gastric bypass procedures. Adverse side effects include gastroesophageal reflux disease, esophagitis, transient hypocalcemia, musculoskeletal pain, renal impairment, ocular side effects, jaw necrosis, and atypical femur fracture. Zoledronic acid: A bisphosphonate given by IV infusion over at least 15 min, 5 mg once/yr may be used in patients who are unable to tolerate oral bisphosphonates. It is contraindicated in patients with acute renal failure.

- Biologic agents: Denosumab is a human monoclonal antibody that inhibits osteoclast formation and prevents resorption for treatment of postmenopausal osteoporosis. Dosage is 60 mg subcutaneously every 6 mo. Romosozumab is a monoclonal antibody that increases bone formation and decreases bone resorption by binding to sclerostin. It may be considered for patients who are at high risk for fracture and cannot tolerate any other osteoporotic therapies. Dosage is two consecutive subcutaneous injections (105 mg each) for a total dose of 210 mg once monthly. It should not be used in patients who have had a myocardial infarction or stroke in the past yr.
- Teriparatide is a recombinant human parathyroid hormone used for postmenopausal women with osteoporosis who are at high risk for fracture, especially vertebral fractures. It is also used in men with primary or hypogonadal osteoporosis who are at high risk of fracture. It is administered by injection 20 mcg qd SC into the thigh or abdominal wall. Use for >2 yr is not recommended. It stimulates bone formation and reduces the risk of fracture but may increase the risk of stroke in older women with osteoporosis. Common side effects include headaches,



*Patients with fragility fractures and a T-score above −1.0 should be evaluated for other causes of pathologic fracture.

FIG. 3 Diagnosis and management of osteoporosis.

BOX 5 Recommended Laboratory Investigations for Individuals with Osteoporosis

Recommended screening in all patients
Serum calcium, albumin, phosphorus*,†,‡,§
Serum creatinine*,†,‡,§

TABLE 3 Diagnostic Categories for Osteoporosis Based on World Health Organization Criteria

Category	Definition
Normal	BMD not more than 1 SD below the young adult mean value
Low bone mass (osteopenia)	BMD lying between 1 and 2.5 SD below the young adult mean value
Osteoporosis	BMD more than 2.5 SD below the young adult mean value

BMD, Bone mineral density; *SD,* standard deviation.
From World Health Organization data, 1994. In Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

TABLE 4 Recommended Supplementation of Calcium and Vitamin D

Individual Age Categories	Elemental Calcium	Vitamin D*
Birth-6 mo	400 mg	200 IU
6-12 mo	600 mg	200 IU
1-10 yr	800 mg	200 IU
11-24 yr	1200-1500 mg/day	400 IU
Women and men 25-65 yr: Premenopausal or postmenopausal women taking estrogen	1000 mg/day	400-600 IU
Postmenopausal women, no estrogen	1500 mg/day	400-600 IU for men and women >65 yr
Pregnant and lactating women	1200-1500 mg/day	400 IU
National Osteoporosis Foundation guidelines	1200 mg	800-1000 IU

*These recommendations are guidelines and may be sufficient for healthy individuals with normal 25-hydroxyvitamin D levels. In many circumstances, however, they are insufficient.
From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

myalgia, hypercalcemia, and hypercalciuria. Trials involving abaloparatide, a selective activator of the parathyroid hormone type 1 receptor have also shown reduced risk of new vertebral and nonvertebral fractures in postmenopausal women with osteoporosis.
- Estrogen prescription drugs or raloxifene should not be prescribed to treat women with osteoporosis.

CHRONIC Rx

- Lifelong attention to behavior modification issues (nutrition, physical activity, fracture prevention strategies) and compliance with pharmacologic intervention. Recommendations include weight-bearing and muscle-strengthening exercises, smoking cessation, reduced alcohol intake, and adoption of fall prevention strategies.
- There is little evidence to guide physicians about long-term bisphosphonate therapy. The decision to continue drug therapy beyond 5 yr should reflect reassessment of risk and benefit. The risk of atypical fracture of the femur increases after 5 yr of bisphosphonate use. It is reasonable to consider a drug holiday in postmenopausal women who are not at high fracture risk after 3 yr (IV) to 5 yr (oral) of bisphosphonate therapy. Continued treatment may be advisable in those at highest risk.
- Continuing need to eliminate high-risk factors when possible and to optimally manage secondary causes of osteoporosis.

DISPOSITION

Goals for diagnosis and treatment include identification of women at risk; initiation of preventive measures for all women lifelong; institution of treatment modalities that will result in a decrease in fracture risk; and reduction of morbidity, mortality, and unnecessary institutionalization, thereby improving quality of independent life and productivity. Table E5 summarizes the effect of major treatment options on the risk of vertebral, nonvertebral, and hip fractures.

REFERRAL

- To reproductive endocrinologist, medical endocrinologist, gynecologist, or rheumatologist if unfamiliar with diagnosis and management of osteoporosis
- If multidisciplinary management is required, to other specialties depending on presence of acute fracture and/or secondary associated disorders

PEARLS & CONSIDERATIONS

COMMENTS

- Osteonecrosis of the jaw is a known complication of high-dose IV bisphosphonate therapy for cancer; however, there is considerable debate on whether low-dose bisphosphonates used for osteoporosis can also cause this disorder. Evidence for this is inconclusive.
- Long-term use (>10 yr) of bisphosphonates has been reported to increase risk of atypical subtrochanteric or femoral shaft fractures in several uncontrolled case series. Prodromal symptoms of thigh pain, lack of trauma prior to the procedure, and specific radiologic characteristics (cortical thickening) have been reported. The evidence remains inconclusive. Patients can be reassured that short or intermediate use of bisphosphonates does not increase the risk of atypical femoral fractures. Current strategies should include considering a 12-mo interruption in therapy after 5 yr in patients who are clinically stable and considering teriparatide treatment in individuals who experience an atypical fracture while receiving bisphosphonate therapy.
- Increased risk of esophageal cancer and atrial fibrillation have been reported as possible adverse effects of bisphosphonate therapy.

BOX E4 Investigations for Secondary Osteoporosis in Older People with Low Trauma Fractures or Low Bone Mineral Density

- Full blood count
- ESR or CRP
- Biochemical profile: Including renal function, adjusted serum calcium, and alkaline phosphatase
- Thyroid function tests
- Consider serum testosterone, sex hormone–binding globulin, LH, FSH (men)
- Serum and urine electrophoresis (vertebral fractures)
- Serum 25OHD and PTH

CRP, C-reactive protein; *ESR,* erythrocyte sedimentation rate; *FSH,* follicle-stimulating hormone; *LH*, luteinizing hormone; *PTH,* parathyroid hormone; *25OHD,* 25 hydroxyvitamin.
From Fillit HM: *Brocklehurst's textbook of geriatric medicine and gerontology,* ed 8, Philadelphia, 2017, Elsevier.

FIG. E4 Regional osteoporosis. Hand radiograph in early rheumatoid arthritis (RA) shows periarticular osteopenia at the metacarpophalangeal and interphalangeal joints, with joint space narrowing and juxta-articular erosions. The periarticular osteopenia is the earliest radiographic feature of RA and is related to hyperemia, synovial inflammation, and local cytokines that stimulate osteoclastic bone resorption. (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2015, WB Saunders.)

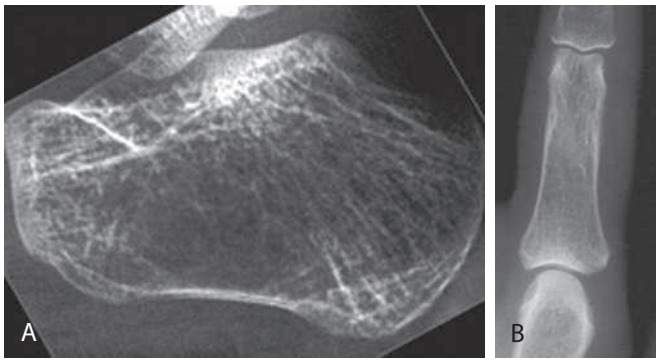

FIG. E5 General osteoporosis. Radiographic features include reduced radiographic density (osteopenia) with reduction in the number of trabeculae, which may be destroyed completely, and the bone cortex becomes thinned as evident in the lateral radiograph of the calcaneus **(A)** and radiograph of the phalanx **(B).** When these features are present, bone densitometry using dual-energy x-ray absorptiometry (DEXA) should be suggested. (From Pope TL et al: *Musculoskeletal imaging,* ed 2, Philadelphia, 2015, WB Saunders.)

TABLE E5 Effect of Major Treatment Options on the Risk of Vertebral, Nonvertebral, and Hip Fractures

	Vertebral Fractures	Nonvertebral Fractures	Hip Fractures
Alendronate	A	A	A
Etidronate	A	ND	ND
Risedronate	A	A	A
Raloxifene	A	ND	ND
Strontium ranelate	A	A	(A)
Teriparatide	A	A	ND
Denosumab	A	A	A
Zoledronate*	A	A	A
Ibandronate*	A	(A)	ND
Calcium and vitamin D*	ND	A	A

A indicates evidence from randomized, controlled trials and/or meta-analysis; (A) reflects that a beneficial effect on fracture risk was found only in post hoc subgroup analysis; ND indicates that fracture reduction has not been demonstrated.
*Not included in current National Institute for Health and Clinical Excellence (NICE) guidance.
From Fillit HM: *Brocklehurst's textbook of geriatric medicine and gerontology,* ed 8, 2017, Elsevier.

BASIC INFORMATION

DEFINITION

Otitis externa refers to a variety of conditions causing inflammation and/or infection of the external auditory canal (and/or auricle and tympanic membrane). There are six subgroups of otitis externa:

1. Acute localized otitis externa (furunculosis)
2. Acute diffuse bacterial otitis externa (i.e., "swimmer ear")
3. Chronic otitis externa
4. Eczematous otitis externa
5. Fungal otitis externa (otomycosis)
6. Invasive or necrotizing (malignant) otitis externa

SYNONYMS

See "Definition."

ICD-10CM CODES

H60.90	Unspecified otitis externa, unspecified ear
H60.2	Malignant otitis externa
H60.3	Other infective otitis externa
H60.5	Acute otitis externa, non-infective
H60.8	Other otitis externa

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- Among the most common disorders
- An estimated 10% of people develop external otitis during their lifetime
- Affects 3% to 10% of patients seeking otologic care

PREVALENCE (IN U.S.):

- Diffuse otitis externa is most often seen in swimmers and in hot, humid climates, conditions that lead to water retention in the ear canal. In the U.S., 44% of AOE-related healthcare visits occur June to August.
- Necrotizing otitis externa is more common in elderly, diabetics, and immunocompromised patients.

PREDOMINANT SEX: None

PREDOMINANT AGE:

- Occurs at all ages, however incidence is highest during childhood and decreases with age
- Necrotizing otitis externa: Typically occurs in elderly: Mean age >65 yr

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The two most common symptoms are otalgia, ranging from pruritus to severe pain exacerbated by motion (e.g., chewing), and otorrhea. Patients may also experience aural fullness and hearing loss as a result of swelling with occlusion of the canal. More intense symptoms may occur with bacterial otitis externa, with or without fever, and lymphadenopathy (anterior to tragus). Findings unique to specific forms of the infection include:

- Acute localized otitis externa (furunculosis):
  1. Occurs from infected hair follicles, usually in the outer third of the ear canal, forming pustules and furuncles
  2. Furuncles are superficial and pointing or deep and diffuse
- Impetigo:
  1. In contrast to furunculosis, this is a superficial spreading infection of the ear canal that may also involve the concha and the auricle
  2. Begins as a small blister that ruptures, releasing straw-colored fluid that dries as a golden crust
- Erysipelas:
  1. Caused by group A streptococcus (*Streptococcus pyogenes*, GAS)
  2. May involve the concha and canal
  3. May involve the dermis and deeper tissues
  4. Area of cellulitis, often with severe pain
  5. Fever, chills, malaise
  6. Regional adenopathy
- Eczematous or seborrheic otitis externa:
  1. Stems from a variety of dermatologic problems that can involve the external auditory canal
  2. Severe itching, erythema, scaling, crusting (Fig.E1), and fissuring possible
- Acute diffuse otitis externa (swimmer ear):
  1. Begins with itching and a feeling of pressure and fullness in the ear that becomes increasingly tender and painful
  2. Mild erythema and edema of the external auditory canal, which may cause narrowing and occlusion of the canal (Fig.E2), leading to hearing loss
  3. Minimal serous secretions, which may become profuse and purulent
  4. Tympanic membrane may appear dull and infected
  5. Usually absence of systemic symptoms such as fever, chills
- Otomycosis:
  1. Chronic superficial infection of the ear canal and tympanic membrane
  2. In primary fungal infection, major symptom is intense itching
  3. In secondary infection (fungal infection superimposed on bacterial infection), major symptom is pain
  4. Fungal growth of variety of colors
- Chronic otitis externa:
  1. Dry and atrophic canal
  2. Typically lack of cerumen
  3. Itching, often severe, and mild discomfort rather than pain
  4. Occasionally mucopurulent discharge
  5. With time, thickening of the walls of the canal, causing narrowing of the lumen
- Necrotizing otitis externa (also known as malignant otitis externa). Typically seen in older patients with diabetes or in patients who are immunocompromised
  1. Redness, swelling, and tenderness of the ear canal
  2. Classic finding of granulation tissue on the floor of the canal and the bone–cartilage junction
  3. Small ulceration of necrotic soft tissue at bone–cartilage junction
  4. Most common symptoms: Pain (often severe) and otorrhea
  5. Lessening of purulent drainage as infection advances
  6. As the infection advances, osteomyelitis of the base of the skull and temporomandibular joint osteomyelitis can develop
  7. Facial nerve palsy often the first and only cranial nerve defect
  8. Possible involvement of other cranial nerves

ETIOLOGY

- Box 1 summarizes common pathogens in otitis externa
- Acute localized otitis externa: *Staphylococcus aureus*
- Impetigo:
  1. *S. aureus* including MRSA
  2. *Streptococcus pyogenes* (GAS)
- Erysipelas: GAS
- Eczematous otitis externa:
  1. Seborrheic dermatitis
  2. Atopic dermatitis
  3. Psoriasis
  4. Neurodermatitis
  5. Lupus erythematosus
- Acute diffuse otitis externa:
  1. Swimming
  2. Hot, humid climates
  3. Tightly fitting hearing aids
  4. Use of ear plugs
  5. *Pseudomonas aeruginosa*
  6. *S. aureus* including MRSA
- Otomycosis:
  1. Prolonged use of topical antibiotics and steroid preparations
  2. Uncontrolled diabetes mellitus can contribute to risk
  3. *Aspergillus* (80% to 90%)
  4. *Candida*
- Chronic otitis externa: Persistent low-grade infection and inflammation
- Necrotizing otitis externa (NOE):

BOX 1 Common Pathogens in Otitis Externa

Gram-negative Organisms
Pseudomonas aeruginosa
Pseudomonas spp. Nov. "otitidis"
Proteus mirabilis
Serratia marcescens

Gram-positive Organisms
Staphylococcus aureus
Staphylococcus epidermidis
Corynebacterium auris
Enterococcus faecalis

Fungi and Yeasts
Aspergillus fumigatus
Candida albicans
Candida parapsilosis

From Cherry JD et al: *Feigin and Cherry's pediatric infectious diseases*, ed 8, Philadelphia, 2019, Elsevier.

1. Complication of persistent otitis externa
2. Extends through Santorini fissures, small apertures at the bone-cartilage junction of the canal, into the mastoid and along the base of the skull
3. *P. aeruginosa*

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute otitis media
- Bullous myringitis
- Mastoiditis
- Foreign bodies
- Neoplasms
- Contact dermatitis
- Eczema
- Ramsey-Hunt syndrome
- Seborrhea
- Otomycosis
- Referred pain
- Table 1 describes the differential diagnosis of painful external ear and auditory canal disorders.

WORKUP

Thorough history and physical examination

LABORATORY TESTS

- Cultures from the canal are usually not necessary unless the condition does not respond to treatment.
- Leukocyte count normal or mildly elevated.
- Erythrocyte sedimentation rate is often quite elevated in malignant otitis externa.

IMAGING STUDIES

- CT scan is the best technique for defining bone involvement and extent of disease in malignant otitis externa.
- MRI is slightly more sensitive in evaluation of soft tissue changes and intracranial extension of infection.
- Gallium scans are more specific than bone scans in diagnosing NOE.
- Follow-up scans are helpful in determining efficacy of treatment. NOTE: Expert opinion supports history and physical examination as the best means of diagnosis. Persistent pain that is constant and severe should raise the question of NOE (particularly in the elderly, diabetics, and immunocompromised patients).

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Cleansing and debridement of the ear canal with cotton swabs and hydrogen peroxide or other antiseptic solution allows a more thorough examination of the ear.
- If the canal lumen is edematous and too narrow to allow adequate cleansing, a cotton wick or gauze strip inserted into the canal serves as a conduit for topical medications to be drawn into the canal. Usually remove wick after 2 days.
- Local heat is useful in treating deep furunculosis.
- Incision and drainage is indicated in treatment of superficial pointing furunculosis.

ACUTE GENERAL Rx

Topical medications:

- An acidifying agent such as 2% acetic acid (Vosol) inhibits growth of bacteria and fungi
- Topical antibiotics (in the form of otic or ophthalmic solutions) or antifungals, often in combination with an acidifying agent and a steroid preparation. Direct application of topical agents to the infected site is a key element in the treatment of external otitis regardless of severity. Proper installation of eardrops entails tilting the head toward the opposite shoulder, pulling the superior aspect of the auricle upward, and filling the ear canal with drops. In young children, the earlobe should be pulled downward to fill the canal
- The ideal antibiotic regimen should have coverage against the most common pathogens, *S. aureus* and *P. aeruginosa*
- Side effect profile can also influence choice of treatment. Ototoxicity is the most important concern with aminoglycoside drugs, including neomycin, tobramycin, and gentamicin. Aminoglycosides are a significant potential source for iatrogenic hearing loss and balance dysfunction, particularly in the presence of tympanic membrane perforation. Allergic contact dermatitis is commonly associated with neomycin when used for prolonged courses. Topical fluoroquinolones can cause local irritation
- The following are some of the available preparations:
  1. Neomycin otic solutions and suspensions:
     a. With polymyxin-B-hydrocortisone (Cortisporin)
     b. With hydrocortisone-thonzonium (Coly-Mycin S)
  2. Polymyxin-B-hydrocortisone (Otobiotic)
  3. Quinolone otic solutions:
     a. Ofloxacin 0.3% solution (Floxin Otic)
     b. Ciprofloxacin 0.3% with hydrocortisone (Cipro HC)
  4. Quinolone ophthalmic solutions:
     a. Ofloxacin 0.3% (Ocuflox)
     b. Ciprofloxacin 0.3% (Ciloxan)
  5. Aminoglycoside ophthalmic solutions:
     a. Gentamicin sulfate 0.3% (Garamycin)
     b. Tobramycin sulfate 0.3% (Tobrex)
     c. Tobramycin 0.3% and dexamethasone 0.1% (TobraDex)
  6. Chloramphenicol 0.5% otic solution or 0.25% ophthalmic solution (Chloromycetin)
  7. Gentian violet (methylrosaniline chloride 1%, 2%)
  8. Antifungals:
     a. Amphotericin B 3% (Fungizone lotion)
     b. Clotrimazole 1% solution (Lotrimin)
     c. Tolnaftate 1% (Tinactin)
- Topical preparations should be applied qid (bid for quinolones, antifungals), generally for 3 days after cessation of symptoms (average 10-14 days total)

TABLE 1 Differential Diagnosis of Painful External Ear and Auditory Canal Disorders

Disorder	Clinical Features
Acute otitis externa	Diffuse redness, swelling, and pain of the canal with greenish to whitish exudate; often very tender pinna
Malignant otitis externa	Rapidly progressive, severe swelling and redness of pinna, which may be laterally displaced
Dermatitis	
Eczema	History of atopy, presence of lesions elsewhere; lesions are scaly, red, pruritic, and weeping
Contact	History of cosmetic use or irritant exposure; lesions are scaly, red, pruritic, and weeping
Seborrhea	Scaly, red, papular dermatitis; scalp may have thick, yellow scales
Psoriasis	History or presence of psoriasis elsewhere; erythematous papules that coalesce into thick, white plaques
Cellulitis	Diffuse redness, tenderness, and swelling of the pinna
Furuncles	Red, tender papules in areas with hair follicles (distal third of the ear canal)
Infected periauricular cyst	Discrete, palpable lesions; history of previous swelling at same site; cellulitis may develop, obscuring cystic structure
Insect bites	History of exposure; lesions are red, tender papules
Herpes zoster	Painful, vesicular lesions in the ear canal and tympanic membrane in the distribution of cranial nerves V and VII
Perichondritis	Inflammation of the cartilage, usually secondary to cellulitis
Tumors	Palpable mass, destruction of surrounding structures
Foreign body	Foreign body may cause secondary trauma to the ear canal or become a nidus for an infection of the ear canal
Trauma	Bruising and swelling of external ear; there may be signs of basilar skull fracture (cerebrospinal fluid otorrhea, hemotympanum)

From Kliegman RM, Lye PS, Bordini BJ, et al, editors: *Nelson pediatric symptom-based diagnosis*, Philadelphia, 2018, Elsevier, table 4.1, p. 62, in Kliegman, RM: *Nelson textbook of pediatrics,* ed 21, Philadelphia, 2020, Elsevier.

Systemic antibiotics:
- Reserved for when the infection has spread beyond the ear canal.
- Treatment usually for 10 days with ciprofloxacin 750 mg q12h or ofloxacin 400 mg q12h, or with antistaphylococcal agent (e.g., dicloxacillin or cephalexin 500 mg q6h). Use Bactrim or clindamycin when MRSA suspected or cultured at one DS twice a day instead of cephalexin or dicloxacillin. For malignant otitis externa (due to Pseudomonas aeruginosa in >90% of cases), effective agents are meropenem 1 g IV q8h or ciprofloxacin 400 mg IV q12h or 750 mg PO q12h or cefepime 2 g q12h.

Treatment for NOE:
- Requires prolonged therapy up to 3 mo; whether to use oral parenteral therapy is based on clinical judgment
- Oral quinolones, ciprofloxacin 750 mg q12h or ofloxacin 400 mg q12h may be appropriate initial therapy or used to shorten the course of IV therapy
- Intravenous antipseudomonals with or without aminoglycosides are also appropriate
- Local debridement

Pain control:
- May require NSAIDs or opioids
- Topical corticosteroids to reduce swelling and inflammation

CHRONIC Rx
- Patients prone to recurrent infections should try to identify and avoid precipitants to infection.
- Swimmers should try tight-fitting ear plugs or tight-fitting bathing caps and remove all excess water from the ears after swimming.
- Treat underlying systemic diseases and dermatologic conditions that predispose to infection.
- Hearing aids should be removed nightly and regularly cleaned.

DISPOSITION
Inadequate treatment of otitis externa may lead to NOE and mastoiditis.

REFERRAL
To an otolaryngologist:
- NOE
- Treatment failure
- Severe pain

PEARLS & CONSIDERATIONS
Otitis externa varies in severity from a mild irritation of the external acoustic canal (swimmer ear) that resolves spontaneously by simply removing the offending agent (stay out of freshwater or wear ear plugs when swimming) to a life-threatening infection with the risk of intracranial extension, gram-negative bacterial meningitis, and severe neurologic impairment with multiple cranial neuropathy. Do not miss severe malignant otitis externa in patients who are diabetic or immunocompromised.

FIG. E1 Patient with acute otitis externa, with purulent drainage from the ear canal and mild edema and erythema of the pinna. (From Cherry JD et al: *Feigin and Cherry's pediatric infectious diseases*, ed 8, Philadelphia, 2019, Elsevier.)

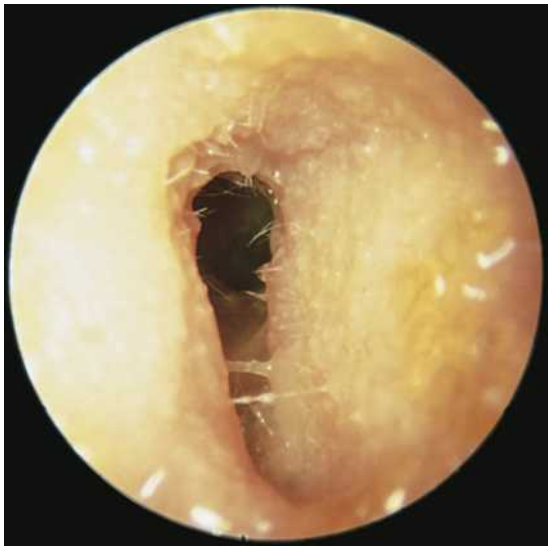

FIG. E2 Acute otitis externa. (From Swartz MH: *Textbook of physical diagnosis, history and examination,* ed 7, Philadelphia, 2014, Elsevier.)

BASIC INFORMATION

DEFINITION

Acute otitis media (AOM) is defined by infected middle ear fluid resulting in moderate to severe bulging of the tympanic membrane (TM) or new onset of otorrhea not due to acute otitis externa. Care should be taken to differentiate AOM from serous otitis media, which involves noninfected middle ear fluid that does not result in bulging of the TM. Serous otitis media does not require antibiotic treatment.

SYNONYMS

Acute suppurative otitis media
Purulent otitis media
Acute otitis media
AOM

ICD-10CM CODES

H65.3	Chronic mucoid otitis media
H66.0	Acute suppurative otitis media
H66.4	Suppurative otitis media, unspecified
H66.9	Otitis media, unspecified
H66.1	Chronic tubotympanic suppurative otitis media
H66.2	Chronic atticoantral suppurative otitis media

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- Affects patients of all ages but is largely a disease of infants and young children.
- Affects approximately 80% of all children by age 5 yr.
- Occurs three or more times in one third of all children by age 3 yr.
- Costs associated with otitis media exceed $5 billion, with 40% of the costs occurring from patients ages 1 to 3.
- One of the most common indications for antibiotic prescription among children.

PEAK INCIDENCE:

- AOM occurs at all ages but is most prevalent between 6 and 24 mo of age.
- A second peak in incidence occurs between 4 and 6 yr of age.
- AOM is most frequent in the fall, winter, and early spring (coincident with peak respiratory virus prevalence in the community).
- Incidence of infection declines with age; AOM is seen infrequently in adults.

RISK FACTORS:

- Daycare attendance
- Limited or no breastfeeding
- Tobacco smoke exposure
- Pacifier use
- Craniofacial anomalies
- Immune globulin G (IgG) or subclass deficiencies

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Moderate to severe bulging of the TM.
- Fluid in the middle ear along with signs and symptoms of local inflammation.
  1. Erythema with diminished light reflex (Fig. E1)
- As infection progresses, middle ear exudation occurs (exudative phase); the exudate rapidly changes from serous to purulent (suppurative phase).
- Retraction and poor mobility of the TM ensue, and the TM begins to bulge.
- At any time during the suppurative phase, the TM may rupture, releasing the middle ear contents (otorrhea).
- Erythema of the TM without other abnormalities is not a diagnostic criterion for acute otitis media (AOM) because it may occur with any inflammation of the upper respiratory tract, crying, or nose blowing.
- Symptoms:
  1. Rapid- or recent-onset otalgia, ranging from slight discomfort to severe, is the most common presenting symptom.
  2. Hearing loss while middle ear fluid is present.
  3. Otorrhea (if TM has ruptured).
  4. Systemic symptoms such as fever, listlessness, irritability, decreased appetite, vomiting, and diarrhea are common. Vertigo, facial swelling, nystagmus, tinnitus, lethargy, and facial nerve palsies can occur as complications of AOM.
  5. Table 1 summarizes symptom scoring systems designed to aid in diagnosis.
- After an episode of AOM:
  1. Persistence of effusion for wks or mos (called secretory, serous, or nonsuppurative otitis media).
  2. Fever and otalgia usually absent.
  3. Hearing loss possible (10 to 50 dB, with predominant involvement of the low frequencies).
  4. Manifestations of the sequelae and complications of otitis media are summarized in Table E2.

ETIOLOGY

- Most common etiology is a viral upper respiratory tract infection, which causes inflammation and dysfunction of the eustachian tube and transient aspiration of nasopharyngeal secretions into the middle ear (Fig. 2). Bacterial colonization from the nasopharynx in conjunction with eustachian tube dysfunction leads to infection.
- May occasionally develop as a result of hematogenous spread or by direct invasion from the nasopharynx.
- Conjugated pneumococcal vaccination of children has resulted in decreases in *Streptococcus pneumoniae* causing AOM.
- Most common bacterial pathogens:
  1. *S. pneumoniae* causes up to half of cases and is the least likely of the major pathogens to resolve without treatment.
  2. *Haemophilus influenzae.*
  3. *Moraxella catarrhalis.*
  4. Of increasing importance, infection caused by penicillin-nonsusceptible *S. pneumoniae* (MIC >0.1 mg/ml), ranging from 8% to 34%. About 50% of PNSSP isolates are penicillin-intermediate (MIC 0.1 to 2.0 mg/ml).
  5. Group A streptococci is associated with higher rates of TM perforation than AOM caused by other pathogens.
- Viral pathogens:
  1. Respiratory syncytial virus (RSV)
  2. Rhinovirus
  3. Adenovirus
  4. Influenza
- Others:
  1. *Mycoplasma pneumoniae*
  2. *Chlamydia trachomatis*
  3. *Streptococcus pyogenes* (Latin America)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Otitis externa
- Otitis media with effusion (OME): An algorithm for distinguishing between acute otitis media and otitis media with effusion is illustrated in Fig. 3
- Referred pain from mouth, nasopharynx, or throat
- Section II describes the differential diagnosis of earache

WORKUP

Thorough otoscopic examination. AOM is a visual diagnosis based on viewing the tympanic membrane. Adequate visualization of the tympanic membrane may require removal of cerumen and debris.

- Tympanometry
  1. Measures compliance of the tympanic membrane and middle ear pressure
  2. Detects the presence of fluid, but cannot determine whether the fluid is infected
- Acoustic reflectometry
  1. Measures sound waves reflected from the middle ear
  2. Is useful in infants >3 mo
  3. Increased reflected sound correlated with the presence of effusion, but cannot determine whether the fluid is infected

LABORATORY TESTS

- Tympanocentesis.
  1. Not necessary in most cases because the microbiology of middle ear effusions has been shown to be extremely consistent
  2. May be indicated in:
     a. Patients who do not respond to treatment in 72 hours or those who experience multiple treatment failures
     b. Immunocompromised patients
- Cultures of the nasopharynx are not helpful.
- Blood counts (generally unnecessary)usually reveal leukocytosis with polymorphonuclear elevation.
- Plain mastoid radiographs (generally unnecessary) reveal haziness in the periantral cells that may extend to entire mastoid.
- CT or MRI may be indicated if serious complications are suspected (meningitis, brain abscess, severe mastoiditis).

TABLE 1 Acute Otitis Media Symptom Scoring Systems Designed to Aid in Diagnosis

3-Item Otitis Media Score (OM-3)	Ear Treatment Group Symptom Questionnaire (ETG-5)	Acute Otitis Media Faces Scale (AOM-FS)	Otoscopic Severity Scale (OS-8)	Acute Otitis Media Severity of Symptom Scale (AOM-SOS)	Otitis Media Clinical Severity Index (OM-CSI) 30-Point Scale[a]	Otitis Media Clinical Severity Index (OM-CSI) 10-Point Scale[a]
Physical suffering	Ear pain	Seven facial expressions ranging from no problem to extreme problem	Eight categories of TM inflammation[b]	Ear pain	Ear pain	Ear pain
Emotional distress	Fever			Ear tugging	Fever	Fever
Limitation of activities	Irritability			Irritability	Irritability	Irritability
	Appetite			Decreased play	Fever at examination	Fever at examination
	Sleep quality			Decreased appetite	TM erythema	TM erythema
				Difficulty sleeping	TM mobility	TM mobility
				Fever	TM position	TM position
					Effusion color	Effusion color
					Otorrhea	Otorrhea

TM, Tympanic membrane.
[a]The 30-point scale used a 2- to 5-point Likert scale and the 10-point scale used a 2- to 3-point Likert scale.
[b]0 = normal; 1 = erythema only; 2 = erythema, air-fluid level, clear fluid; 3 = erythema, complete effusion, no opacification; 4 = erythema, opacification with air-fluid level or air bubbles, no bulging; 5 = erythema, complete effusion, opacification, no bulging; 6 = erythema, bulging rounded doughnut appearance of the tympanic membrane; 7 = erythema, bulging, complete effusion and opacification with bulla formation.

Rx TREATMENT

ACUTE GENERAL Rx

Hydration, avoidance of irritants (e.g., tobacco smoke), nasal decongestants, cool mist humidifier, and oral ibuprofen or acetaminophen. Topical procaine or lidocaine preparations (if available) are an alternative to oral analgesics for children ≥2 yr but should not be used in children with tympanic membrane perforation.

Antimicrobials:

NOTE: Most uncomplicated cases of AOM resolve spontaneously, without complications. Studies have demonstrated limited therapeutic benefit from antibiotic therapy. Watchful waiting is appropriate for children who look well, can be comforted with supportive care, and are old enough to easily evaluate. Children <24 mo with bilateral AOM should receive antibiotic therapy. Children with severe signs or symptoms (moderate or severe otalgia or otalgia for ≥48 hr or temperature ≥39°C) should also receive antibiotic therapy. Fig. E4 illustrates an algorithm for management of acute otitis media in pediatric populations.

When opting to use antibiotic therapy:

- Amoxicillin remains the drug of choice for first-line treatment of uncomplicated AOM despite increasing prevalence of drug-resistant *S. pneumoniae.*
- Treatment failure is defined by lack of clinical improvement of signs or symptoms after 3 days of therapy.
- With treatment failure, in the absence of an identified etiologic pathogen, therapy should be redirected to cover:
  1. Drug-resistant *S. pneumoniae*
  2. β-lactamase–producing strains of *H. influenzae* and *M. catarrhalis*
- Agents fulfilling these criteria include amoxicillin/clavulanate, second-generation (e.g., cefuroxime axetil, cefaclor) or third-generation (e.g., oral cefdinir or cefpodoxime or IM ceftriaxone) cephalosporins. Cefaclor, cefixime, loracarbef, and ceftibuten should be avoided given their limited activity against pneumococci.
- Cross-resistance between TMP/SX and macrolides and the β-lactams exists; therefore patients who do not respond to amoxicillin are more likely to have infections resistant to TMP/SMX and macrolides.
- Fluoroquinolones are not indicated as first- or second-line therapy for AOM and should be avoided in young children due to risks of musculoskeletal effects and limited dosing guidance.

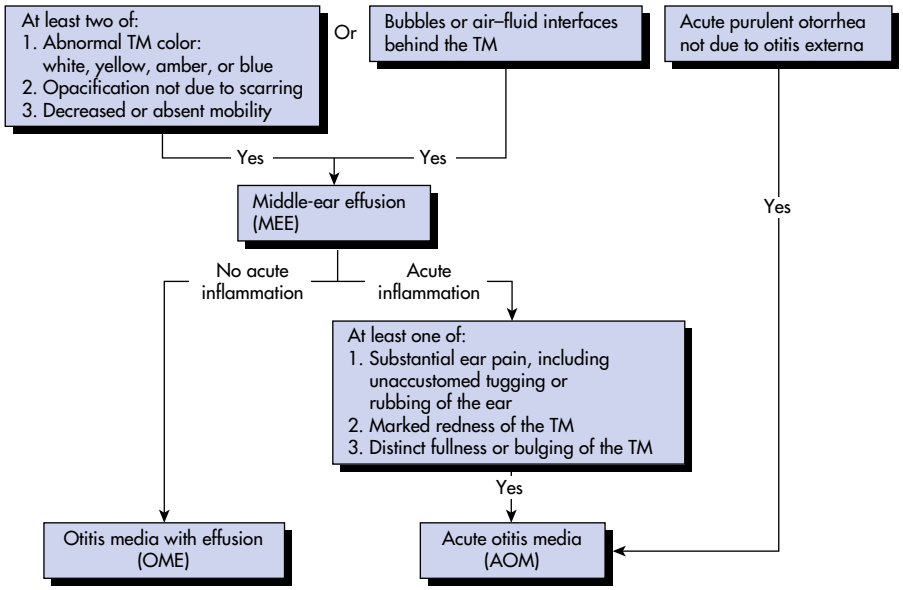

FIG. 3 Algorithm for distinguishing between acute otitis media and otitis media with effusion. *TM,* tympanic membrane. (From Kliegman RM: *Nelson Textbook of Pediatrics*, ed 21, Philadelphia, 2020, Elsevier.)

- Treatment should be modified according to cultures and sensitivities when available.
- Treatment course is 10 days for children <2 yr and those with severe symptoms, 7 days for children age 2 to 5 yr, and 5 to 7 days for children ≥6 yr.
- Follow-up should be tailored to clinical improvement and concern for neurocognitive developmental delays in at-risk children. Standard follow-up of all cases is no longer recommended.
- Antibiotic prophylaxis to reduce the frequency of AOM episodes in children with recurrent AOM is not recommended.
- Table E3 summarizes suggested antibiotics for treatment of otitis media and for patients who have failed first-line antibiotic treatment.

NOTE: Effusions may persist for 8 wk or longer in many cases of adequately treated otitis media.

SURGICAL Rx

- There is no evidence to support the routine use of myringotomy, but in severe cases it provides prompt pain relief and accelerates resolution of infection.
- Purulent secretions retained in the middle ear can lead to increased pressure that may lead to spread of infection to contiguous areas. Myringotomy to decompress the middle ear is sometimes necessary to avoid complications such as mastoiditis, facial nerve paralysis, labyrinthitis, meningitis, and brain abscess.

CHRONIC Rx

- Myringotomy and tympanostomy tube placement for persistent or recurrent middle ear effusion unresponsive to medical therapy can be considered if fluid has persisted for ≥3 mo if bilateral or ≥6 mo if unilateral.
- Adenoidectomy, with or without tonsillectomy, often is advocated for treatment of recurrent otitis media, although evidence for this procedure is controversial.
- Long-term complications include tympanic membrane perforations, cholesteatoma, tympanosclerosis, ossicular necrosis, toxic or suppurative labyrinthitis, hearing loss, and intracranial suppuration.

DISPOSITION

Patients can be treated at home as outpatients with the rare exception of patients with evidence of local suppurative complications (e.g., meningitis, acute mastoiditis, brain abscess, cavernous sinus, or lateral vein thrombosis).

REFERRAL

- To otorhinolaryngologist in cases of:
  1. Medical treatment failure
  2. An uncertain diagnosis; adults with one or more episodes of AOM should be referred for evaluation to rule out an underlying process (e.g., malignancy)
  3. Any of the above-mentioned acute and chronic complications

PEARLS & CONSIDERATIONS

COMMENTS

- Otoscopic findings are critical for accurate AOM diagnosis.
- AOM microbiology has changed with use of pneumococcal conjugate vaccine (PCV13).
- Antibiotics are modestly more effective than no treatment but cause adverse effects in 4% to 10% of children.
- Most antibiotics have comparable clinical success.

Prevention:

- Vaccinate against common pathogens.
- Breastfeed and bottle-feed infants in an upright position.
- Avoid irritants (e.g., tobacco smoke).

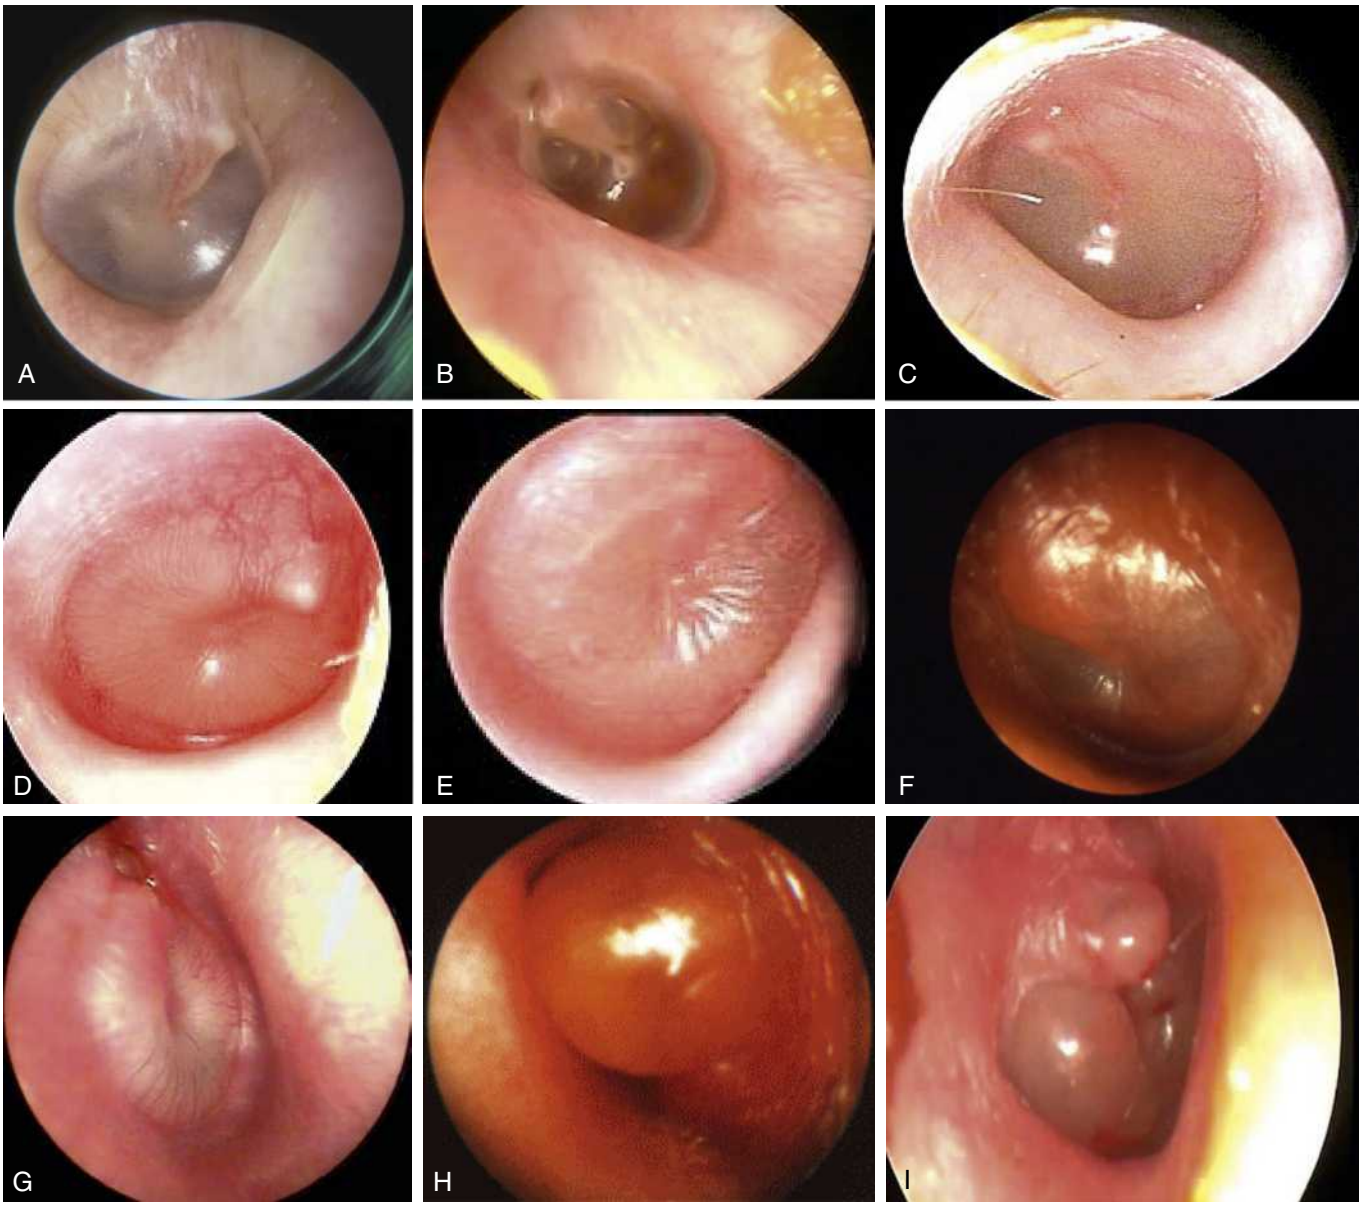

FIG. E1 Transition from normal to otitis media with effusion (OME) to acute otitis media. A, Normal tympanic membrane with pearly gray, translucent appearance. **B,** OME with air bubbles. **C-D,** OME fully filled with effusion; note retracted and translucent tympanic membrane with prominent head of the malleus. **E,** Slight bulging with semiopaque white tympanic membrane. **F,** Bulging semiopaque tympanic membrane. **G,** Markedly bulging, donut appearance, opaque, white tympanic membrane. **H-I,** Severe bulging with bullae formation. (Courtesy Dr. Hoberman, University of Pittsburgh. In Cherry JD et al: *Feigin and Cherry's pediatric infectious diseases*, ed 8, Philadelphia, 2019, Elsevier.)

TABLE E2 Manifestations of the Sequelae and Complications of Otitis Media

Complication	Clinical Features
Acute	
Perforation with otorrhea	Immobile tympanic membrane secondary to visible perforation, exudate in ear canal
Acute mastoiditis with periostitis	Tenderness and erythema over mastoid process, no destruction of bony trabeculae
Acute mastoid osteitis	Destruction of bony trabeculae; tenderness and erythema over mastoid process coupled with outward displacement of pinna
Petrositis	Infection of perilabyrinthine cells; may present with otitis, paralysis of lateral rectus, and ipsilateral orbital or facial pain (Gradenigo syndrome)
Facial nerve palsy	Peripheral cranial nerve VII paralysis
Labyrinthitis	Vertigo, fever, ear pain, nystagmus, hearing loss, tinnitus, nausea and vomiting
Lateral sinus thrombosis	Headache, fever, seizures, altered states of consciousness, septic emboli
Meningitis	Fever, headache, nuchal rigidity, seizures, altered states of consciousness
Extradural empyema	Fever, headache, seizures, altered states of consciousness
Subdural empyema	Fever, headache, seizures, altered states of consciousness
Brain abscess	Fever, headache, seizures, altered states of consciousness, focal neurologic examination findings
Nonacute	
Chronic perforation	Immobile tympanic membrane secondary to perforation
Otitis media with effusion (OME)	Immobile, opaque tympanic membrane
Adhesive otitis	Irreversible conductive hearing loss secondary to chronic OME
Tympanosclerosis	Thickened white plaques may cause conductive hearing loss
Chronic suppurative otitis media	Following acute otitis media with perforation, secondary infection with *Staphylococcus aureus, Pseudomonas aeruginosa*, or anaerobes develops, causing chronic otorrhea
Cholesteatoma	White, pearl-like, destructive tumor with otorrhea arising near or within tympanic membrane; may be secondary to chronic negative middle ear pressure
Otitic hydrocephalus	Increased intracranial pressure secondary to AOM; signs and symptoms include severe headaches, blurred vision, nausea, vomiting, papilledema, diplopia (abducens paralysis)

AOM, Acute otitis media.

From Kliegman RM, Lye PS, Bordini BJ, Toth H, Basel D, editors: *Nelson pediatric symptom-based diagnosis*, Philadelphia, 2018, Elsevier, Table 4.6, p 67. In Kliegman, RM: *Nelson Textbook of Pediatrics*, ed 21, Philadelphia, 2020, Elsevier.

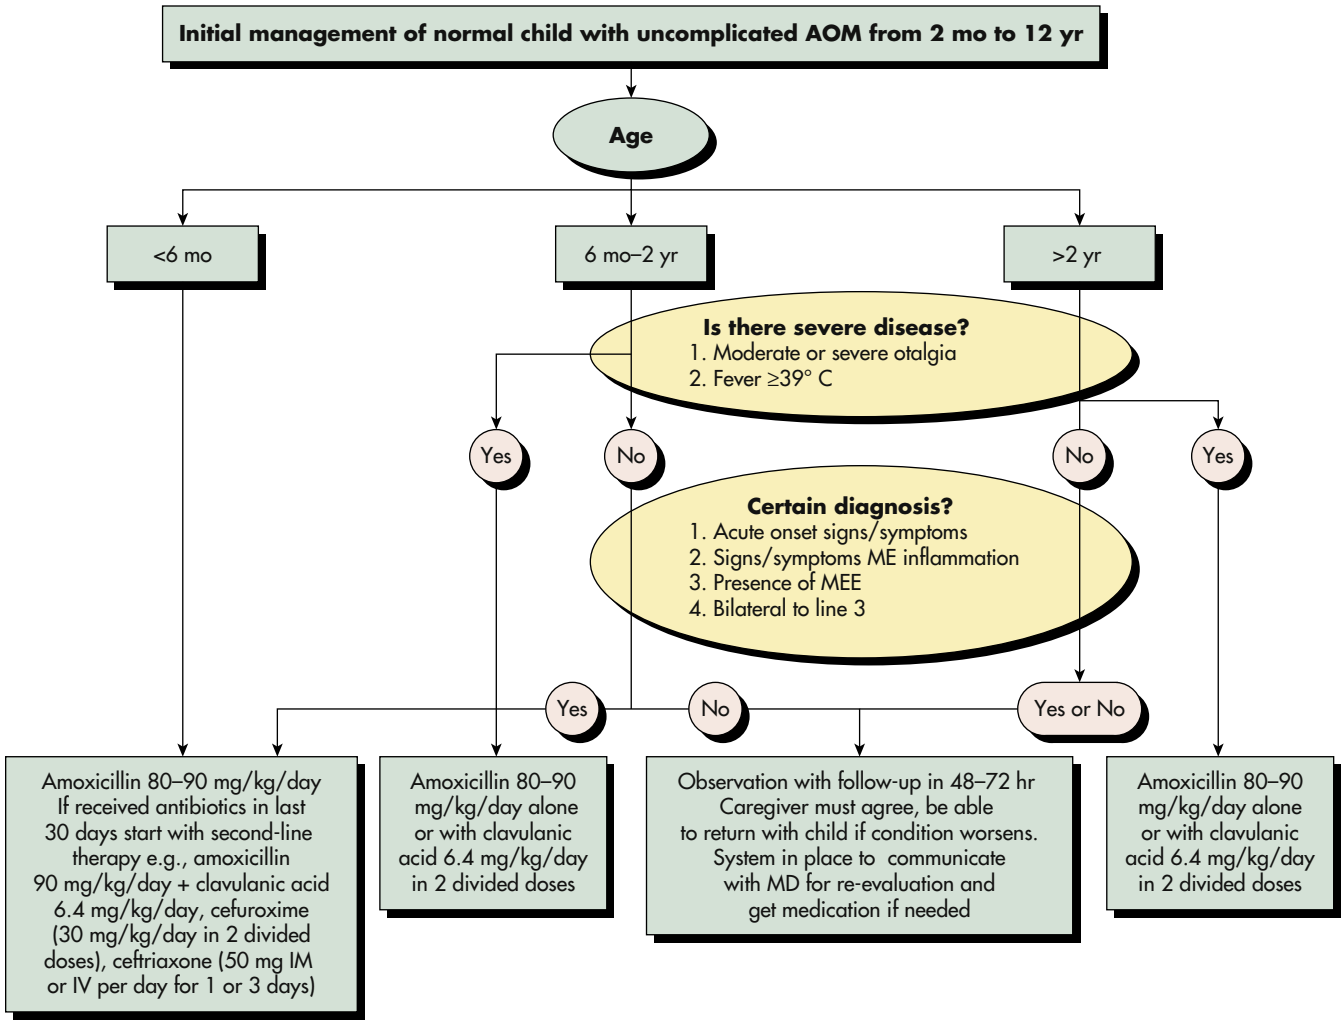

FIG. E4 Congenital chronic otitis media with cholesteatoma. (From Chole RA, Sudhoff HH: *Chronic otitis media, mastoiditis, and petrositis*. In Flint PW, Haughey BH, Lund VJ et al (eds): *Cummings otolaryngology—head and neck surgery*, ed 5, Philadelphia, 2010, Elsevier, Fig 139-6. In Kliegman RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.)

TABLE E3 Suggested Antibiotics for Treatment of Otitis Media and for Patients Who Have Failed First-Line Antibiotic Treatment

Initial Immediate or Delayed Antibiotic Treatment		Antibiotic Treatment After 48-72 hr of Failure of Initial Antibiotic Treatment	
Recommended First-Line Treatment	**Alternative Treatment (If Penicillin Allergy or Suspicion of Beta Lactamase-Producing Organisms)**	**Recommended Treatment**	**Alternative Treatment**
Amoxicillin (Pathogens include *Pneumococcus*, *H. influenzae* non-type B, *Moraxella)*	Cefdinir	Amoxicillin-clavulanate	Ceftriaxone
or	*or*	*or*	Failure of second antibiotic
Amoxicillin-clavulanate Ceftriaxone IM/IV for 1-3 days	Cefpodoxime Ceftriaxone Levofloxacin	Ceftriaxone	Azithromycin Tympanocentesis*

Antibiotic Dosage

- Amoxicillin 90 mg/kg/day bid for 10 days
- Amoxicillin-clavulanate (ratio 14:1) 90 mg/kg/day of amoxicillin component bid for 10 days
- Ceftriaxone 50 mg/kg/day qd IM, IV for 1-3 days
- Cefdinir 14 mg/kg/day qd for 10 days
- Cefpodoxime 10 mg/kg/day bid for 10 days
- Levofloxacin 20 mg/kg/day bid if ≤5 yr for 10 days; 10 mg/kg/day bid if >5 yr for 10 days
- Azithromycin 10 mg/kg/day on day 1 QD then 5 mg/kg/day days 2-5 qd or 10 mg/kg/day for 3 days QD or 20 mg/kg once

IM, Intramuscular; *IV*, intravenous; *bid*, twice daily; *qd*, once daily.
*Tympanocentesis for those who fail second-line therapy.
From Kliegman RM: *Nelson textbook of pediatrics*, ed 21, Philadelphia, 2020, Elsevier.

Otosclerosis (Otospongiosis)

BASIC INFORMATION

DEFINITION

Otosclerosis is conductive hearing loss caused by fixation of the stapes, resulting in gradual hearing loss. Most commonly, it affects both ears, with approximately 15% of cases affecting only one ear.

ICD-10CM CODES

H80	Otosclerosis
H80.0	Otosclerosis involving oval window, non-obliterating
H80.1	Otosclerosis involving oval window, obliterating
H80.2	Cochlear otosclerosis
H80.8	Other otosclerosis
H80.9	Otosclerosis, unspecified
H80.93	Unspecified otosclerosis, bilateral

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Most common cause of hearing loss in young adults

PEAK INCIDENCE: Onset of hearing impairment usually occurs between third and fifth decade of life.

PREVALENCE (IN U.S.):

- Clinically apparent in approximately five cases per 1000 persons, although subclinical histologically confirmed disease prevalence is higher.
- More common in northern white populations.
- Rare among Africans and Asians.
- Pregnancy is associated with acceleration of the disease.

PREDOMINANT SEX: Female:male ratio of 2:1

PREDOMINANT AGE: Symptoms start between ages 20 and 40 yr, with slowly progressive conductive hearing loss.

GENETICS: Autosomal dominant inheritance with incomplete penetrance in about 40% to 45% of patients

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients present with slowly progressive hearing loss, tinnitus (80%), family history of otosclerosis, sensorineural hearing loss, and vestibular symptoms (vertigo/dizziness).
- Tympanic membrane is normal in most cases. Tested with pneumatic otoscopy to rule out middle ear effusion, tympanic membrane perforation, or other cause of conductive hearing loss.
- Rinne test with 512-Hz tuning fork abnormal with bone conduction greater than air conduction (this suggests at least 15- to 20-dB conductive hearing loss).
- Weber test with 512-Hz tuning fork lateralizes to affected ear.

ETIOLOGY

- The disease is characterized by abnormal resorption and deposition of bone forming the otic capsule, resulting in disorganized fibrotic bone rich in blood vessels.
- The process involves an early stage of bone remodeling (otospongiosis), a transitional phase, and a late phase of sclerotic bone formation (otosclerosis).
- There is some evidence to suggest a relationship between the measles virus and the development of otosclerosis.
- Exact etiology is unknown.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hearing loss from any cause: Cochlear otosclerosis, aural polyps, granulomas, tumors, osteogenesis imperfecta, chronic ear infections, trauma, Paget disease.
- Table E1 describes common types of conductive and sensorineural hearing loss.

WORKUP

- The diagnosis is based mainly on clinical history and audiometry findings.
- Audiometry will show a conductive hearing loss and may show the characteristic Carhart notch, which is a depressed bone conduction threshold at 2000 Hz. Stapedial reflex may be absent.

LABORATORY TESTS

None, unless infection suspected

IMAGING STUDIES

High-resolution CT scan with fine cuts through the temporal bone is not essential but may be helpful in confirming the diagnosis or in ruling out other causes of hearing loss, such as mass or other anatomic abnormalities. Diffuse sclerosis may be seen in advanced disease, but findings may be subtle or absent, and a negative CT scan does not rule out the diagnosis. However, recent studies suggest that the CT scan's sensitivity in identifying otosclerosis may be as high as 95% (Fig. E1).

TREATMENT

NONPHARMACOLOGIC THERAPY

- All patients with otosclerosis may use hearing aids as an alternative to surgery.
- Oral fluoride therapy has been shown to be beneficial in patients with sensorineural hearing loss as a result of otosclerosis.

CHRONIC Rx

- Surgical treatment with stapedectomy or stapedotomy is the treatment of choice.

TABLE E1 Common Types of Conductive and Sensorineural Hearing Loss

Conductive Hearing Loss	Sensorineural Hearing Loss
Otitis media with effusion	Presbycusis (hearing loss with aging)
TM perforation	Ototoxicity
Tympanosclerosis	Ménière disease
Retracted TM (eustachian tube dysfunction)	Idiopathic loss
Ossicular problems	Noise-induced loss
Otosclerosis	Perilymphatic fistula
Foreign body in ear canal	Hereditary (congenital) loss
Cerumen impaction	Multiple sclerosis
Tumor of the ear canal or middle ear	Diabetes
Cholesteatoma	Syphilis, acoustic neuroma

TM, Tympanic membrane.
From Rakel RE [ed]: *Principles of family practice,* ed 6, Philadelphia, 2002, WB Saunders.

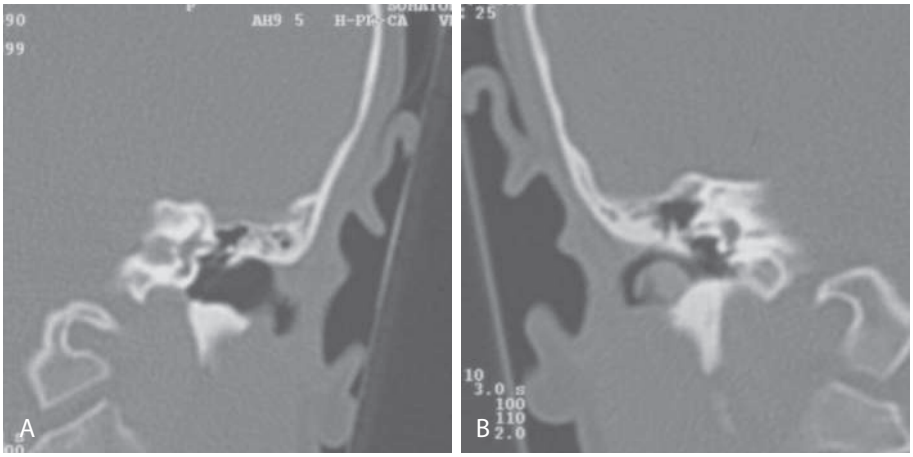

FIG. E1 A patient with conductive hearing loss. By comparing the normal **(A)** and abnormal **(B)** sides on a computed tomography scan, the practitioner clearly can appreciate the narrowing of the oval window. This results in fixation of the stapes footplate and conductive hearing loss. (From Grainger RG et al [eds]: *Grainger & Allison's diagnostic radiology,* ed 4, Philadelphia, 2001, Churchill Livingstone.)

1. Carried out in the worse-hearing ear first; the better-hearing ear may be addressed 6 to 12 mo later.
2. Results in improved hearing in approximately 90% of patients.
3. 2% of patients may develop persistent profound sensorineural hearing loss as a result of surgery.

- If left untreated, the disease will progress to a maximal conductive hearing loss of up to 60 dB. Rarely does the disease cause sensorineural hearing loss or lead to complete deafness.

REFERRAL

To ENT specialist for surgery if moderate hearing loss suspected

PEARLS & CONSIDERATIONS

COMMENTS

A full ENT evaluation in a young or middle-aged person with hearing loss is mandatory unless the cause is obvious (such as trauma or repeated infection).

PATIENT & FAMILY EDUCATION

http://american-hearing.org/disorders/otosclerosis/

AUTHOR: **Louis Insalaco, MD**

BASIC INFORMATION

DEFINITION

Ovarian cancer is not one disease but a constellation of distinct cancer subtypes classified according to their tissue of origin. About 90% of tumors are epithelial ovarian cancers, 5% are gram cell tumors, and 5% are sex cord-stromal tumors. A classification of ovarian epithelial tumors is summarized in Table 1.

SYNONYMS

Epithelial ovarian cancer
Germ cell tumor
Sex cord stromal tumor
Ovarian tumor of low malignant potential

ICD-10CM CODES

C56.9	Malignant neoplasm of unspecified ovary
C56.1	Malignant neoplasm of right ovary
C56.2	Malignant neoplasm of left ovary

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 12.9 to 15.1 cases/100,000 persons; ~25,000 new cases annually. Lifetime risk for developing ovarian cancer is 1.3%. It is the leading cause of gynecologic cancer-related deaths.

PREVALENCE: It is most commonly diagnosed in those 55 to 64 yr of age.

RISK FACTORS:

- Low parity
- Delayed childbearing
- Smoking
- Polycystic ovary syndrome
- Endometriosis
- High-fat diet
- Lynch II syndrome (nonpolyposis colon cancer, endometrial cancer, breast cancer, and ovarian cancer clusters in first- and second-degree relatives)
- Breast-ovarian familial cancer syndrome
- Site-specific familial ovarian cancer
- The **strongest** risk factors are advancing age and family history of ovarian and breast cancer
- Factors that **decrease** the risk of ovarian cancer include previous pregnancy, oral contraceptive pill use, hysterectomy, tubal ligation, or salpingectomy
- Table 2 summarizes risk and protective factors for ovarian cancer

GENETICS: The greatest risk factors of ovarian cancer are a family history and associated genetic syndromes. More than 90% of inherited ovarian malignancies are associated with *BRCA1 and BRCA2* mutations. *BRCA* mutations interact with and affect DNA repair proteins. The estimated lifetime risk of ovarian cancer for patients with either of these mutations is 65% to 74%.

Genetic counseling is recommended for certain patients, including those with:

- Epithelial ovarian cancer at any age
- Breast cancer diagnosed at age 45 yr or younger
- Breast cancer with two distinct and sequential primaries, the first one diagnosed at age 50 yr or younger
- Breast cancer that is triple-negative and diagnosed at age 60 yr or younger
- Breast cancer at any age, with at least one close relative diagnosed at age 50 yr or younger
- Breast cancer diagnosed at any age, with two or more close relatives with breast cancer; one close relative with epithelial ovarian cancer; or two close relatives with pancreatic cancer or aggressive prostate cancer
- Breast cancer, with a close male relative at any age who has breast cancer
- Breast cancer and Ashkenazi Jewish ancestry
- A family with a known deleterious *BRCA1* or *BRCA2* mutation

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- 60% present with advanced disease
- Abdominal fullness, early satiety, dyspepsia
- Pelvic pain, back pain, constipation
- Pelvic or abdominal mass
- Lymphadenopathy (inguinal)
- Sister Mary Joseph nodule (umbilical mass)

ETIOLOGY

- Can be inherited as site-specific familial ovarian cancer (two or more first-degree relatives have ovarian cancer)
- Breast-ovarian cancer syndrome (clusters of breast and ovarian cancer among first- and second-degree relatives)
- Lynch syndrome
- No family history and unknown etiology in the majority of ovarian cancer cases

TABLE 1 Classification of Ovarian Epithelial Tumors

Terminology	Notes
Serous Tumors	Most common epithelial tumor group
Adenocarcinoma	More than 85% involve the ovarian surface or adjacent structures
	Includes low (~10%) and high (~90%) grade carcinomas
Noninvasive low-grade serous carcinoma (LGSC)	Grade 1, synonymous with micropapillary/cribriform borderline
Borderline	Can be intracystic or involve the ovarian surface
Benign	Includes adenofibroma
Mucinous Tumors	Include intestinal (common) and müllerian (less common) types
Adenocarcinoma	Includes borderline tumors with "intraepithelial carcinoma"
Borderline	
Benign	
With mural nodules	
Endometrioid Tumors	
Adenocarcinoma	High-grade carcinomas overlap with high-grade serous carcinomas (HGSCs)
Carcinosarcoma	
Adenosarcoma	
Borderline	Also known as *proliferative cystadenoma/adenofibroma;* including squamous morules
Benign	
Clear Cell Tumors	
Adenocarcinoma	Papillary and adenofibromatous types
Borderline	Occur in adenofibromas
Benign	Very rare
Transitional Cell Tumors	
Malignant	Includes malignant Brenner tumors and the rare transitional cell carcinoma
Borderline	Typically proliferating Brenner tumors
Benign	Usually Brenner tumors
Squamous Cell Tumors	
Malignant	Rare squamous carcinomas with or without a coexisting teratoma
Benign	Epidermoid cysts
Mixed Epithelial Tumors	
Malignant	Commonly a mixture of high-grade serous and endometrioid (high-grade müllerian)
Borderline and benign	Overlap with serous and müllerian mucinous tumors, also called "seromucinous borderline tumors"
Benign	
Undifferentiated or Unclassified	

Modified from the World Health Organization in Crum CP et al: *Diagnostic gynecologic and obstetric pathology*, ed 3, Philadelphia, 2018, Elsevier.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Primary peritoneal cancer mesothelioma
- Benign ovarian tumor
- Functional ovarian cyst
- Endometriosis
- Ovarian torsion
- Pelvic kidney
- Pedunculated uterine fibroid
- Primary cancer from breast, gastrointestinal tract, or other pelvic organ metastasized to the ovary

TABLE 2 Risk and Protective Factors for Ovarian Cancer

Increased Risk	Protective
Lifestyle and diet factors	Lifestyle and diet factors
Aging	Soy intake
Obesity	Flavonoids
Tall stature	High-calcium
Animal fat intake	Sun exposure
α-linolenic acid	Long sleep
Dairy foods	Metformin
Lactose product	
Cigarette use	
Diabetes mellitus	
Reproductive factors	Reproductive factors
Menopausal hormone therapy	Oral contraceptive
Menopausal age	Breastfeeding
Infertility	Tubal sterilization
Polycystic ovarian syndrome	Salpingectomy
Endometriosis	Hysterectomy
Pelvic inflammatory disease	Parity
Genetic factors	

From Niederhuber JE: *Abeloff's Clinical Oncology*, ed 6, Philadelphia, 2020, Elsevier.

WORKUP

- Definitive diagnosis made at laparotomy; epithelial ovarian cancer most common type of ovarian cancer (90% of ovarian cancer)
- Careful physical and history, including family history
- Exclusion of nongynecologic etiologies
- Observation of small cystic masses in premenopausal women for regression for 2 mo
- FIGO classification of ovarian carcinoma is described in Table 3
- Referral to specialists who have extensive training and experience in treating ovarian cancer significantly increases survival after an ovarian cancer diagnosis

LABORATORY TESTS

- Complete blood count.
- Chemistry profile including liver tests and calcium (to evaluate for paraneoplastic syndrome).
- CA-125 or lysophosphatidic acid level. Use of these tests for annual screening is controversial, and most experts warn against universal screening with this marker. Only about 50% of early-stage ovarian cancers will be associated with elevated CA-125. Additionally, false elevations may occur with uterine leiomyoma, endometriosis, pregnancy, and intraabdominal infections. The PLCO cancer screening trial revealed that annual screening based on CA-125 and vaginal ultrasound is ineffective, and diagnostic follow-up of false positives resulted in 15% serious complication rate.
- Consider: Human chorionic gonadotropin, inhibin, alpha-fetoprotein, neuron-specific enolase, and lactate dehydrogenase in patients at risk for germ cell tumors.
- A panel of three serum biomarkers (apolipoprotein A-1 [ApoA-1], transthyretin [TTR], and transferrin [TF]) has been reported useful in distinguishing normal samples from early-stage ovarian cancer with a sensitivity of 84% and normal samples from late-stage ovarian cancer with a sensitivity of 97%.
- *BRCA1/2* testing is recommended for all women with ovarian cancer.

IMAGING STUDIES

- Ultrasound
- Chest x-ray
- CT or MRI of abdomen and pelvis help evaluate extent of disease (Fig. E1)
- Mammogram

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

Virtually all cases of ovarian cancer involve surgical exploration. This includes:

- Abdominal cytology
- Total abdominal hysterectomy and bilateral salpingo-oophorectomy (except in early stages in which fertility preservation is an issue)
- Omentectomy
- Diaphragm sampling
- Selective lymphadenectomy (pelvic and paraaortic nodes)
- Primary cytoreduction with a goal of residual tumor diameter <2 cm
- Bowel surgery, splenectomy if needed to obtain optimal (<2 cm) cytoreduction
- Conventional treatment includes surgical debulking (cytoreduction) followed by chemotherapy. However, patients with low-grade, well-differentiated stage I ovarian cancer do not benefit from adjuvant chemotherapy

ACUTE GENERAL Rx

- Optimal cytoreduction (debulking) is generally followed by chemotherapy (except in some early-stage disease [stage I without high-risk features is treated with surgery alone]).
- Cisplatin-based combination chemotherapy is used for stage II or greater, 6-mo treatment. Compared with IV paclitaxel plus cisplatin, IV paclitaxel plus intraperitoneal cisplatin and paclitaxel improves survival rates in patients with optimally debulked stage III ovarian cancer.
- Chemotherapy regimens continue to change as research continues. Bevacizumab, a humanized antivascular endothelial growth factor monoclonal antibody, has been shown to be effective in improving progression-free survival in women

TABLE 3 International Federation of Gynecology and Obstetrics (FIGO) Classification of Ovarian Carcinoma

Stage I	Growth limited to the ovaries:
	Stage I_A: Growth limited to one ovary, no ascites and no tumor present on the external surface; capsule intact
	Stage I_B: Growth limited to both ovaries, no ascites and no tumor present on the external surface; capsule intact
	Stage I_C: Stage 1_A or 1_B where there is tumor on the surface of either ovary; or with ruptured capsules or with ascites containing malignant cells or positive peritoneal washings. Surgical spillage of a malignant cyst upgrades the patient to I_C, although it is unlikely that this event affects prognosis.
Stage II	Growth involving one or both ovaries with pelvic extension:
	Stage II_A: Extension and/or metastases to the uterus and tubes
	Stage II_B: Extension to other pelvic tissues
	Stage II_C: Stage II_A or II_B with tumor on the surface of either ovary or positive peritoneal washings or malignant ascites
Stage III	Growth involving one or both ovaries with peritoneal implants outside the pelvis or positive retroperitoneal or inguinal lymph nodes:
	Stage III_A: Microscopic seeding of abdominal peritoneal surfaces
	Stage III_B: Macroscopic disease outside the pelvis less than 2 cm in diameter
	Stage III_C: Abdominal implants greater than 2 cm and/or positive nodes
Stage IV	Growth involving one or both ovaries with distant metastases including parenchymal (but not superficial) liver metastases and pleural effusions containing malignant cells

From Symonds EM, Symonds IM: *Essential obstetrics and gynaecology*, ed 4, London, 2004, Churchill Livingstone.

with ovarian cancer. Trials using bevacizumab during and up to 10 mo after carboplatin and paclitaxel chemotherapy have shown prolongation of the median progression-free survival by about 4 mo in patients with advanced epithelial ovarian cancer.

- PARP inhibitors are up-and-coming chemotherapeutic agents that have been used for maintenance therapy and have been shown to improve progression-free survival among patients with platinum-sensitive high-grade serous cancers. PARP inhibitors work by pharmacologically inhibiting the enzyme poly (ADP-ribose) polymerase. Three PARP inhibitors are currently FDA approved for different indications. Olaparib, an oral polymerase inhibitor, was approved in 2014 and has shown antitumor activity in patients with high-grade serous ovarian cancer with or without *BRCA1* and *BRCA2* germline mutations. Rucaparib was approved in 2016 to treat high-grade serous cancers with *BRCA1* and *BRCA2* germline or somatic mutations. Lastly, Niraparib was approved in 2017 for use in high-grade serous cancers with or without *BRCA1* and *BRCA2* mutations.
- Second-look surgery when chemotherapy is complete generally is no longer recommended because this has not been shown to improve survival.
- In most cases, neoadjuvant (presurgical) chemotherapy has no advantage over postsurgical initiation of chemotherapy. However, some trials have shown that neoadjuvant chemotherapy followed by interval debulking surgery is not inferior to debulking surgery followed by chemotherapy as a treatment option for patients with bulky stage IIIC or IV ovarian carcinoma. Complete resection of all macroscopic disease, whether performed as primary treatment or after neoadjuvant chemotherapy, remains the objective whenever cytoreductive surgery is performed.

CHRONIC Rx

- If CA-125 elevated, may have recurrent disease
- Physical and pelvic examinations every 3 mo for 2 yr, every 4 mo during third yr, then every 6 mo
- Routine monitoring of CA-125 at every visit does not improve survival and should be reserved for addressing specific clinical concerns
- Yearly Pap smear
- A treatment approach algorithm for recurrent ovarian cancer is illustrated in Fig. 2

DISPOSITION

- Overall 5-yr survival rates remain low because of the preponderance of late-stage disease:
  1. Stage I and II: 80% to 100%
  2. Stage III: 15% to 20%
  3. Stage IV: 5%
- Younger patients (<50 yr) in all stages have a considerably better 5-yr survival than older patients (40% vs. 15%)
- Among women with high-grade serous ovarian cancer, *BRCA2* mutation, but not *BRCA1* deficiency, is associated with improved survival, improved chemotherapy response, and genome instability compared with *BRCA* wild-type
- Among patients with invasive epithelial ovarian cancer (EOC), having a germline mutation in *BRCA1* or *BRCA2* is associated with improved 5-yr overall survival. *BRCA2* carriers have the best prognosis

COMMENTS

- The U.S. Preventive Services Task Force has concluded that current evidence does not show any mortality benefit to routine screening for ovarian cancer with transvaginal ultrasonography or single-threshold serum CA-125 testing and that the harms of such screening are at least moderate. This recommendation applies to asymptomatic women who are not known to have a high-risk hereditary cancer syndrome.
- Oral contraceptives reduce the risk of ovarian cancer by 40% to 50%. The greatest risk reduction is present after ≥15 yr of oral contraceptive use.
- Patients at high risk for developing ovarian cancer (*BRCA1/BRCA2* gene mutation, hereditary nonpolyposis colorectal cancer syndrome) should consider prophylactic salpingo-oophorectomy after childbearing is complete. Prophylactic bilateral salpingo- oophorectomy reduces ovarian cancer by 80%. It is recommended by age 35 to 40 yr for *BRCA1* carriers and by age 45 for *BRCA2* carriers. If surgery is declined, the National Comprehensive Cancer Network guidelines recommend intensive surveillance with pelvic and abdominal sonogram and serum CA-125 every 6 mo starting at age 35 or 10 yr earlier than cancer diagnosis in family member.

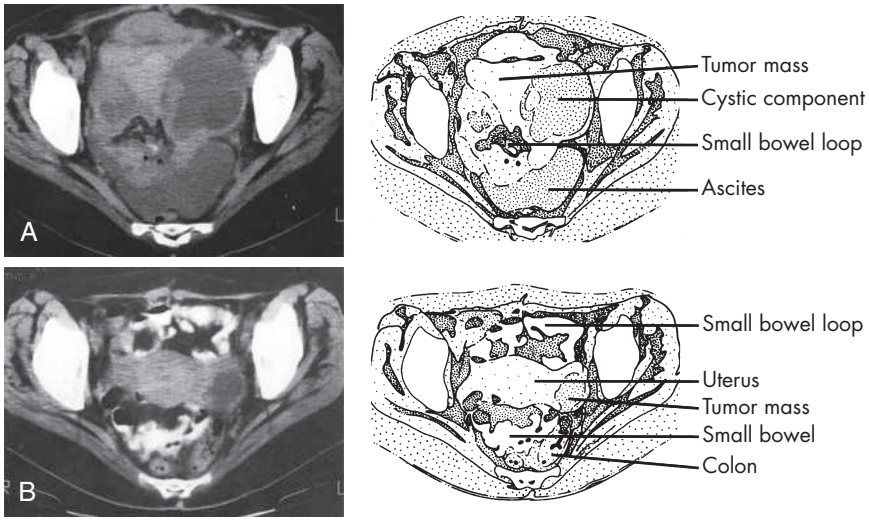

FIG. E1 Response to chemotherapy. A 51-yr-old woman presented with a rapid increase in abdominal girth. **A,** On computed tomography (CT) scan, she was found to have a 12 x 8 cm ovarian mass with a cystic component; peritoneal involvement was extensive, and 6 L of ascites was removed. Pathologic examination showed a poorly differentiated tumor. It was not resectable, and she was treated with combination chemotherapy. After one cycle of therapy, her abdomen returned to normal size. **B,** A CT scan reveals only a small residual ovarian mass. Surgery after four cycles of chemotherapy showed no gross or microscopic tumor. She received four more cycles of chemotherapy but relapsed 1 yr later with abdominal metastases. (From Skarin AT: *Atlas of diagnostic oncology,* ed 3, St Louis, 2003, Mosby.)

BASIC INFORMATION

DEFINITION

Benign ovarian neoplasms are often clinically indistinguishable from their malignant counterparts. Therefore, all persistent adnexal masses must be considered malignant until proven otherwise. Nonneoplastic tumors include:

- Germinal inclusion cyst
- Follicle cyst
- Corpus luteum cyst
- Pregnancy luteoma
- Theca lutein cysts
- Sclerocystic ovaries
- Endometrioma

Neoplastic tumors derived from coelomic epithelium include:

- Cystic tumors: Serous cystadenoma, mucinous cystadenoma, mixed forms
- Tumors with stromal overgrowth: Fibroma, adenofibroma, Brenner tumor

Tumors derived from germ cells are dermoids (benign cystic teratomas)

ICD-10CM CODES

D27.0 Benign neoplasm of right ovary
D27.1 Benign neoplasm of left ovary
D27.9 Benign neoplasm of unspecified ovary

EPIDEMIOLOGY & DEMOGRAPHICS

- **Reproductive years:**
  1. Most common benign ovarian neoplasms: Serous cystadenoma and benign cystic teratoma
  2. Most common adnexal mass: Functional cyst
  3. Risk of malignancy increases after age 40 yr
- **Infants:** Adnexal masses are usually follicular cysts attributable to maternal hormone stimulation that regress during first few mos of life.
- **Childhood:**
  1. Adnexal masses are rare.
  2. 9% to 11% malignant.
  3. Almost always dysgerminomas or teratomas (germ cell origin).
  4. Frequency of malignancy is inversely correlated with age.
- **Adolescence:**
  1. Most common adnexal mass is a functional cyst.
  2. Most common neoplastic ovarian tumor is a benign cystic teratoma.
  3. Solid/cystic adnexal tumors are rare and almost always dysgerminomas or malignant teratomas.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Usually asymptomatic
- Pelvic pain or pressure
- Dyspareunia
- Abdominal pain ranging from mild to severe peritoneal irritation
- Increasing abdominal girth or distention
- Adnexal mass of pelvic examination
- Children: Abdominal or rectal mass, early-onset puberty

ETIOLOGY

- Physiologic
- Endometriosis
- Unknown

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ovarian torsion
- Endometrioma
- Uterine fibroid
- Ectopic pregnancy
- Tubo-ovarian abscess
- Paratubal or paraovarian cyst
- Hydrosalpinx
- Malignancy: Ovary, fallopian tube, colon
- Diverticular abscess, diverticulitis
- Appendiceal abscess, appendicitis (especially in children)
- Urethral diverticulum
- Nerve sheath tumors
- Distended bladder
- Pelvic kidney
- Retroperitoneal cyst or neoplasm

WORKUP

- Complete history and physical examination
- Pelvic or rectovaginal examination to reveal firm, irregular, mobile mass
- Pelvic ultrasound
- Laparoscopy or laparotomy to establish diagnosis

LABORATORY TESTS

- Pregnancy test
- Serum tumor markers:
  1. Cancer antigen 125 (CA-125)
  2. Alpha-fetoprotein (endodermal sinus tumor, immature teratoma)
  3. Beta-human chorionic gonadotropin
  4. Lactate dehydrogenase (dysgerminoma)

IMAGING STUDIES

Ultrasound (Fig. 1):

- May differentiate adnexal mass from other pelvic masses

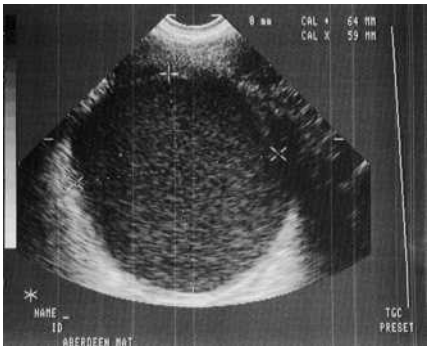

FIG. 1 Ultrasonogram reveals a cyst 6.5 cm across, which was found at laparotomy to be an endometrioma full of altered blood, the so-called chocolate cyst. This may cause cyclical or chronic pelvic pain. (From Greer IA et al: *Mosby's color atlas and text of obstetrics and gynecology,* London, 2000, Harcourt.)

- Features that increase risk of malignancy include solid component, papillae, multiple septations or solitary thick septa, ascites, matted bowel, bilaterality, irregular borders
- CT scan with contrast
- Colonoscopy or barium enema, if symptomatic

TREATMENT

NONPHARMACOLOGIC THERAPY

Repeat pelvic examination, typically with transvaginal pelvic ultrasound, for premenopausal women in 4 to 6 wk to rule out persistent cyst.

ACUTE GENERAL Rx

Indications for surgery:

- Postmenopausal or premenarchal palpable adnexal mass
- Adnexal mass with suspicious ultrasound features
- Adnexal mass greater than 10 cm
- Suspected torsion or rupture

CHRONIC Rx

- Depends on diagnosis
- Possible suppression of formation of new cysts by oral contraceptives

DISPOSITION

- Depends on diagnosis.
- One study showed that all malignant masses demonstrated growth within 7 mo. Expert opinion recommends limiting observation of stable masses without solid components to 1 yr and with solid components to 2 yr.

REFERRAL

- If malignancy suspected
- If surgery required

Over-the-Counter Medication in Pregnancy

BASIC INFORMATION

DEFINITION

Over-the-counter (OTC) medications are pharmacologic agents that patients can buy without a physician's prescription. They come in different forms, such as pills, creams, ointments, patches, or drops.

SYNONYM

Medications without a prescription

ICD-10CM CODE

V22.1 Supervision of otherwise normal pregnancy

EPIDEMIOLOGY AND DEMOGRAPHICS

INCIDENCE: More than 90% of women take some form of OTC medications in pregnancy.
PEAK INCIDENCE: Majority of use occurs in winter and spring due to common respiratory illnesses.

DIAGNOSIS

WORKUP

At the initial prenatal visit, a full history and physical should be performed. Patients should be asked regarding all prescription and OTC medication use, along with herbals and supplements in order to ensure that no harmful or dangerous substances are being used.

COUNSELING

Despite their availability, certain OTC medications can have significant side effects, interact with other medications, and can be toxic when exceeding recommended doses. Patients should therefore be cautious and aware of these issues when taking OTC medications.

PEARLS AND CONSIDERATIONS

COMMENTS

- OTC medications are most commonly used for treatment of cough/cold, allergies, gastrointestinal issues, skin rashes/lesions, and pain relief.
- In general, pregnant women are excluded from clinical trials to determine drug safety, and the majority of information regarding fetal effects results from animal studies. Due to this lack of information, many OTC medications are not rated as category A according to the FDA risk classification system (Table E1).
- Certain medications are considered to be safe in pregnancy due to widespread use with no well-known association with teratogenicity (Table E2), whereas others have been known to have a causal relationship with adverse effects in pregnancy (Table E3).

TABLE E1 Food and Drug Administration Pregnancy Risk Classification System

Category	Definition
Category A	Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in any trimester of pregnancy.
Category B	Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women.
Category C	Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies in humans. However, potential benefits may warrant use of the drug in pregnant women despite potential risks.
Category D	There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans. However, potential benefits may warrant use of the drug in pregnant women despite potential risks.
Category X	Studies in animals or humans have demonstrated fetal abnormalities, and there is positive evidence of human fetal risk based on available data. Risks involved in use of this drug by pregnant women clearly outweigh potential benefits.

TABLE E2 Over-the-Counter Medications Considered to Be Relatively Safe in Pregnancy*

Drug Name	Drug Class	FDA Risk Classification
Folic acid	Dietary supplement	A
Pseudoephedrine	Decongestant	B
Cetirizine	Antihistamine	B
Diphenhydramine	Antihistamine	B
Ranitidine	Antihistamine	B
Dimenhydrinate	Antiemetic	B
Loperamide	Anti-diarrheal	C
Hydrocortisone (topical)	Corticosteroid	C
Dextromethorphan	Antitussive	C
Docusate sodium	Stool softener	C
Omeprazole	Proton pump inhibitor	C
Calcium carbonate	Antacid	C
Simethicone	Antiflatulent	C

FDA, Food and Drug Administration.
*Despite claims regarding the relative safety of these products, questions remain about their risks in pregnancy. For example, pseudoephedrine was considered low risk based on older cohort studies, but newer data show some association with birth defects such as hemifacial microsomia, small intestinal atresia, and gastroschisis.

TABLE E3 OTC Medications to Use with Caution in Pregnancy

Drug Name	Drug Class	FDA Risk Classification	Safety Concerns
Aspirin	Salicylate	B	Associated with neonatal hemorrhage and increased perinatal mortality. Can be used in specific situations, such as maternal clotting disorders or history of pre-eclampsia
Guaifenesin	Expectorant	C	Possible increased risk of neural tube defects if used in the first trimester, but otherwise considered safe in pregnancy
Caffeine	Stimulant	C	Associated with spontaneous abortion in high doses; use with caution
Ibuprofen, Naproxen	NSAID	D	Associated with oligohydramnios, premature closure of ductus arteriosus in third trimester, and fetal nephrotoxicity
Nicotine	Stimulant	D	Associated with intrauterine growth restriction and preterm birth; however, nicotine replacement is preferable to smoking in pregnancy

FDA, Food and Drug Administration; *NSAID,* nonsteroidal anti-inflammatory drug; *OTC,* over-the-counter.

- The most sensitive period during a pregnancy is the first trimester due to organogenesis. Therefore, any medications that are not absolutely essential should be avoided during this time.

PATIENT & FAMILY EDUCATION

Patients should be referred to the CDC website (cdc.gov/pregnancy/meds) for information regarding the use of specific medications.

Paget Disease of Bone PTG

BASIC INFORMATION

DEFINITION

Paget disease of bone is a focal disorder of chaotic bone remodeling with increased osteoblastic and osteoclastic activity that results in disorganized woven and lamellar bone (Fig. E1) in one or more skeletal sites. The end result is bone of poor quality that is enlarged, hypervascular, and susceptible to deformation and fracture.

SYNONYM

Osteitis deformans

ICD-10CM CODES

M88.9	Osteitis deformans of unspecified bone
M88.0	Osteitis deformans of skull
M88.1	Osteitis deformans of vertebrae
M88.869	Osteitis deformans of unspecified lower leg
M88.89	Osteitis deformans of multiple sites
M90.60	Osteitis deformans in neoplastic diseases, unspecified site
M90.679	Osteitis deformans in neoplastic diseases, unspecified ankle and foot
M90.68	Osteitis deformans in neoplastic diseases, other site
M90.69	Osteitis deformans in neoplastic diseases, multiple sites

EPIDEMIOLOGY & DEMOGRAPHICS

Epidemiologic data suggest an origin of Paget disease in Great Britain spreading to other areas by English colonists beginning in the seventeenth century. Highest prevalence occurs in Eastern and Western Europe and in those who have emigrated to New Zealand, Australia, South Africa, and North America. Paget is rarely seen in Japanese, Chinese, Asian Indians, sub-Saharan Africans, and Middle Eastern Arabs.

- Most commonly diagnosed in those aged >50 yr and rare before 40 yr.
- Prevalence estimates of up to 3% of population aged >50 yr and up to 10% in those aged >90 yr.

PREDOMINANT SEX: Variable preponderance of males
PREDOMINANT AGE: Middle or advanced yr
FAMILIAL INCIDENCE: Common, family history positive in up to 40% of cases

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most common sites of involvement: Pelvis (70%), lumbar spine (53%), sacrum, femur (55%), skull (42%), tibia (30%) (Fig. E2), humerus, scapula
- Uncommon: Hand, foot, fibula
- Lesions in one (monostotic) or more bones (polyostotic)
- Gradual progression of disease in affected bone(s) with rare appearance at new site(s)
- Many patients are asymptomatic, but up to 40% of patients who come to medical attention present with bone pain
- Symptoms and signs include bone and articular pain often related to secondary arthritis, bone deformities and enlargement, increased warmth over pagetic bone, skull enlargement, nerve entrapment or compression syndromes, cranial nerve deficits especially deafness (Fig. E3), spinal cord compression and vascular steal syndromes, fissure fractures, fractures, and neoplastic degeneration

ETIOLOGY

Fig. E4 illustrates the pathophysiology of Paget disease. Extensive epidemiologic and laboratory data are in keeping with potential role of paramyxoviral infection of osteoclasts in a genetically susceptible individual with or without documented genetic mutations.

DIAGNOSIS

Diagnosis is often suspected in asymptomatic patients with isolated elevation of alkaline phosphatase without evidence of liver disease.

DIFFERENTIAL DIAGNOSIS

- Osteosclerosis
- Hyperphosphatasia
- Familial expansile osteolysis
- Fibrous dysplasia
- Skeletal neoplasm (primary or metastatic)
- Osteomalacia with secondary hyperparathyroidism

LABORATORY TESTS

- Increase in serum alkaline phosphatase or bone-specific alkaline phosphatase
- Increase in urine NTx/creatinine ratio or plasma CTx
- Bone biopsy is rarely needed but may be necessary in selected cases to rule out sarcomatous degeneration or metastatic disease

IMAGING STUDIES

Bone scintigraphy (Fig. E5) is the most sensitive test for delineating the extent and site of pagetic lesions but nonspecific in that areas of uptake may be related to arthritis or metastatic lesions. Radiographs (Fig. E6) will further delineate characteristic pagetic changes (thickening of cortical bone, coarsened trabecular markings, distortion and expansion of involved bone).

TREATMENT

Indications for therapy include extensive or symptomatic disease; neurologic complications; involvement of weight-bearing bones, skull, vertebrae, and other areas of critical involvement (e.g. in proximity to joints); prevention of excess bleeding from an orthopedic procedure on pagetic bone; and if serum alkaline phosphatase is more than 4 times the upper limit of normal.

NONPHARMACOLOGIC THERAPY

- Optimization of calcium and vitamin D intake and appropriate guidance regarding ambulatory needs.
- Orthopedic stabilization may be required for patients with pseudofractures.

SPECIFIC THERAPY

Bisphosphonates are the mainstay of therapy and include oral alendronate or risedronate and intravenous pamidronate or zoledronic acid. A one-time dose of zoledronic acid (5mg IV) may be effective in controlling symptoms for over 3 yr.

- SC salmon calcitonin when bisphosphonates are not tolerated or are contraindicated as in those with GFR of <35 ml/min
- Acetaminophen, aspirin, and nonsteroidal drugs for relief of pain

DISPOSITION

- Without treatment, progression of disease is common.
- With treatment, remissions of varying duration in most patients. Bisphosphonates can normalize bone turnover in a high proportion of patients, but evidence that long-term suppression of bone turnover prevents complications or improves the clinical outcome is currently inconclusive.
- Careful and regular clinical and biochemical follow-up at 3 to 6-mo intervals with necessity of retreatment in patients with continued pagetic activity or reactivation.
- With first-ever intravenous dose of pamidronate or zoledronic acid, patients may experience a flulike syndrome that may be prevented with acetaminophen.

FIG. E6 Paget disease of the bone. Frontal radiograph of the pelvis shows marked prominence of the trabeculae in the right ilium, ischium, and pubic bones, with small lytic areas identified as compatible with the later stages of Paget disease. (From Specht N [ed]: *Practical guide to diagnostic imaging,* St Louis, 1998, Mosby.)

BASIC INFORMATION

DEFINITION

Paget disease of the breast is a malignant disease that presents itself as a scaly, sore, eroding, bleeding ulcer of the nipple. It represents an extension of a ductal adenocarcinoma of the breast. Microscopically, typical large clear cells (Paget cells) with pale and abundant cytoplasm and hyperchromatic nuclei with prominent nucleoli are found in the epidermal layer. Paget disease is more often associated with primary invasive or in situ carcinoma of the breast.

ICD-10CM CODES

C50.0	Malignant neoplasm of nipple and areola
C50.011	Malignant neoplasm of nipple and areola, right female breast
C50.012	Malignant neoplasm of nipple and areola, left female breast
C50.019	Malignant neoplasm of nipple and areola, unspecified female breast
C50.021	Malignant neoplasm of nipple and areola, right male breast
C50.022	Malignant neoplasm of nipple and areola, left male breast
C50.029	Malignant neoplasm of nipple and areola, unspecified male breast

EPIDEMIOLOGY & DEMOGRAPHICS

- 1% to 3% of new female breast cancer cases
- Peak incidence ages 50s through 60s

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Variable; most often reveals an erythematous, irregularly bordered plaque that starts on the nipple and spreads to the areola.
- Itching or burning nipple and/or reported lump. Itching/burning may occur before lesion.
- Very minimal scaly lesion that may bleed when scales are lifted.
- Typical ulcer located on nipple with serous fluid weeping or small amount of bleeding coming from it (Fig. E1) Bloody discharge may also occasionally occur.
- Palpable carcinoma in the breast of some patients.
- 20% with no palpable mass will have suspicious finding on mammogram.

ETIOLOGY

- Exact origin unknown
- Possibly migration of either in situ or invasive carcinoma cells in breast to nipple skin to produce Paget disease

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Chronic dermatitis
- Florid papillomatosis of the nipple or nipple adenoma
- Eczema
- Skin cancer

WORKUP

- Clinically apparent
- Careful breast examination with diagnosis in mind
- Palpable mass or mammographic lesions in 50% of patients

LABORATORY TESTS

Biopsy of nipple lesion

IMAGING STUDIES

Mammograms to search for possible primary carcinoma

TREATMENT

NONPHARMACOLOGIC THERAPY

- Paget disease without palpable mass and negative mammogram:
  1. Consideration of wide excision of nipple with radiation
  2. Mastectomy is also an option
- Paget disease with palpable mass or abnormal mammogram findings:
  1. Mastectomy
  2. Breast conservation surgery and whole breast radiation

Presence of underlying in situ or invasive carcinoma in mastectomy specimen of majority of patients.

Evaluation of axilla is the same for other breast cancers and depends on underlying type.

ACUTE GENERAL Rx

Systemic adjuvant therapy depending on extent of invasive carcinoma found

DISPOSITION

- Parallel prognosis to that of breast cancer patient without Paget disease
- Prognosis is better in those without palpable mass
- Regular follow-up as in other invasive or in situ carcinoma patients

REFERRAL

At outset, all suspicious nipple lesions should be referred for evaluation and treatment.

BASIC INFORMATION

DEFINITION

Chronic pain is pain that persists for longer than the expected time frame (typically >3 mo) or that is associated with progressive, nonmalignant disease. Pain is an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage. The perception of pain is influenced by physiologic, psychological, and social factors. Chronic pain may be the direct result of an underlying disease process, or it may be a separate condition in its own right.

SYNONYMS

Chronic pain management
Nonmalignant chronic pain
Pain management

ICD-10CM CODES

G89.21	Chronic pain due to trauma
G89.22	Chronic post-thoracotomy pain
G89.3	Neoplasm-related pain (acute) (chronic)
G89.4	Chronic pain syndrome
G89.28	Other chronic post-procedural pain
G89.29	Other chronic pain

EPIDEMIOLOGY & DEMOGRAPHICS

Estimates of the prevalence of chronic pain in the U.S. vary widely. A 2011 report from the Institute of Medicine, *Relieving Pain in America*, estimates that 116 million adults live with chronic pain at a cost of almost $635 billion per yr. Chronic pain is the third leading cause of physical impairment in the U.S. and the leading cause of disease burden and disability globally. Patients with chronic pain may also experience mood changes, depression, sleep disturbances, fatigue, and decreased overall physical functioning.

CLINICAL PRESENTATION

- History: Comprehensive patient assessment, including history of present illness (cause of pain, location, timing, characteristics, exacerbating/relieving factors, triggers), past therapies (pharmacologic and nonpharmacologic and outcomes of these therapies), medical history, family and social history, psychiatric history (including history of depression, anxiety, abuse, and/or other psychological disorders), substance use history, allergies, sleep patterns and disturbances, and current medications. Social supports, coping mechanisms, and spirituality can also help guide development of a treatment plan.
- Pain assessment should be performed at each visit; includes pain intensity (1 to 10), response to medication, and attributes of pain. Standardized templates for both initial and follow-up pain assessment have been developed by various organizations. The Brief Pain Inventory is an example of a widely used assessment tool. In addition, a functional assessment should be performed. Tools such as the Functional Ability Questionnaire (FAQ5) can guide the clinician in determining a patient's functional status. Lastly, consider assessment of a patient's risk for substance abuse.
- Physical examination: Directed at systems affected by pain (often musculoskeletal) and neurologic examination.
- Look for contributing factors (e.g., comorbidities, lifestyle factors) and barriers to effective care (e.g., behavioral, social, insurance). Increasing evidence points to a relation between obesity and chronic pain.
- Components of a comprehensive assessment of cancer pain are summarized in Box 1.

ETIOLOGY

Mechanisms of chronic pain can be divided into three broad categories:

- Nociceptive—pain arising from damage to peripheral tissue from injury or inflammatory, mechanical, or metabolic causes
- Neuropathic—peripheral nerve impairment
- Central—central disturbance in pain processing

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Depends on etiology:
  1. Nociceptive—osteoarthritis, rheumatoid arthritis, postsurgical pain, posttraumatic, cancer pain
  2. Neuropathic—postherpetic neuralgia, diabetic neuropathy, nerve root compression
  3. Central—fibromyalgia, irritable bowel syndrome, chronic headache, phantom limb
- Many chronic pain syndromes may involve one or more of the previously named mechanisms. The etiology of pain in cancer patients is summarized in Box 2.
- Depression and anxiety disorders can be both a cause and a result of chronic pain, so temporal association of these disorders is important.
- Coping mechanisms also can contribute to the risk of developing chronic pain. For example,

BOX 1 Components of A Comprehensive Assessment of Cancer Pain

I. Detailed history of current pain problem
  A. Catalog of pain (number and locations)
  B. Information for each type of pain
    1. Intensity (0-10)
    2. Locations and radiation
    3. Onset and changes over time
    4. Temporal pattern (e.g., constant or intermittent) and quality (e.g., burning)
    5. Exacerbating and relieving factors
    6. Associated neurologic or vasomotor abnormalities
    7. Other associated factors
    8. Interference with the patient's life
    9. Current therapeutic modalities (e.g., schedule, efficacy, and adverse effects)
    10. Prior therapeutic modalities (e.g., schedule, efficacy, and adverse effects)
II. Oncologic history
  A. Histologic type
  B. Presentation: Date, stage, and sites of involvement
  C. Antineoplastic therapies: Dates, types, doses, toxicities, and response to each therapy
  D. Current sites of disease: Stable, responding, or progressive
  E. Patient expectations and goals
III. Medical history—may be affected by pain therapies
  A. Coexisting diseases
  B. Medications and allergies
  C. Substance abuse history
  D. Other constitutional symptoms such as anorexia, fatigue, sedation and other changes in mental status, nausea, vomiting, dysphagia, dyspnea, constipation, urinary and sexual dysfunction, depression, dry mouth; also, the ability to take medications by mouth and the presence of a central venous catheter
IV. Personal and social history
  A. Background: Age, education, employment, marital status, place of residence, religious affiliation, and cultural and ethnic background
  B. Current status: Functional status, caregivers and their health and availability, support system
V. Physical examination
VI. Review of additional information
  A. Medical records, radiologic and laboratory studies
  B. Family members, physicians and/or nurses who know the patient and his or her illness
VII. Differential diagnosis
VIII. Recommendations regarding workup and therapy
IX. Reassessment

From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

anxiety and fear about pain is associated with an increased likelihood of developing chronic pain. Patients with a passive attitude toward treating pain (e.g., rest, medication use) also are associated with higher rates of chronic pain than those with active attitudes.
- Genetic factors play a role. There are at least 150 genes that contribute to chronic pain. It has been shown to be a heritable phenotype, although no one set of genes has been identified as the culprit.
- Factors such as socioeconomic background, employment status, physical activity, sleep disorders, and weight can have a bidirectional effect on chronic pain.

WORKUP

- Workup should be directed at identifying the source of pain. Identification of the mechanism of pain will guide the development of an appropriate treatment plan.
- Laboratory testing, imaging studies, and/or electromyographic (EMG) studies should be used when etiology of chronic pain is unknown or unclear, when comorbidities are suspected, and as the history and physical examination direct.
- Consider use of random urine drug screens or other tests to screen for presence of illegal drugs, unreported prescribed medications, or alcohol use.

Rx TREATMENT

- Studies increasingly support the application of a multidisciplinary, biopsychosocial approach that addresses the multiple facets of pain and includes the patient's perspective and goals
- Therapeutic goal is the reduction of pain (elimination of chronic pain is generally unlikely and providers need to discuss these limitations with patients at outset)
- A written care plan that includes methods to address the patient's personal goals, improve sleep, increase physical activity, manage stress, and reduce pain

NONPHARMACOLOGIC THERAPY

- Exercise (recommended for all patients and tailored to individual abilities and needs). Recent studies demonstrate the benefit of tai chi for patients with osteoarthritis and therapeutic exercise for those with all forms of chronic pain
- Modalities: Heat therapy, cold therapy, transcutaneous electrical nerve stimulation (TENS) units, manipulative therapy, cognitive behavioral therapy, psychological counseling and physical therapy
- Electrostimulation therapy: TENS units
- Behavioral therapies: Cognitive behavioral therapy, hypnosis, biofeedback, relaxation therapy, mindfulness
- Music therapy (in conjunction with other types of therapy)
- Surgery (rarely considered a first-line therapy for chronic pain)

GENERAL PHARMACOLOGIC Rx

- Short-acting antiinflammatory and analgesic medications (e.g., acetaminophen/NSAIDs/opioids). Avoid use of NSAIDs in patients with hypertension, congestive heart failure (CHF), or any type of chronic kidney disease (CKD). These medications should be considered first-line therapy for all patients without contraindications
- Topical analgesics (lidocaine, NSAIDs, capsaicin)
- Trigger-point or joint injections (immediate anesthetic plus long-acting corticosteroids)
- Epidural steroid injections
- Nerve blocks (Table 1)
- Antidepressants (tricyclic and selective serotonin reuptake inhibitors)
- Anticonvulsant medications (e.g., carbamazepine, valproic acid, gabapentin, pregabalin); particularly helpful for neuropathic conditions
- Ketamine (N-methyl-d-aspartate [NMDA] receptor antagonist). Recent studies have been done on its use in patients with opioid tolerance and hyperalgesia. The efficacy of ketamine is moderate to weak, and it only should be considered as third-line

BOX 2 Etiology of Pain in Patients with Cancer

A. Direct tumor involvement (70%)
   1. Invasion of bone
   2. Invasion or compression of neural structures
   3. Obstruction of hollow viscus or ductal system of solid viscus
   4. Vascular obstruction or invasion
   5. Mucous membrane ulceration or involvement
B. Cancer-induced syndromes (<10%)
   1. Paraneoplastic syndromes
   2. Pain associated with debility (e.g., bedsores, constipation, rectal or bladder spasms)
   3. Other (e.g., postherpetic neuralgia)
C. Diagnostic or therapeutic procedures (20%)
   1. Procedure-related pain (e.g., bone marrow aspiration or biopsy and lumbar puncture)
   2. Acute postoperative pain or postsurgical syndromes (e.g., postmastectomy, postthoracotomy, and postamputation syndromes)
   3. After radiation (e.g., injury to plexus or spinal cord, mucositis, and enteritis)
   4. After chemotherapy (e.g., mucositis, peripheral neuropathy, and aseptic necrosis)
D. Pain unrelated to the malignancy or its treatment (<10%)

From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

TABLE 1 Regional Anesthetic Techniques

	Types of Blocks	Examples	Indications	Comments
Local anesthetic blocks	Diagnostic	Intercostal nerve block	Determine etiology of pain and the response and adverse effects following local therapies	Analgesic effect will last only hours
	Treatment of sympathetically maintained pain	Stellate ganglion block	Sympathetically maintained pain	Repeated blocks might be needed
	Trigger point injections	Trigger point injection	Myofascial pain syndrome	Repeated blocks might be needed
Neurolytic (alcohol or phenol) blocks	Peripheral	Intercostal nerve blocks	Chest wall tumor	Pain relief usually lasts several mo
	Visceral	Celiac plexus block Superior hypogastric block Ganglionic impar block	Pancreatic cancer Gastrointestinal or genitourinary cancers	Pain relief usually lasts several mo
	Neuraxial	Epidural	Pain localized to two or three dermatomes	Pain relief usually lasts several mo
		Intrathecal neurolysis Spinal cord stimulator		

From Niederhuber JE: Abeloff's *clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

TABLE 2 Commonly Used Adjuvant Analgesics for Cancer Pain

Drug Category	Indications	Drugs	Common Toxicities	Comments
Antidepressants	Neuropathic pain	Amitriptyline Nortriptyline Desipramine Duloxetine Venlafaxine	Sedation, dry mouth, constipation, postural hypotension, urinary retention	Begin with low doses and increase the dose every few days
Anticonvulsants	Neuropathic pain	Carbamazepine Pregabalin Clonazepam Gabapentin	Drowsiness, dizziness, nausea, rash, bone marrow depression	Monitor platelets with carbamazepine
Corticosteroids	Spinal cord compression, increased intracranial pressure, visceral distention	Dexamethasone Methylprednisolone Prednisone	Gastritis, insomnia, fluid retention, hyperglycemia, myopathy, increased appetite	
Muscle relaxants	Muscle spasm	Diazepam Baclofen Methocarbamol Cyclobenzaprine	Sedation, dizziness, nausea, weakness, confusion	
Benzodiazepines	Muscle spasm, myoclonus, anxiety, insomnia	Diazepam Lorazepam Alprazolam Midazolam Temazepam	Sedation, delirium, hypotension, headache, respiratory depression	Not analgesics; synergistic effect with opioids can cause respiratory depression
Antispasmodics	Gastrointestinal or bladder spasm	Diphenoxylate and atropine Loperamide Scopolamine patch Dicyclomine	Sedation, dry mouth, constipation	
Neuroleptics	Delirium, agitation, nausea and vomiting, hiccups	Olanzapine Risperidone Quetiapine Haloperidol Prochlorperazine	Sedation, orthostatic hypotension, confusion, extrapyramidal reactions	Useful for symptoms other than pain
Bisphosphonates	Bone pain	Pamidronate Zoledronic acid Alendronate Risedronate Ibandronate Etidronate Denosumab	Hypocalcemia, fever, gastrointestinal disturbances, anemia	Delays time to painful skeletal events; also used with analgesics for bone pain

From Niederhuber JE: Abeloff's *clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

treatment. Ketamine also requires regular infusion, and its efficacy is limited by side effects (mainly psychological).
- Implantable methods, epidural and intrathecal drug delivery systems, dorsal column stimulators
- Treatment of insomnia and sleep disorders to reduce pain with standard sleep-inducing agents (trazodone, antihistamines)
- Many patients may require combination drug therapy (CDT) for adequate control of pain, with appropriate attention given to interactions and side effects. Commonly used adjuvant analgesics for cancer pain are summarized in Table 2

OPIOID THERAPY

- Although a mainstay of treatment over the past two decades, limited evidence is available demonstrating the efficacy of both immediate- and long-acting opioid preparations. Some patients with severe chronic pain syndromes may still benefit from this form of treatment. Full opioid agonists are generally the drug of choice for severe chronic cancer pain. Tenets of opioid prescribing are summarized in Box 3.
- Opioids are rarely beneficial in the treatment of inflammatory or mechanical pain and are not indicated for treatment of headaches. Recent studies also have demonstrated the development of hyperalgesia with long-term opioid use.
- The Centers for Disease Control and Prevention has published detailed guidelines for prescribing opioids for chronic pain in light of rising rates of opioid addiction and overdose. The guidelines include when and with whom to use opioid therapy, opioid selection, dosing, duration, and follow-up, along with assessment of the risks, benefits, and discontinuation of therapy.
- Current recommendations include aiming for daily opioid doses of <50 MME/day to limit the risk of overdose and side effects, prescribing naloxone to patients receiving daily doses >50 MME/day due to risk of overdose, avoiding concomitant use with benzodiazepines, and avoiding doses >90 MME/day, or referral to a pain management specialist for close monitoring.
- Sustained-release opioids (used for moderate to severe pain that has failed other therapeutic interventions): Oxycodone, morphine sustained release(SR), methadone (use with caution), or fentanyl patch; short-acting opioids can be used in conjunction with these agents for management of breakthrough pain. Conversion to a long-acting opioid should be based on an equi-analgesic conversion. Table E3 compares morphine milligram equivalent doses for commonly prescribed opioids.

Table 4 provides guidelines for opioid dose selection, conservative initial starting doses for opioid-naïve individuals, and conversion ratios for opioid rotation in patients on chronic opioids. Titration of these medications should not exceed the equivalent of 100 mg morphine/Day to avoid risk of overdose. Box E4 summarizes CDC recommendations for prescribing opioids for chronic pain outside of active cancer and palliative and end-of-life care. Box E5 summarizes the interpretation of recommendation categories and evidence types.

MEDICAL MARIJUANA

- Limited studies on efficacy, side effects, or outcomes for use in CNCP
- Some small randomized controlled trials (RCTs) show benefit of low-dose cannabinoids for chronic neuropathic pain

BOX 3 Management Approach: Tenets of Opioid Prescribing

- Order opioids on a scheduled "around-the-clock" basis to optimize relief.
- Order an as-needed opioid to treat breakthrough or incidental pain.
- Initiate a prophylactic bowel regimen at the same time opioids are prescribed. Patients usually require a combination of stool softeners and stimulant laxatives to treat opioid-induced constipation.
- Treat opioid-induced nausea and vomiting with aggressive antiemetic management, which includes giving patients antiemetics on an around-the-clock basis. Patients often become tolerant to this adverse effect several days after beginning opioids.
- Once baseline opioid requirements are determined, sustained-release opioid preparations can be used to reduce the number of pills taken each day.
- Teach the patient and family about the purpose and benefits of opioids to allay their fears about adverse effects and addiction. This instruction will improve patient compliance.
- Frequent assessment of pain relief is paramount during the opioid titration period. Titrate doses based on the patient's report of pain relief and/or the amount of as-needed opioid that has been required for patient comfort.
- Maximize the doses of one opioid before changing to another agent or route. Changes should be made primarily because of toxicities. For example, a patient taking 200 mg of controlled-release morphine every 12 hr and 200 mg of immediate-release morphine daily for breakthrough pain should have the dose of controlled-release morphine increased to 300 mg every 12 hr if he or she is not experiencing significant opioid adverse effects. This approach is more likely to be beneficial than beginning titration with subcutaneous or intravenous morphine or oral hydromorphone.
- Refer to equianalgesic tables when initiating or changing a patient's analgesic regimen.
- Avoid chronic administration of intramuscular or rectal opioids.
- Avoid chronic administration of meperidine, which can be associated with the accumulation of normeperidine, a neurotoxic metabolite.

From Niederhuber JE: *Abeloff's clinical oncology,* ed 6, Philadelphia, 2020, Elsevier.

COMPLEMENTARY & ALTERNATIVE MEDICINE

Acupuncture and massage (evidence-based for some indications). Acupuncture is most likely to benefit patients with low back pain, neck pain, chronic idiopathic or tension headache, migraine, and knee osteoarthritis. Recent evidence has demonstrated the benefit of modalities such as yoga, tai chi, and music therapies. Supplements, although popular, do not have substantial evidence to recommend for or against their use.

REFERRAL

- Pain medicine specialist or multidisciplinary pain clinic: Useful when primary therapies fail, in patients with complex pain conditions, in patients requiring a high daily morphine milligram equivalent (MME), or for invasive therapies
- Consider referral to an addiction specialist if patient has a history of substance abuse or addiction
- Psychiatry/psychological services for counseling, if needed

PEARLS & CONSIDERATIONS

- Patient consent should be obtained in the form of a written treatment agreement before initiating treatment. This agreement should outline the goals of therapy, use of a single provider or treatment team and a single pharmacy, limitations on dose and number of prescribed medications, prohibition on use with alcohol or sedating medications, keeping medication safe and secure, prohibition on selling or sharing medication, limitations on refills, compliance with all components of the treatment plan, the role of drug screening, and consequences of non-adherence.
- Follow-up assessment should occur every 1 to 6 mo and include a complete pain assessment (see earlier), review of the type of long-acting analgesic used and dosage, use of breakthrough analgesics, side effects and their management, use of nonpharmacologic therapies, and adjunct medication use.

COMMENTS

- Medication dependence and addiction should not be confused. Most patients receiving chronic opioid therapy can become dependent on these medications for pain relief but opioid addiction does not occur. Patients exhibiting signs of addiction often will seek escalating doses of medication, request refills of prescriptions earlier than planned, and engage in drug-seeking activities (e.g., emergency department visits between prescriptions, seeking multiple prescriptions).
- Side effects need not preclude use of opioid medications and should be anticipated. Antiemetics can aid in controlling nausea. Constipation can be managed with stool softeners and laxatives.
- The emphasis of comprehensive pain management for non–cancer-related chronic pain has led to a fourfold increase in prescribing of opioid medications in the U.S. This increase in opiate use has also led to a rise in the misuse and abuse of these medications. Providers should proceed with caution before initiating pain management with opiate medications and should familiarize themselves with processes and tools for pain assessment and medication management. Forty-two states have developed prescription drug monitoring programs (PDMPs) to assist providers in identifying issues of abuse, polypharmacy, and misuse of controlled substances.

TABLE 4 Guidelines for Opioid Dose Selection, Conservative Initial Starting Doses for Opioid-Naïve Individuals, and Conversion Ratios for Opioid Rotation in Patients on Chronic Opioids

Opioid Naïve	Morphine SR	Codeine	Oxycodone	Hydrocodone	Hydromorphone	Methadone	Fentanyl	Oxymorphone
Initial dose and range in opioid-naive patient (starting dose range for repeated dosing)*	15 mg (15-30 mg q8-12h)	30 mg (15-60 mg q4-6h)	5 mg (5-15 mg q4-6h)	5 mg (5-10 mg q4-6h)	2 mg (2-4 mg q4-6h)	2.5 mg q6-12h	NA	5 mg q4-6h
Opioid Tolerant Converting from:	Morphine PO	Codeine	Oxycodone	Hydrocodone	Hydromorphone	Methadone	Fentanyl	Oxymorphone
Morphine IM 10 mg (the gold standard for opioid comparisons)	20-30 mg	60-90 mg†	5 mg	5-10 mg q4-6h	2 mg	2.5 mg	25-μg patch/72 hr	5 mg (the gold standard for opioid comparisons)
Morphine SR 30 mg PO q8-12h, 60-90 mg/24h		30-90 mg q4h	3-45 mg/24 hr oxycodone, approx. 50% of morphine dose	30-45 mg/24 hr	12-18 mg/24 hr	24-hr dose morphine 30-90 mg 4:1 conversion 90-300 mg 8:1 conversion >300 mg 12:1	25-mcg patch/72 hr	5 mg q12h ER
Codeine 30-60 mg q4h	15-30 mg q3-4h		5-7.5 mg q4h	5-10 mg q4h	12 mg/24 hr	2.5 mg q8-12h	12.5-μg patch/72 hr	2.5-5 mg q4-6h IR
Oxycodone 5 mg q3-4h	10 mg	30-60 mg q3-4h		5-10 mg q4h	12 mg/24 hr	2.5 mg q8-12h	25-μg patch/72 hr	5 mg q4-6h IR
Hydrocodone 10 mg q3-4h	15 mg	30-60 mg q3-4h	5 mg q3-4h		12 mg/24 hr		12.5-μg patch/72 hr	2.5-5 mg q4-6h IR
Hydromorphone 2 mg q4h	10 mg		5 mg	5-10 mg q4h		2.5 mg q8-12h	25-μg patch/72 hr	5 mg q4-6h IR
Methadone 5 mg q8h	20 mg SR q8h		10 mg q3-4h		4 mg q4-6h		25-μg patch/72 hr	5 mg q12h ER
Fentanyl 25 μg/hr patch	90 mg morphine per 24 hr (1 μg to 4 mg morphine)					5 mg q8-12h		5 mg q12h ER
Oxymorphone ER 5 mg q12h	15 mg SR q12h		5 mg q8-12h	10 mg q4-6h	12 mg/24 hr	5 mg q8-12h	25-μg patch/72 hr	

NOTE: Recommended starting doses are low and should be titrated upward slowly to minimize adverse effects. Limitations of equianalgesic tables exist because they are based on single-dose studies in opioid-naïve individuals. Convert opioid 1 to morphine equivalents and calculate dose of opioid 2 according to conversion ratio, then reduce the calculated dose for opioid 2 by one third to one half to ensure safety of the 24-hr total daily dose. Rescue dose is 10% to 20% of daily opioid dose given every 3 to 4 hr as needed. Titration upward for unrelieved pain should be by 25% to 30% of the current 24-hr dose, adjusted by daily amount of rescue medications needed over a several-wk period. Equivalent or equianalgesic doses for the different opioid preparations vary in different publications.

ER, Extended release; *IM*, intramuscular; *IR*, immediate release; *PO*, by mouth; *SR*, Sustained release.

*Conservative low equianalgesic starting doses for opioid-naïve individuals adapted from published recommendations.

†Doses above 1.5 mg/kg not recommended because of increase in side effects.

BOX E4 CDC Recommendations for Prescribing Opioids for Chronic Pain Outside Active Cancer, Palliative, and End-of-Life Care

Determining When to Initiate or Continue Opioids for Chronic Pain

1. Nonpharmacologic therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and nonopioid pharmacologic therapy, as appropriate.
2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic expectations for pain and function, and should consider how therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3. Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and the patient's and clinician's responsibilities for managing therapy.

Opioid Selection, Dosage, Duration, Follow-Up, and Discontinuation

4. When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.
5. When opioids are started, clinicians should prescribe the lowest effective dose. Clinicians should use caution when prescribing opioids at any level. They should reassess carefully the evidence of individual benefits and risks when increasing the dose to ≥50 morphine milligram equivalents (MME)/day, and they should avoid increasing it to ≥90 MME/day or should carefully justify a decision to titrate it to ≥90 MME/day.
6. Long-term opioid use often begins with treatment of acute pain. When they are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or fewer often is sufficient; more than 7 days will rarely be needed.
7. Clinicians should evaluate risks and benefits in patients within 1 to 4 wk of starting opioid therapy for chronic pain or 1 to 4 wk of dose escalation. Clinicians should discuss risks and benefits of continued therapy with patients every 3 mo or more frequently. If benefits do not outweigh risks of continued opioid therapy, clinicians should optimize other therapies and work with patients to taper opioids to lower dosages or discontinue them.

Assessing Risk and Addressing Harms of Opioid Use

8. Before starting and periodically during continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including offering naloxone when factors that increase risk for opioid overdose are present. These include history of overdose, history of substance use disorder, higher opioid dosages (≥50 MME/day), and concurrent benzodiazepine use.
9. Clinicians should review the patient's history of controlled substance prescriptions and use state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, at time intervals ranging from every prescription refill to every 3 mo.
10. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider retesting at least annually to assess for prescribed medications, other controlled prescription drugs, and illicit drugs.
11. Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
12. Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioral therapies) for patients with opioid use disorder.

All recommendations are category A (apply to all patients outside active cancer treatment, palliative care, and end-of-life care) except recommendation 10 (designated category B, with individual decisionmaking required).
CDC, Centers for Disease Control and Prevention. From Dowell D et al: CDC Guideline for Prescribing Opioids for Chronic Pain—United States, 2016, *JAMA* 315(15):1624-1645, 2016.

BOX E5 Interpretation of Recommendation Categories and Evidence Types

Recommendation Categories

Based on evidence type, balance between desirable and undesirable effects, values and preferences, and resource allocation (cost)
Category A recommendation: Applies to all persons; most patients should receive the recommended course of action
Category B recommendation: Individual decisionmaking needed; different choices will be appropriate for different patients. Clinicians help patients arrive at a decision consistent with patient values and preferences and specific clinical situations

Evidence Type

Based on study design and a function of limitations in study design or implementation, imprecision of estimates, variability in findings, indirectness of evidence, publication bias, magnitude of treatment effects, dose-response gradient, and constellation of plausible biases that could change effects
Type 1 evidence: Randomized clinical trials or overwhelming evidence from observational studies
Type 2 evidence: Randomized clinical trials with important limitations, or exceptionally strong evidence from observational studies
Type 3 evidence: Observational studies or randomized clinical trials with notable limitations
Type 4 evidence: Clinical experience and observations, observational studies with important limitations, or randomized clinical trials with several major limitations

From Dowell D et al: CDC Guideline for Prescribing Opioids for Chronic Pain—United States, 2016, *JAMA* 315(15):1624-1645, 2016.

BASIC INFORMATION

DEFINITION

The Diabetes Control and Complications Trial (DCCT) demonstrated in patients with type 1 diabetes mellitus (T1DM) that intensive insulin therapy may slow the rate of secondary complications of diabetes at the expense of causing life-threatening, iatrogenic hypoglycemia. Pancreas transplantation (PTX) is the most effective treatment for glycemic control and forestalling microvascular end-organ damage in T1DM. Compared to insulin-based treatment of T1DM, functional pancreata result in euglycemia; do not cause hypoglycemia; and lead to improvements of retinopathy, peripheral neuropathy, and progression of native diabetic nephropathy (DN) or recurrence of diabetic nephropathy (DN) in the transplanted kidney.

Currently, PTX is not only the first choice for organ replacement in T1DM but also in patients with type 2 diabetes mellitus (T2DM) with BMI ≤28 mg/kg/m^2 and patients undergoing pancreatectomy for malignancy localized to the pancreas or chronic pancreatitis with irreversible damage.

SYNONYMS

Simultaneous kidney-pancreas transplant (SPK)
Pancreas after Kidney transplant (PAK)
Pancreas transplant alone (PTA)

ICD-10CM CODES

Z76.82	Pancreas transplant candidate
Z94.3	Pancreas transplant status (CMS-HCC)

EPIDEMIOLOGY & DEMOGRAPHICS

Since the first SPK transplant in 1966 the outcomes, surgical technique, immunosuppression, and complications of pancreas transplant modalities have evolved and improved. In the past 30 yr more than 31,000 PTX procedures have been performed in the United States. The success in survival of PTX and recipients is the result of better procurement techniques, changes in pancreas exocrine drainage from the urinary bladder to the small intestine (Figs. 1 and 2), and advances in immunosuppression.

The introduction in the 1980s of OKT3 and calcineurin inhibitors such as cyclosporine was pivotal in improving PTX outcomes. With the introduction of rabbit antithymocyte globulin in the late 1990s (replacing OKT3) and tacrolimus (replacing cyclosporine), there has been an additional reduction in PTX loss in the first 90 days posttransplant and in PTX rejection. Similarly, the survival of the kidney (native or transplant) has improved due to reduction of nephrotoxicity and chronic immune injury.

INCIDENCE: Despite an increasing prevalence of DM, the number of PTX in the United States decreased from 2006 through 2012 but reversed in 2014. Since then, the PTX overall numbers have remained relatively stable. The preferred modality of PTX is the SPK, representing more than 70% of all PTX in 2017. The SPK recipient is usually a patient with T1DM with end-stage kidney disease or advanced CKD stage 4 with an eGFR of ≤20 ml/min per 1.73 m^2. SPK transplants are most commonly performed when recipients are already obligated to immunosuppressive therapy by the kidney graft. Thus the added surgical risk of a PTX is minimized. SPK grafts have the lowest rate of kidney transplant failure at 4.9%, 16.6%, and 34.9% at 1, 5, and 10 yr posttransplantation, respectively.

With respect to organ survival, accurate rates of pancreas graft loss are more difficult to ascertain given the lack of a precise definition of pancreas graft failure and that pancreas graft losses are not usually reported. The remaining 30% are solitary PTX performed after kidney transplantation (PAK) or in nonuremic patients with or without DN with brittle (or labile) diabetes (including recurrent episodes of hypoglycemia and/or hypoglycemic unawareness; PTA).

The PAK has a kidney graft failure of 2.9%, 16.1%, and 47.1% after 1, 5 and 10 yr, respectively. The slightly poorer long-term outcomes of PAK likely reflects kidney graft age and cumulative injury before PTX. Of all PTX modali-

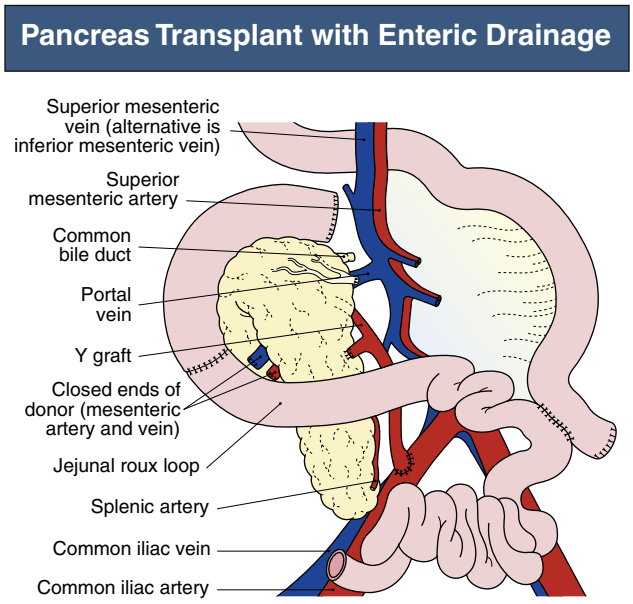

FIG. 1 Pancreas transplant with enteric (portal) drainage. (From Feehally J et al: *Comprehensive clinical nephrology,* ed 6, Philadelphia, 2019, Elsevier.)

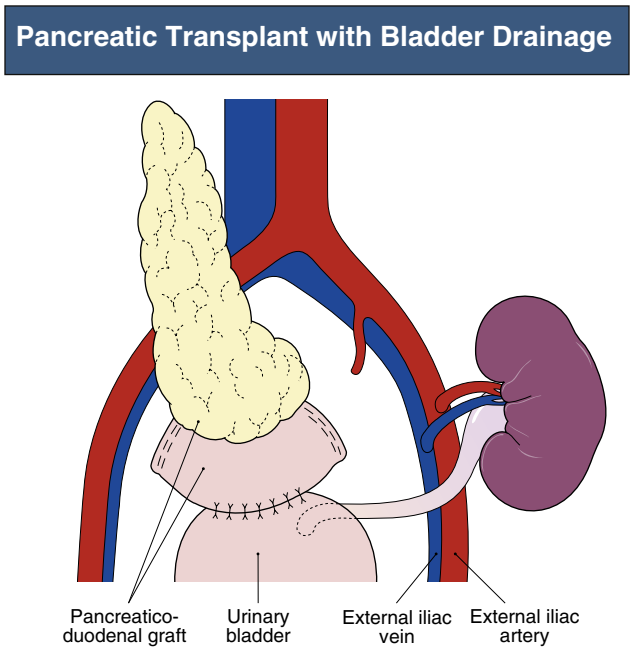

FIG. 2 Pancreas transplant with bladder drainage. The pancreas may be placed in either the intraperitoneal or extraperitoneal position. (From Feehally J et al: *Comprehensive clinical nephrology,* ed 6, Philadelphia, 2019, Elsevier.)

ties, PTA is the least-favored modality due to poor pancreas survival. Concerning the kidney benefits of PTA, however, reversal of DN has been demonstrated by clinical measurements and histology after 5 or more yr of euglycemia.

Regarding active PTX waiting list (WL) candidates in 2014, 55.2% of SPK, 50.6% of PTA, and 39.7% of PAK were transplanted within 3 yr. The median waiting time to transplant in 2016 to 2017 decreased to 12.9 and 22.8 mo for SPK and PTA, respectively.

PREVALENCE: There are 24,557 functional SPK and 8,885 solitary PTX (i.e., PKA and PTA), respectively, in the United States. There are only 48 SPK and 24 PTA from living donors. The most recent SPK and PTA from living donors were performed in 2013 and 2008, respectively. Currently all PTX donors are deceased. African American and Hispanic donors of PTX account for 33.1% of all PTX performed by 2017, and no donors were ≥65 yr old.

PREDOMINANT SEX AND AGE: The typical SPK candidate has T1DM (80%), is 35 to 49 yr old, 55.4% are male, and 40% have a BMI of 18.5 to 25 kg/m^2. Although the majority of pancreas wait-listed patients are Caucasian, there has been an increase in PTX candidates who are African American, Hispanic, and Asian. In addition there is an increase in the proportion of candidates aged ≥50 yr reflecting the changes in organ allocation allowing for PTX of T2DM.

RISK FACTORS: The risk factors for PTX loss are similar to other transplanted organs: African American race, recipients of two or more transplants, high titers of antidonor antibody, and long waiting time. The most common causes of graft failure are death with a functional graft due to cardiovascular disease, infections, malignancies, surgical complications, and rejection. PTXs are particularly susceptible to graft rejection, with an incidence of 15% to 21% at 1 yr and 27% to 30% at 5 yr posttransplant. These frequencies greatly exceed those of kidney transplant rejection.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The exam of PTX recipients is no different than that of other organ recipients. PTX is surgically placed in the right lower quadrant of the abdomen. Abdominal pain is a common sign of rejection, graft thrombosis (complicating 5% to 10% of PTX), and pancreatitis (complicating 3% of PTX). Fever is a common finding in viral infections of the PTX (e.g., cytomegalovirus, adenovirus) or intrabdominal bacterial infections. An anastomotic leak is a rare and serious complication, contributing to 4% of graft failures. The diagnosis is suggested by peritonitis, fever, leukocytosis, and confirmed by imaging studies.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Acute rejection
- Surgical complications
- Transplant pancreatitis
- Viral infections: CMV, adenovirus, Coxsackie virus, and mumps virus
- Posttransplant lymphoproliferative lymphoma occurs more commonly in pancreatic transplants compared to kidney transplants

In bladder-drained PTX, urological complications include urethral stenosis and hemorrhagic cystitis, recurrent urinary tract infections, severe metabolic acidosis, and volume depletion from exocrine sodium bicarbonate loss in urine. These complications often require surgical conversion from bladder drainage to enteric drainage.

WORKUP

Laboratory tests:

- Graft monitoring:
  1. Amylase and lipase levels (lipase being more specific)
  2. Fasting blood glucose level
  3. Fasting C-peptide level
  4. Hemoglobin A1c
  5. Bladder-drained PTX: Urinary amylase may be helpful
- Specific tests:
  1. Viral polymerase chain reaction: Cytomegalovirus, adenovirus, BK virus, mumps rubulavirus
  2. PTX biopsy
  3. Bacterial cultures as indicated: Blood, urine, peritransplant collections
- Elevated fasting glucose or hemoglobin A1c levels or a low fasting C-peptide level predict poor graft survival. In these circumstances, the risks associated with treatment of graft rejection may outweigh its benefits.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Surgical conversion of pancreatic graft bladder drainage to enteric drainage
- Acute rejection: Acute immunosuppression with antithymocyte globulin, IV pulse glucocorticoids, antiproliferative agents (mycophenolate-based drugs or mTOR inhibitors—everolimus or rapamycin), and calcineurin inhibitor (i.e., tacrolimus)
- Chronic or maintenance immunosuppression: Generally comprised of calcineurin inhibitor (i.e., tacrolimus), antiproliferative agent (Mycophenolate based drugs or mTOR inhibitors—everolimus or rapamycin, and calcineurin inhibitor) and glucocorticoids

DISPOSITION

Admission to intensive care or transplant floor depending on severity of clinical presentation. Management may require consultations to infectious diseases and urology where appropriate.

PEARLS & CONSIDERATIONS

- Weekly monitoring of PTX function for the first mo, twice monthly during the first 6 mo, and monthly afterward.
- PTX recipients must always be maintained on glucocorticoid steroids.
- Immunosuppressant medication changes must always be done in collaboration with a transplant specialist.
- Coronary artery disease (CAD) is the most common cause of death in PTX recipients regardless of age.
- PTX recipients should be on statin and low-dose ASA.
- PTX recipients should undergo screening for CAD yearly in prevalent patients and every 2 yr in patients without a history of documented CAD.
- PTX recipients have a greater risk of stroke and peripheral vascular disease than the general population.

BASIC INFORMATION

DEFINITION

Pancreatic cancer is an adenocarcinoma derived from pancreatic duct epithelium. Microscopic premalignant pancreatic lesions in the pancreatic ducts are referred to as pancreatic intraepithelial neoplasia (PIN) in which there is a stepwise progression from low grade to high grade associated with accumulating genetic alterations. Intraductal papillary mucinous neoplasms (IPMN) are a second type of precursor to pancreatic cancer that are associated with an overall risk of invasive cancer of approximately 25%, especially in those arising from the main pancreatic duct.

ICD-10CM CODES

C25.9	Malignant neoplasm of pancreas, unspecified
C25.0	Malignant neoplasm of head of pancreas
C25.1	Malignant neoplasm of body of pancreas
C25.2	Malignant neoplasm of tail of pancreas
C25.3	Malignant neoplasm of pancreatic duct

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: In the U.S., it is estimated that there were 56,770 new cases and 45,750 deaths in 2019. It is the fourth leading cause of cancer-related death in the U.S. The majority of patients present with advanced disease, and less than 20% of patients present with potentially resectable tumors.
PREDOMINANT SEX: Male:female ratio of 2:1
PREDOMINANT AGE: Median age at diagnosis is 71 yr

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Presenting symptoms are generally related to location:

- Jaundice (60% to 70% of pancreatic cancers are located in the head of the pancreas)
- Abdominal pain: Generally dull upper abdominal pain or vague abdominal discomfort
- Weight loss
- Anorexia/change in taste, asthenia
- Nausea
- Uncommonly: Depression, gastrointestinal bleeding, acute pancreatitis (from obstruction of the pancreatic duct), back pain
- Trousseau syndrome (hypercoagulability in the setting of malignancy) may be initial presentation in some patients
- Table 1 summarizes demographic features and presenting symptoms in pancreatic cancer patients

Physical findings:

- Icterus
- Cachexia, temporal wasting
- Ascites, peripheral lymphadenopathy, hepatomegaly
- Excoriations from scratching pruritic skin

ETIOLOGY

Unknown, but several conditions have been associated with pancreatic cancer:

- Smoking
- Alcoholism
- Genetics: up to 20% of patients have a family history of the disease
- Genetic syndromes and associated genes: Hereditary pancreatitis (*PRSS1, SPINK1*), Peutz-Jeghers syndrome (*STK11[LKB1]*), familial atypical multiple mole and melanoma syndrome (*p16*), hereditary breast and ovarian cancer syndromes (*BRCA1, BRCA2, PALB2*), ataxia telangiectasia (*ATM*), Li-Fraumeni syndrome (*P53*)
- Gallstones
- Diabetes mellitus (present in at least 50% of patients with pancreatic cancer)
- Chronic pancreatitis
- Diet rich in animal fat
- Occupational exposure: Oil refining, paper manufacturing, chemical industry
- Overweight or obesity during early adulthood is associated with a greater risk of pancreatic cancer and a younger age of disease onset. Obesity at an older age is associated with a lower overall survival in patients with pancreatic cancer
- There are four major driver genes for pancreatic cancer: *KRAS*, *CDKN2A*, *TP53*, and *SMAD4. KRAS* mutation and alterations in *CDKN2A* are early events in pancreatic cancer tumorigenesis
- Table 2 summarizes nongenetic and genetic risk factors for pancreatic cancer

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Common duct cholelithiasis
- Cholangiocarcinoma
- Common duct stricture
- Sclerosing cholangitis
- Primary biliary cirrhosis
- Autoimmune pancreatitis
- Drug-induced cholestasis (e.g., phenothiazines)
- Other pancreatic tumors (islet cell tumor, cystadenocarcinoma, epidermoid carcinoma, sarcomas, lymphomas)

WORKUP

Initial laboratory testing includes complete blood count, serum chemistries. The bile duct antigen CA 19-9 is not used as a screening test but can be utilized as a modality for detecting recurrence and for therapeutic monitoring in patients undergoing therapy.

As per updated consensus guidelines, all patients diagnosed with pancreatic cancer should undergo assessment of risk for hereditary syndromes known to be associated with an increased risk of cancer. Germline genetic testing for cancer susceptibility should be considered even if family history is unremarkable.

Routine Laboratory Tests	% Abnormal
Alkaline phosphatase	80
Bilirubin	55
Total protein	15
Amylase	15
Hemoglobin	60

IMAGING STUDIES

- Multidetector helical CT (Fig. E1) with IV administration of contrast is the imaging procedure of choice for initial evaluation.
- Endoscopic ultrasonography (Fig. E2) is useful when the diagnosis is strongly suspected and tissue is required for diagnostic purposes. Fine-needle aspiration biopsy combined with endoscopic ultrasonography is the preferred modality for evaluation of cystic or mass lesions to determine malignancy.
- Endoscopic retrograde cholangiopancreatography (ERCP, Fig. E3) is useful in patients with jaundice needing an endoscopic stent to relieve obstruction.
- PET scans are of limited value in pancreatic cancer and are not part of standard management.

TABLE 1 Demographic Features and Presenting Symptoms and Signs in Patients with Unresectable (Palliated) and Resectable (Resected) Pancreatic Cancer

	Palliated (*N* = 256)	Resected (*N* = 512)
Demographic Features		
Age, average (yr)	64.0	65.8
Men/women	57%/43%	55%/45%
Race	91% white	91% white
Symptoms and Signs (%)		
Abdominal pain	64	36*
Jaundice	57	72*
Weight loss	48	43

Noninvasive Imaging	% Abnormal
Abdominal ultrasonography	60
Abdominal CT scan (with contrast) (Fig. E4)	90
Abdominal MRI scan	90

Invasive Imaging	% Abnormal
ERCP	90
CT scan or ultrasonography-guided needle aspiration cytology	90-95

STAGING

2018 AJCC eight edition staging system for Pancreatic Cancer

PRIMARY TUMOR (T):

T_X	Primary tumor cannot be assessed
T_0	No evidence of primary tumor
T_1	Tumor <2 cm
T_2	Tumor >2 cm and <4 cm
T_3	Tumor >4 cm
T_4	Tumor involves celiac axis or superior mesenteric artery (unresectable primary)

LYMPH NODES (N):

N_0	No regional lymph nodes
N_1	metastasis in 1-3 regional lymph nodes
N_2	metastasis in >4 regional lymph nodes

DISTANT METASTASES (M):

M_X	Presence of distant metastasis cannot be assessed
M_0	No distant metastasis
M_1	Distant metastasis

STAGING GROUPS:

I_A	T_1, N_0, M_0
I_B	T_2, N_0, M_0
II_A	T_3, N_0, M_0
II_B	T_{1-3}, N_1, M_0
III	T_{1-3}, N_2, M_0 T_4, any N, M_0
IV	Any T, any N, M_1

Rx TREATMENT

Treatment sequencing strategies are summarized in Fig. 5 and Table 3.

SURGERY FOR RESECTABLE DISEASE

- Classification of resectability of pancreatic cancer per the National Comprehensive Cancer Network and Surgical Oncology Expert Consensus Statement is summarized in Table 4.
- Curative cephalic pancreaticoduodenectomy (Whipple procedure) for tumors in the head and neck of the pancreas is appropriate for only 10% to 20% of patients whose lesion is <5 cm, solitary, and without locoregional invasion. Surgical mortality rate can be up to 5%. Tumors in the body or tail of the pancreas are removed by means of a distal pancreatectomy, which often includes a splenectomy. Due to the complexity of surgery and risk for significant morbidity and mortality, current guidelines recommend that pancreatic resections be carried out in centers that perform at least 15 to 20 cases annually. In addition, a recent review concluded that high-volume institutions are associated with higher negative-margin status and higher 5-yr survival rates, and that patients are more likely to receive multimodality therapy at these centers.

ADJUVANT THERAPY

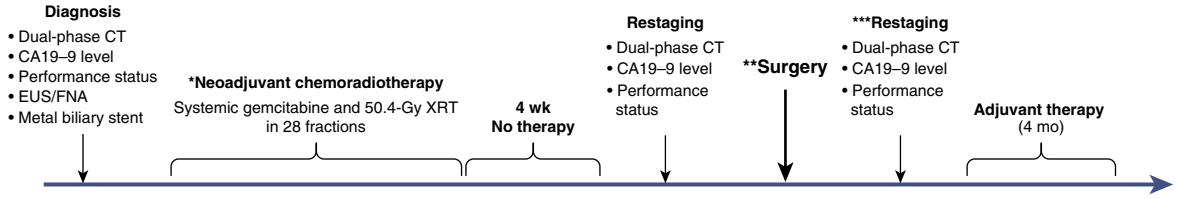
Adjuvant chemotherapy has been demonstrated to improve postoperative survival in multiple randomized trials and is considered the standard of care in patients with resected cancers.

- The use of single agent 5-fluorouracil (5-FU) or gemcitabine is associated with median survival in the 20 to 24-mo range and reserved for patients with older age or borderline status.
- The combination of gemcitabine and capecitabine is superior to gemcitabine alone in the adjuvant setting, with median overall survival in the 28-mo range.
- Most recently, the use of a triplet chemotherapy combination regimen (FOLFIRNOX; 5-FU, oxaliplatin, and irinotecan) in this setting strikingly improves outcomes with median overall survival reported at 54 mo.

The use of adjuvant radiotherapy in this setting is controversial and is best limited to patients with poor risk features, margin-positive surgery, or with multiple nodal or extranodal tumor involvement. An emerging strategy is the use of neoadjuvant preoperative chemotherapy combined with radiotherapy in patients with resectable pancreatic cancer. Palliative therapeutic ERCP with metal or plastic stents is performed for biliary decompression.

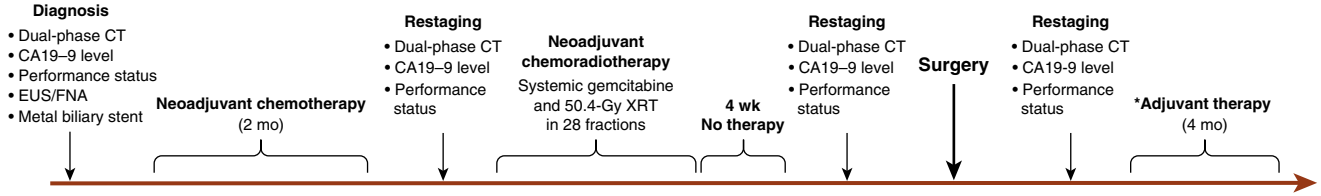
RECURRENT/METASTATIC DISEASE

In patients with metastatic disease, accepted upfront chemotherapy treatment approaches have demonstrated improvement in survival outcomes. Acceptable chemotherapy regimens for locally advanced and metastatic disease are summarized in Table 5.



*Systemic therapy alone (FOLFIRINOX, gem-nab) is being considered by many clinicians because of the efficacy of these regimens in advanced disease and the challenges of delivering FOLFIRINOX in the adjuvant setting after such a large operation.
**Surgery is typically performed in the fifth week after the completion of XRT.
***Patients are restaged during postop week six if their recovery has been uncomplicated; however, there is no need to restage if recovery is complicated and the patient is not a suitable candidate to receive further systemic therapy.

A



*The benefit of further postoperative/adjuvant systemic therapy after a more prolonged induction phase is being questioned, especially in those patients of advanced age or when postoperative recovery is slow.

B

FIG. 5 Schematic representation of treatment sequencing in **(A)** resectable and **(B)** borderline resectable pancreatic cancer (PC). *CA19-9*, Cancer antigen 19-9; *CT*, computed tomography; *EUS*, endoscopic ultrasound scan; *FNA*, fine-needle aspiration; *FOLFIRINOX*, 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin; *gem-nab*, gemcitabine/nab-paclitaxel; *XRT,* external radiotherapy. (From Cameron JL, Cameron AM: *Current surgical therapy*, ed 12, Philadelphia, 2017, Elsevier.)

TABLE 3 Comparison of Treatment Sequencing Strategies for Patients with Pancreatic Cancer (outside of a clinical trial)

Stage	NCCN	MCW
Resectable	• Surgery • Restaging • Adjuvant therapy (+/– chemoradiotherapy; 6 mo)	• Neoadjuvant chemoradiotherapy (5.5 wk)* • Restaging • Surgery • Restaging • Adjuvant therapy (4 mo)
Borderline resectable	• Neoadjuvant therapy (regimen not specified) • Restaging • Surgery • Restaging • Consider adjuvant therapy	• Neoadjuvant chemotherapy (2 mo) • Restaging • Neoadjuvant chemoradiotherapy (5.5 wk) • Restaging • Surgery • Restaging • Adjuvant therapy (4 mo)
Locally advanced	• Chemotherapy • Restaging • Chemoradiotherapy in selected patients	• Chemotherapy (minimum 4 mo) • Restaging • Chemoradiotherapy • Restaging • Surgery in highly selected patients
Metastatic	• Systemic therapy • Clinical trial	• Systemic therapy • Clinical trial

NOTE: Clinical trials are preferred in all patients with pancreatic cancer (regardless of stage of disease) who have a performance status acceptable for treatment.
FOLFIRINOX, 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin; *gem-nab*, gemcitabine/nab-paclitaxel; *MCW*, Medical College of Wisconsin; *NCCN*, National Comprehensive Cancer Network.
*Systemic therapy alone (FOLFIRINOX, gem-nab) is being considered by many clinicians because of the efficacy of these regimens in advanced disease and the challenges of delivering FOLFIRINOX in the adjuvant setting after such a large operation.
From Cameron JL, Cameron AM: *Current surgical therapy*, ed 12, Philadelphia, 2017, Elsevier.

- Treatment options can include the administration of gemcitabine alone, combination regimen consisting of 5-fluorouracil, leucovorin, irinotecan, and oxaliplatin (FOLFIRINOX), or the combination of nab-paclitaxel plus gemcitabine. Multiagent regimens have an improved survival outcome compared with single-agent therapy. Liposomal irinotecan in combination with infusional 5-fluorouracil is now also approved in the setting of progressive cases.
- The use of maintenance olaparib (after systemic chemotherapy) among patients with a germline *BRCA* mutation in metastatic pancreatic cancer has demonstrated improvement in progression-free survival compared with placebo.
- Poor survival outcomes are seen in patients with poor performance status, significant weight loss, and with liver metastases.
- Combined chemotherapy and radiotherapy can be utilized in the case of patients with locally advanced but unresectable cases and confers a modest improvement in median overall survival.

DISPOSITION

- Adjuvant postoperative chemotherapy has a significant survival benefit in patients with resected pancreatic cancer.
- Adjuvant chemotherapy with FOLFIRINOX regimen significantly delays the development of recurrent disease after complete resection of pancreatic cancer. Median survival in this setting is approximately 54 mo.
- Pancreatic cancer is usually diagnosed at an advanced stage and is resistant to therapy. Median survival for locally unresectable disease is about 14 to 16 mo, while the median survival for metastatic disease is 10 to 12 mo.

PEARLS & CONSIDERATIONS

COMMENTS

- Risk factors for pancreatic cancer and recommendations for screening of individuals at risk are summarized in Tables 6 and 7.
- The U.S. Preventive Services Task Force (USPSTF) recommends against routine screening for pancreatic cancer in

TABLE 4 Classification of Resectability of Pancreatic Cancer per the National Comprehensive Cancer Network and Surgical Oncology Expert Consensus Statement

Resectability Status	Criteria
Resectable	• No distant metastases • No radiographic evidence of SMV and portal vein abutment, distortion, tumor thrombus, or venous encasement • Clear fat planes around the celiac axis, hepatic artery, and SMA

Borderline resectable	• For tumors of the head or uncinate process:
	  • Solid tumor contact with the SMV or portal vein of >180 degrees with contour irregularity of the vein or thrombosis of the vein but with suitable vessel proximal and distal to the site of involvement, allowing for safe and complete resection and vein reconstruction
	  • Solid tumor contact with the IVC
	  • Solid tumor contact with the common hepatic artery without extension to the celiac axis or hepatic artery bifurcation, allowing for safe and complete resection and reconstruction
	  • Solid tumor contact with the SMA ≤180 degrees
	  • Solid tumor contact with variable anatomy (e.g., accessory right hepatic artery, replaced right hepatic artery, replaced common hepatic artery, and the origin of replaced or accessory artery), and the presence and degree of tumor contact should be noted if present, as it may affect surgical planning
	• For tumors of the body or tail:
	  • Solid tumor contact with the celiac axis of ≤180 degrees
	  • Solid tumor contact with the celiac axis >180 degrees without involvement of the aorta and with an intact and uninvolved gastroduodenal artery, thereby permitting a modified Appleby procedure (although some members of the consensus committee preferred this criterion to be in the unresectable category)

Unresectable/locally advanced	• Head of pancreas or uncinate lesions:
	  • Solid tumor contact with the SMA >180 degrees
	  • Solid tumor contact with the celiac axis >180 degrees
	  • Solid tumor contact with the first jejunal SMA branch
	  • Unreconstructable SMV or portal vein because of tumor involvement or occlusion (can be because of tumor or bland thrombus)
	  • Contact with the most proximal draining jejunal branch into the SMV
	• Body and tail lesions:
	  • Solid tumor contact of >180 degrees with the SMA or celiac axis
	  • Solid tumor contact with the celiac axis and aortic involvement
	  • Unreconstructable SMV or portal vein because of tumor involvement or occlusion (can be because of tumor or bland thrombus)
	• For all sites:
	  • Distant metastases
	  • Metastases to lymph nodes beyond the field of resection

Metastatic	• Any presence of distant metastases

From Niederhuber JE: *Abeloff's Clinical Oncology*, ed 6, Philadelphia, 2020, Elsevier.

asymptomatic adults by abdominal palpation, ultrasonography, or serologic markers. The USPSTF found no evidence that screening for pancreatic cancer is effective in reducing mortality rates. There is potential for significant harm because of the low prevalence of pancreatic cancer, limited accuracy of available screening tests, invasive nature of diagnostic tests, and poor outcome of treatment. Alcohol consumption, specifically liquor consumption of three or more drinks per day, increases pancreatic cancer mortality independent of smoking.

- Patients should be referred for pancreatic cancer surgery to high-volume medical centers that perform at least 15 to 20 cases a yr.
- Adjuvant chemotherapy with either a single-agent or doublet regimen for 6 mo has been shown to improve survival and should be recommended in all patients with a maintained performance status after surgical resection. The role of radiotherapy in the adjuvant setting is best restricted to patients who have a high risk for locoregional recurrence.

BASIC INFORMATION

DEFINITION

- Acute pancreatitis is an inflammatory process of the pancreas with intrapancreatic activation of enzymes that may also involve peripancreatic tissue and/or remote organ systems. The diagnosis of acute pancreatitis requires at least two of the following criteria: serum amylase or lipase ≥3 times normal, abdominal pain consistent with pancreatitis, and radiographic findings (CT or MRI) of acute pancreatitis.
- Commonly used scoring systems for acute pancreatitis are described in Table 1.
- The **Revised Atlanta Criteria**[1] use early prognostic signs, organ failure, and local complications to define disease severity:
  1. **Mild pancreatitis:** No organ failure, no local or systemic complications, pancreatitis typically resolves in first wk
  2. **Moderate pancreatitis:** Transient organ failure (≤48 hours) *or* local complications (e.g., pancreatic necrosis, peripancreatic fluid collections, peripancreatic necrosis) *or* exacerbation of comorbid disease
  3. **Severe pancreatitis:** Persistent organ failure (>48 hours)
- The **BALI Score**[2] evaluates only four variables:
  1. BUN ≥25 mg/dl
  2. Age ≥65 yr
  3. LDH ≥300 U/L
  4. Interleukin-6 level ≥300 pg/ml
- These measurements are taken at admission and at 48 hours. Mortality is >25% for a score of 3 and exceeds 50% with a score of 4.
- **Severe acute pancreatitis (SAP)** is diagnosed by the presence of any of the following four criteria:
  1. Organ failure with one or more of the following: Shock (systolic blood pressure <90 mm Hg), pulmonary insufficiency (Pa_{O_2} ≤60 mm Hg), renal failure (serum creatinine >2 mg/dl after rehydration), and gastrointestinal bleeding (>500 ml/24 hr)
  2. Local complications such as necrosis, pseudocyst, or abscess
  3. At least three of Ranson criteria (see tables) *or*
  4. At least eight of the Acute Physiology and Chronic Health Evaluation II (APACHE II) criteria

ICD-10CM CODES

K85.0	Idiopathic acute pancreatitis
K85.1	Biliary acute pancreatitis
K85.2	Alcohol induced acute pancreatitis
K 85.3	Drug induced pancreatitis
K85.6	Other acute pancreatitis
K85.9	Acute pancreatitis, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

- The incidence of pancreatitis is increasing in the U.S. Admissions for acute pancreatitis have increased dramatically, and acute pancreatitis was the number-one GI-related cause for admission across U.S. hospitals in 2012. There are >270,000 cases of acute pancreatitis reported annually in the U.S., with 40%+ due to gallstone disease (most common cause) and 30% due to alcohol.
- Incidence in urban areas is twice that of rural areas (20/100,000 persons in urban areas).
- 20% of patients have necrotizing pancreatitis; the remainder have interstitial, or edematous, pancreatitis.
- Drugs are responsible for less than 5% of all cases of acute pancreatitis.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Epigastric tenderness and guarding, often radiating to the back; pain usually developing suddenly, reaching peak intensity within 10 to 30 min, severe and lasting several hours without relief. Rarely, some patients can have painless severe pancreatitis
- Nausea and vomiting (up to 90% of cases)
- Hypoactive bowel sounds (from ileus)
- Tachycardia, shock (from decreased intravascular volume)
- Confusion (from metabolic disturbances)
- Fever (SIRS response or infection when pancreatic necrosis is present)
- Decreased breath sounds (pleural effusions) or rales (atelectasis, acute respiratory distress syndrome [ARDS])
- Jaundice (from obstruction or compression of biliary tract)
- Ascites (from tear in pancreatic duct, leaking pseudocyst)
- Palpable abdominal mass (pseudocyst, phlegmon, abscess, carcinoma)
- Evidence of hypocalcemia (Chvostek sign, Trousseau sign)
- Evidence of retroperitoneal bleeding (hemorrhagic pancreatitis):
  1. Ecchymosis around the umbilicus **(Cullen sign)**
  2. Ecchymosis involving the flanks **(Grey Turner sign)**
- Tender subcutaneous nodules (caused by subcutaneous fat necrosis)

TABLE 1 Commonly Used Scoring Systems: Advantages and Disadvantages

System	Scoring	Advantages	Disadvantages
Ranson criteria on admission: 1. Age >55 yr 2. WBC >16 × 10^9/L 3. LDH >350 U/L 4. AST >250 U/L 5. Glucose >200 mg/dl During initial 48 hr: 1. Hgb falls below 10 mg/dl 2. BUN rises by >5 mg/dl 3. Ca <8 mg/dl 4. Pa_{O_2} <60 mm Hg 5. Base deficit >4 mEq/L 6. Fluid sequestration >6 L	One point for each factor listed; score >3 indicates SAP	Well known, relatively easy to calculate	Requires 48 hr to complete evaluation
APACHE II*	Score >8 predicts SAP	Can be calculated within 24 hr of admission	Requires large dataset for processing
BISAP 1. BUN >25 mg/dl 2. Altered mental status 3. Presence of SIRS 4. Age >60 yr 5. Pleural effusions	One point for each factor listed; score >3 indicates SAP	Ease of use, available within 24 hr of admission	Significantly lower sensitivity than either Ranson or APACHE II; results in greater likelihood of missing severe AP
CTSI	Based on radiographic data	Excellent predictor of local complications; can show infected pancreatic necrosis	Requires 72 to 96 hr, making it a poor test for guiding decisions at admission

AP, Acute pancreatitis; *APACHE,* Acute Physiology and Chronic Health Evaluation; *AST,* aspartate aminotransferase; *BISAP,* Bedside Index for Severity in Acute Pancreatitis; *BUN,* blood urea nitrogen; *Ca,* serum calcium; *CTSI,* Computed Tomography Severity Index; *Hgb,* hemoglobin; *LDH,* lactate dehydrogenase; *SAP,* severe acute pancreatitis; *SIRS,* systemic inflammatory response syndrome; *WBC,* white blood cell count.

*Based on diverse variables, including age, physiology, and long-term health; equation available at www.sfar.org/scores2/apache22.html#calcul. Adding body mass index (BMI) to APACHE II (the APACHE 0 score) increases discrimination (1 point added for BMI 26-30; 2 points for BMI >30).

ETIOLOGY

- In >90% of cases: Biliary tract disease (calculi or sludge) or alcohol, most common after 5 to 10 yr of heavy drinking
- Hypertriglyceridemia (usually >1000 mg/dl) from any cause
- Drugs (e.g., thiazides, furosemide, corticosteroids, tetracycline, estrogens, valproic acid, metronidazole, azathioprine, methyldopa, pentamidine, ethacrynic acid, procainamide, amiodarone, sulindac, nitrofurantoin, angiotensin-converting enzyme inhibitors, danazol, cimetidine, piroxicam, gold, ranitidine, sulfasalazine, isoniazid, acetaminophen, cisplatin, didanosine, opiates, erythromycin, metformin, GLP-1 receptor agonists, incretin mimetics)
- Abdominal trauma
- Surgery
- Endoscopic retrograde cholangiopancreatography (ERCP), especially with manipulation of the pancreatic duct
- Infections (predominantly viral)
- Peptic ulcer (penetrating duodenal ulcer)
- Pancreas divisum (congenital failure to fuse of dorsal or ventral pancreas)
- Idiopathic
- Pregnancy
- Vascular (vasculitis, ischemic)
- Hypercalcemia
- Pancreatic carcinoma (primary or metastatic)
- Renal failure
- Hereditary pancreatitis, such as in patients with cystic fibrosis
- IgG4 disease
- Occupational exposure to chemicals: Methanol, cobalt, zinc, mercuric chloride, creosol, lead, organophosphates, chlorinated naphthalenes
- Others: Scorpion venom, obstruction at ampulla region (neoplasm, duodenal diverticula, Crohn disease, rarely celiac disease), hypotensive shock, autoimmune pancreatitis

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- PUD
- Acute cholangitis, biliary colic
- High intestinal obstruction
- Early acute appendicitis
- DKA
- Pneumonia (basilar)
- Myocardial infarction (inferior wall)
- Renal colic
- Ruptured or dissecting aortic aneurysm
- Mesenteric ischemia

LABORATORY TESTS

Pancreatic enzymes:

Amylase is increased, usually elevated in the initial 3 to 5 days of acute pancreatitis. Isoamylase determinations (separation of pancreatic cell isoenzyme components of amylase) are useful in excluding occasional cases of salivary hyperamylasemia. The use of isoamylase rather than total serum amylase reduces the risk of erroneously diagnosing pancreatitis and is preferred by some as initial biochemical test in patients suspected of having acute pancreatitis.

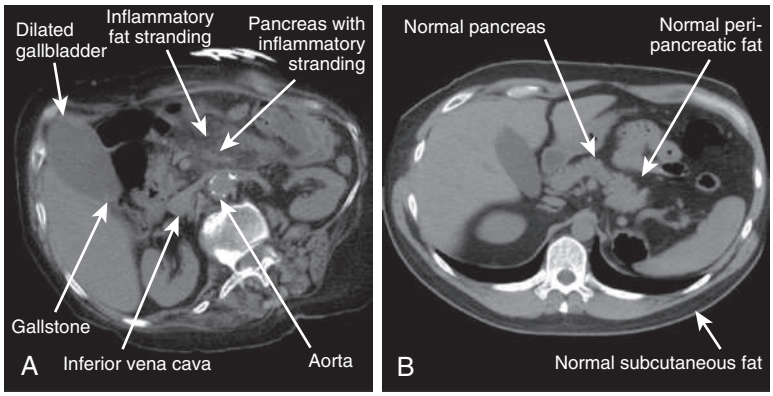

FIG. 1 Gallstone pancreatitis and normal pancreas for comparison, axial computed tomography without contrast. A, Gallstone pancreatitis CT. A dilated gallbladder is visible with a hyperdense dependent lesion consistent with a gallstone. The region of the pancreas shows significant inflammatory stranding. In this patient, the pancreas lies just anterior to the left renal vein, which can be seen crossing anterior to the aorta and entering the inferior vena cava. **B,** A normal pancreas is visible. This pancreas is surrounded by uninflamed fat, which is dark (nearly black). Compare this normal fat with normal subcutaneous fat. (From Broder JS: *Diagnostic imaging for the emergency physician,* Philadelphia, 2011, Saunders.)

Urinary amylase determinations are useful to diagnose acute pancreatitis in patients with lipemic serum, to rule out elevated serum amylase caused by macroamylasemia, and to diagnose acute pancreatitis in patients whose serum amylase is normal.

Serum lipase levels are elevated in acute pancreatitis; the elevation is less transient than serum amylase and more sensitive in patients with alcoholic pancreatitis. Concomitant evaluation of serum amylase and lipase increases diagnostic accuracy of acute pancreatitis. Elevated serum trypsin levels are diagnostic of pancreatitis (in absence of renal failure).

Serum C-reactive protein is an excellent laboratory marker of severity; a level >150 mg/dl at 48 hours is associated with severe pancreatitis.

Rapid measurement of urinary trypsinogen-2 (if available) is useful in the emergency department as a screening test for acute pancreatitis in patients with abdominal pain; a negative dipstick test for urinary trypsinogen-2 rules out acute pancreatitis with a high degree of probability, whereas a positive test indicates need for further evaluation.

Interleukin-6 level: Worse prognosis with level ≥300 pg/ml.

ADDITIONAL TESTS

- Complete blood count: Reveals leukocytosis; hematocrit (Hct) may be initially increased as a result of hemoconcentration; decreased Hct may indicate hemorrhage or hemolysis.
- Blood urea nitrogen (BUN) is increased because of dehydration. Serial BUN measurements are the most valuable lab test for predicting mortality during the initial 48 hr.
- Elevation of serum glucose in a previously normal patient correlates with the degree of pancreatic malfunction and may be related to increased release of glycogen, catecholamines, and glucocorticoid release and decreased insulin release.
- Liver profile: Aspartate aminotransferase (AST) and lactate dehydrogenase (LDH) are increased as a result of tissue necrosis; bilirubin and alkaline phosphatase may be increased from common bile duct obstruction. A threefold or greater rise in serum alanine aminotransferase concentrations is an excellent indicator (95% probability) of biliary pancreatitis.
- Serum calcium is decreased as a result of saponification, precipitation, and decreased parathyroid hormone response.
- Arterial blood gases: Pa_{O_2} may be decreased as a result of ARDS, pleural effusion(s); pH may be decreased as a result of lactic acidosis, respiratory acidosis, and renal insufficiency.
- Serum electrolytes: Potassium may be increased from acidosis or renal insufficiency; sodium may be increased from dehydration.

IMAGING STUDIES

- Abdominal plain films are useful initially to distinguish other conditions that may mimic pancreatitis (perforated viscus). They may reveal localized ileus (sentinel loop), pancreatic calcifications (chronic pancreatitis), blurring of left psoas shadow, dilation of transverse colon, calcified gallstones.
- Chest x-ray may reveal elevation of one or both diaphragms, pleural effusions, basilar infiltrates, or platelike atelectasis.
- Abdominal ultrasonography is useful in detecting gallstones (sensitivity of 60% to 70% for detecting stones associated with pancreatitis). Its availability and noninvasive nature make it the initial imaging study of choice; its major limitation is the presence of distended bowel loops overlying the pancreas.
- CT scan (Fig. 1) is less sensitive than ultrasound in identifying gallstones and exposes the patient to risk of contrast-induced nephropathy. It is, however, superior to ultrasonography in identifying pancreatitis and defining its extent, and it also plays a role in diagnosing pseudocysts (they appear as

TABLE 2 Computed Tomography (CT) Severity Index Score for Pancreatitis*

Grade†	CT Findings	Score
A	Normal pancreas	0
B	Focal or diffuse enlargement of the pancreas, contour irregularities, heterogeneous attenuation, no peripancreatic inflammation	1
C	Grade B plus peripancreatic inflammation	2
D	Grade C plus a single fluid collection	3
E	Grade C plus multiple fluid collections or gas	4
Percent Necrosis Present on CT		
0		
<33		
33-50		
>50		

*Severity Index Score = Grade score + Percent necrosis score. Maximum score = 10; severe disease = 6 or higher.
†Severity of the acute inflammatory process.
From Adams JG et al: *Emergency medicine, clinical essentials,* ed 2, Philadelphia, 2013, Elsevier.

a well-defined area surrounded by a high-density capsule); gastrointestinal fistulization or infection of a pseudocyst can also be identified by the presence of gas within the pseudocyst. Sequential contrast-enhanced CT is useful for detection of pancreatic necrosis. The severity of pancreatitis can also be graded by CT scan (Table 2). (A = normal pancreas, B = enlarged pancreas [1 point], C = pancreatic and/or peripancreatic inflammation [2 points], D = single peripancreatic collection [3 points], E = at least two peripancreatic collections and/or retroperitoneal air [4 points]. Percentage of pancreatic necrosis <30% [2 points], 30% to 50% [4 points], >50% [6 points]. The CT severity index is calculated by adding grade points to points assigned for percentage of necrosis.)

- Magnetic resonance cholangiopancreatography (MRCP) has >90% sensitivity for choledocholithiasis and can identify other anatomic abnormalities.
- Endoscopic ultrasonography (EUS) is a minimally invasive test that provides high-resolution imaging of the pancreas. It is useful to identify anatomic abnormalities of the pancreas and has good sensitivity and specificity for small gallstones (≤5 mm).
- ERCP indications: Useful to perform biliary sphincterotomy and stone removal in the presence of a retained bile duct stone seen on imaging. The role and timing of ERCP in patients with acute biliary pancreatitis has been controversial. Guidelines from the American College of Gastroenterology suggest that urgent ERCP (within 24 hr of admission) is indicated in patients with biliary pancreatitis who have concurrent acute cholangitis, but it is not needed in most patients who do not have evidence of ongoing biliary obstruction.[3,4,5]

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Bowel rest with avoidance of liquids or solids during the acute illness. Limited data suggest that early feeding in patients with acute pancreatitis does not seem to increase adverse events and, for patients with mild to moderate pancreatitis, may reduce length of hospital stay.[6]
- Avoidance of alcohol and any drugs associated with pancreatitis.

ACUTE GENERAL Rx

GENERAL MEASURES:

- Assess severity of pancreatitis (see Table 1).
- An algorithm for the management of acute pancreatitis is described in Fig. 2.
- Maintain adequate intravascular volume with vigorous IV hydration. Aggressive fluid resuscitation (250 to 500 ml/hr) with isotonic crystalloids is critical in managing acute pancreatitis, unless cardiac or renal disease precludes it.
- Patient should remain NPO until clinically improved, stable, and hungry. Enteral feedings are preferred over total parenteral nutrition if supplemental nutrition is necessary. Enteral nutrition reduces mortality, multiple organ failure, systemic infections, and operative interventions more than total parenteral nutrition does in patients with acute pancreatitis. Parenteral nutrition may be necessary in patients who do not tolerate enteral feeding or in whom an adequate infusion rate cannot be reached within 2 to 4 days. Early (within 24 to 48 hr of admission) enteral feeding through a nasogastric (NG) feeding tube has limited evidence to support this strategy. A recent trial did not show superiority of early NG tube feeding, as compared with oral diet after 72 hours, in reducing the rate of infection or death in patients with acute pancreatitis at high risk for complications.
- Nasogastric suction is useful only in severe pancreatitis to decompress the abdomen in patients with ileus.
- Control pain: IV hydromorphone or fentanyl. Meperidine and morphine are also commonly used narcotics for pain control, although morphine has been shown to increase sphincter of Oddi pressure and has delayed metabolite clearance in patients with concomitant renal failure.
- Correct metabolic abnormalities (e.g., replace calcium and magnesium as necessary).
- Prophylactic antibiotics are not recommended, regardless of the severity or presence of pancreatic necrosis.
- An algorithm for the management of acute pancreatitis at various stages is described in Fig. 2.

SPECIFIC MEASURES:

- Pancreatic or peripancreatic infection develops in 30% of patients with pancreatic necrosis. The use of antibiotics is justified if the patient has evidence of septicemia, pancreatic abscess, or pancreatitis caused by biliary calculi with concomitant cholangitis. Their use should generally be limited to 5 to 7 days to prevent development of fungal superinfection. Appropriate empiric antibiotic therapy should penetrate pancreatic necrosis. Options include a carbapenem alone (due to anaerobic coverage) or a quinolone, ceftazidime, or cefepime, combined with an enteric anaerobic agent such as metronidazole. CT-guided fine-needle aspiration (FNA) can be performed to culture the infected necrosis and tailor antibiotic therapy. If sampling of infected necrosis occurs and is sterile, antibiotics should be discontinued
- Surgical therapy has a limited role in acute pancreatitis; it is indicated in the following:
  1. Gallstone-induced pancreatitis: Cholecystectomy when acute pancreatitis subsides. However, randomized trials have shown that patients with mild gallstone pancreatitis can undergo cholecystectomy safely during the first 48 hr of hospitalization
  2. Perforated peptic ulcer
  3. Necrotizing pancreatitis with infected necrotic tissue is associated with an elevated rate of complications and increased risk of death. Traditional treatment has been open necrosectomy; surgical necrosectomy induces a proinflammatory response and is associated with a high complication rate. Recent trials have shown that a step-up approach consisting of percutaneous drainage followed, if necessary, by minimally invasive retroperitoneal necrosectomy may have a lower rate of complications and death. Endoscopic transgastric necrosectomy, a form of natural orifice transluminal endoscopic surgery, has been shown in recent trials to be effective in reducing the proinflammatory response as well as reducing complications
- Identification and treatment of complications:
  1. **Pseudocyst:** Round or spheroid collection of fluid, tissue, pancreatic enzymes, and blood

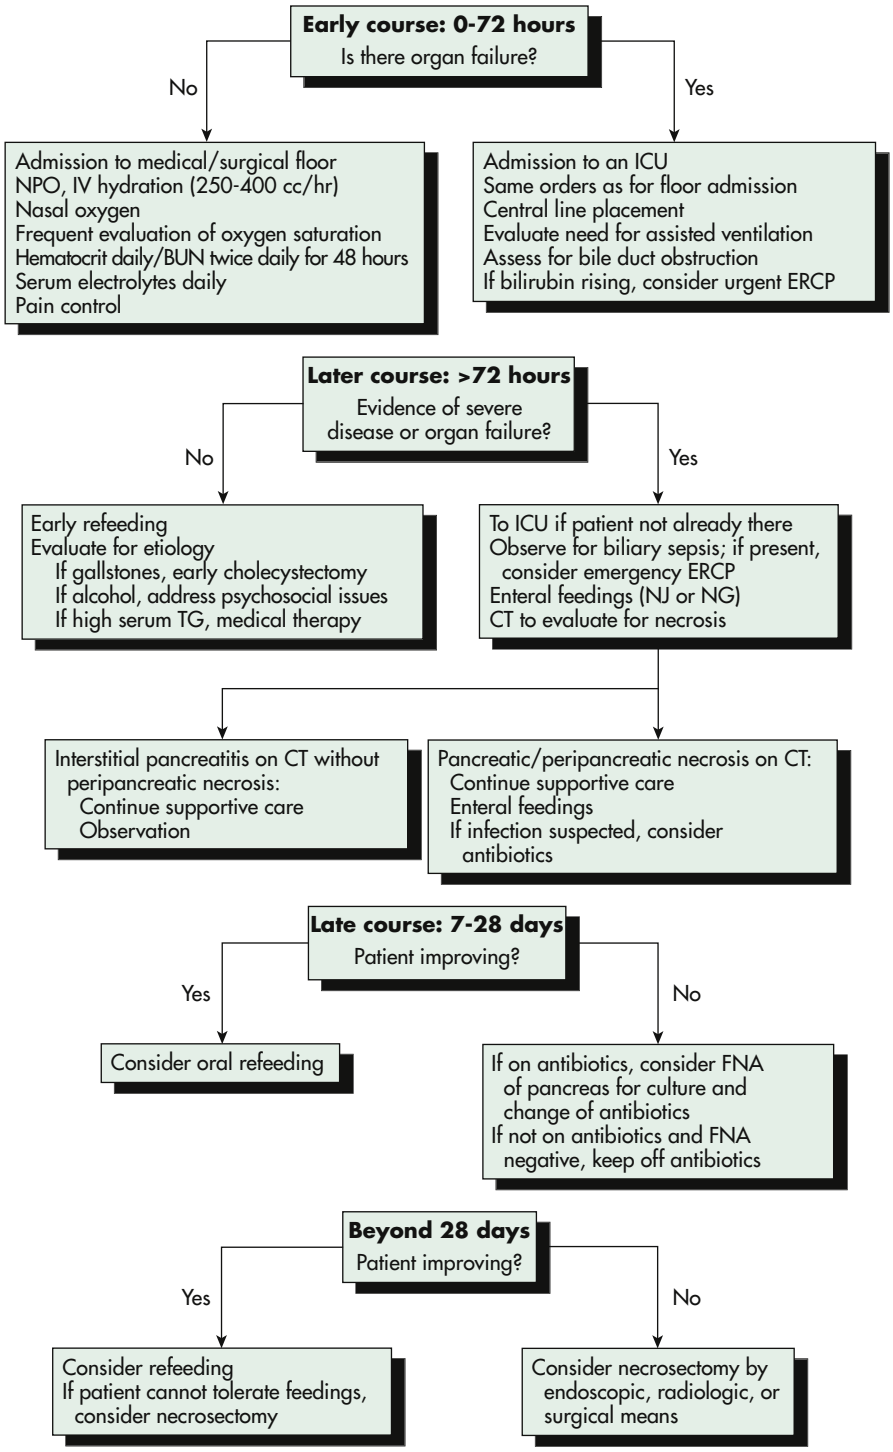

FIG. 2 Algorithm for the management of acute pancreatitis at various stages in its course. *NJ*, Nasojejunal. (From Feldman M, Friedman LS, Brandt LJ: *Sleisenger and Fordtran's gastrointestinal and liver disease*, ed 10, Philadelphia, 2016, Elsevier.)

a. Diagnosed by CT scan or sonography.
b. Treatment: Pancreatic pseudocysts can be drained surgically or endoscopically. The endoscopic approach is preferable when the patient's anatomy is suitable and an experienced endoscopist is available. CT scan or ultrasound-guided percutaneous drainage (with a pigtail catheter left in place for continuous drainage) can be used, but the recurrence rate is high; the conservative approach is to reevaluate the pseudocyst (with CT scan or sonography) after 6 to 7 wk and surgically drain it if the pseudocyst has not decreased in size.
c. Generally, pseudocysts <5 cm in diameter are reabsorbed without intervention, whereas those >5 cm require surgical intervention after the wall has matured.

2. **Phlegmon:** Represents pancreatic edema. It can be diagnosed by CT scan or sonography. Treatment is supportive as it usually resolves spontaneously
3. **Pancreatic abscess:** Diagnosed by CT scan (presence of air in the retroperitoneum); Gram staining and cultures of fluid obtained from guided percutaneous aspiration usually identify bacterial organism. Therapy is surgical (or catheter) drainage and IV antibiotics (carbapenem is the drug of choice)
4. **Pancreatic ascites:** Usually caused by leaking of pseudocyst or tear in pancreatic duct. Paracentesis reveals very high amylase and lipase levels in the pancreatic fluid; ERCP may demonstrate the lesion. Treatment is surgical correction if exudative ascites from severe pancreatitis does not resolve spontaneously
5. **Abdominal compartment syndrome:** Caused by intraabdominal leakage of fluids from volume resuscitation or ascites. Diagnosed with sustained intraabdominal pressure >20 mm Hg with new-onset organ failure
6. **Gastrointestinal bleeding:** Caused by alcoholic gastritis, bleeding varices, stress ulceration, or disseminated intravascular coagulation (DIC)
7. **Renal failure:** Caused by hypovolemia, resulting in oliguria or anuria, cortical or tubular necrosis (shock, DIC), or thrombosis of renal artery or vein
8. **Hypoxia:** Caused by ARDS, pleural effusion, or atelectasis
9. **Vascular:** Splenic, portal, or superior mesenteric vein thrombosis; pseudoaneurysm

THERAPY OF UNCOMMON FORMS OF PANCREATITIS

- **Autoimmune pancreatitis (AIP):** Fibroinflammatory disease characterized by an IgG4 lymphoplasmacytic infiltrate. It is a variant of chronic pancreatitis and has been associated with other autoimmune disorders (e.g., primary sclerosing cholangitis, Sjögren syndrome). The inflammatory process is generally responsive to corticosteroid therapy. Older men aged 60 to 70 yr are primarily affected. Patients present with abdominal pain, weight loss, anorexia, and obstructive jaundice. Immunoglobulin G_4 levels are elevated. Radiographically on CT, the pancreas is diffusely enlarged, with a characteristic smooth, capsulelike rim ("sausage pancreas"). Features of type 1 and type 2 autoimmune pancreatitis are summarized in Table 3. Type II autoimmune hepatitis (idiopathic duct-centric chronic pancreatitis) is associated with inflammatory bowel disease and not related to IgG4 cell deposition.
- **Hypertriglyceridemic pancreatitis (HTGP):** IV insulin therapy is the cornerstone of immediate treatment, with supplemental IV

TABLE 3 Features of Type 1 and Type 2 Autoimmune Pancreatitis

Feature	Type 1	Type 2
Histology	Lymphoplasmacytic infiltration Dense periductal infiltrate without damage to ductal epithelium Storiform fibrosis Obliterative phlebitis Abundant (>10 cells/HPF) IgG4-positive cells Fibroinflammatory process may extend to peripancreatic region	Periductal lymphoplasmacytic and neutrophilic infiltration Destruction of the duct epithelium by neutrophils (granulocytic epithelial lesion, or GEL) Obliterative phlebitis is rare No IgG4-positive cells
Average age at presentation	60-70 yr	40-50, but may present in young adults and even children
Gender predominance	Male	Equal
Usual clinical presentations	Obstructive jaundice (75%) Acute pancreatitis (15%)	Obstructive jaundice (50%) Acute pancreatitis (33%)
Pancreatic imaging	Diffuse pancreatic enlargement (40%) Focal pancreatic enlargement (60%)	Diffuse pancreatic enlargement (15%) Focal pancreatic enlargement (85%)
IgG4	Level elevated in serum (~2/3 of patients) Positive in staining of involved tissues	Not associated
Other organ involvement	Biliary strictures Pseudotumors Kidney Lung Others Retroperitoneal fibrosis Sialoadenitis	Not associated
Associated diseases	See above (other organ involvement)	IBD
Long-term outcome	Frequent relapses	Rare or no relapse

TABLE 4 Prognostic Criteria for Acute Pancreatitis

Ranson Criteria*	Simplified Glasgow Criteria†	Computed Tomography Criteria‡
On admission: Age >55 yr WBC >16,000/μL AST >250 U/L LDH >350 U/L Glucose >200 mg/dl *48 hr after admission:* Hematocrit decrease by >10 BUN increase by >5 mg/dl Ca^{2+} <8 mg/dl Arterial Po_2 <60 mm Hg Base deficit >4 mEq/L Fluid sequestration >6 L	*Within 48 hr of admission:* Age >55 yr WBC >15,000/μL LDH >600 U/L Glucose >180 mg/dl Albumin <3.2 g/dl Ca^{2+} <8 mg/dl Arterial Po_2 <60 mm Hg BUN >45 mg/dl	Normal Enlargement Pancreatic inflammation Single fluid collection Multiple fluid collection

AST, Aspartate aminotransferase; *BUN,* blood urea nitrogen; *LDH,* lactate dehydrogenase; *WBC,* white blood cells.
*Three or more Ranson criteria predict a complicated clinical course. Data from Ranson JH et al: Prognostic signs and nonoperative peritoneal lavage in acute pancreatitis, *Surg Gynecol Obstet,* 143:209-219, 1976.
†Data from Blamey SL et al: Prognostic factors in acute pancreatitis, *Gut* 25:1340, 1984.
‡Grades A and B represent mild disease with no risk of infection or death. Grade C represents moderately severe disease with a minimal likelihood of infection and essentially no risk of mortality. Grades D and E represent severe pancreatitis with an infection rate of 30% to 50% and mortality rate of 15%. Data from Balthazar EJ et al: Acute pancreatitis value of CT in establishing prognosis, *Radiology,* 174:331, 1990.
From Goldman L, Ausiello D (eds): *Cecil textbook of medicine,* ed 24, Philadelphia, 2012, Saunders.

glucose infusion if the serum glucose levels are not elevated. IV heparin was previously used as well, but its effectiveness has come into question. Antihyperlipidemic agents (fibrates) should be initiated as adjuvant therapy as soon as possible for long-term control. Beneficial results have been reported with early (within 48 hr) initiation of apheresis with therapeutic plasma exchange when there is concomitant hypocalcemia, lactic acidosis, or other signs of organ dysfunction.

DISPOSITION

Prognosis varies with the severity of pancreatitis; overall mortality rate in acute pancreatitis is 5% to 10%. Prognostic criteria for acute pancreatitis are described in Table 4.

REFERRAL

- Hospitalization is indicated in moderate to severe cases of pancreatitis.
- Surgical consultation is needed in suspected gallstone pancreatitis, perforated peptic ulcer, or presence of necrotic or infected foci. Acute pancreatitis can generally be attributed to gallstones when patients have both abnormal liver enzymes and gallstones (or sludge) on imaging. Such patients should consider cholecystectomy prior to discharge to prevent recurrent pancreatitis.
- Gastroenterology consultation in severe or recurrent pancreatitis, when ERCP is needed for gallstone pancreatitis, or when the cause of pancreatitis is unclear.
- Consider intensive care unit transfer for patients who require aggressive fluid resuscitation and are at risk of volume overload from cardiac or renal causes. Similarly, consider transfer for patients with developing ARDS, patients with abdominal compartment syndrome (with surgical consultation), and those who require apheresis.

PEARLS & CONSIDERATIONS

- Acute pancreatitis is the most common major complication of ERCP. NSAIDs are potent inhibitors of phospholipase A_2, cyclooxygenase, and neutrophil-endothelial interactions, which play an important role in the pathogenesis of acute pancreatitis. Preliminary trials show that among patients at high risk for post-ERCP pancreatitis, rectal indomethacin (given as two 50-mg indomethacin suppositories administered immediately after ERCP) significantly reduced the incidence of post-ERCP pancreatitis.
- Pancreatic stent placement decreases the risk of post-ERCP pancreatitis.
- Statins reduce risk for pancreatitis in adults. Fibrates do not affect risk for pancreatitis other than in patients with hypertriglyceridemia-induced pancreatitis.
- Diabetes mellitus may develop from extensive pancreatic necrosis.

BASIC INFORMATION

DEFINITION

- A **panic attack** is a relatively brief, sudden episode of intense fear or apprehension, often associated with a sense of impending doom and various uncomfortable and disquieting physical symptoms. Panic attacks may be uncued ("out of the blue") or cued (i.e., triggered by a particular object or situation). Panic attacks may be present in a variety of different anxiety-related disorders (e.g., phobias, social anxiety, obsessive-compulsive disorder). Table 1 describes criteria for diagnosis of panic attack.
- **Panic disorder** is diagnosed after at least two uncued panic attacks have occurred followed by at least 1 mo (or more) of significant concern about future attacks, worry about their implications, or a major change in behavior related to these attacks. The criteria for diagnosis of panic disorder are summarized in Table 2. **Agoraphobia** is anxiety about, and avoidance of, places or situations in which the ability to escape is perceived to be limited or embarrassing or in which help might not be available in the event of having a panic attack.

SYNONYMS

Anxiety attacks
Fear attacks
Ataque de nervios

ICD-10CM CODES
F41.0 Panic disorder
F40.0 Agoraphobia
DSM-5 CODES
300.01 Panic disorder
300.22 Agoraphobia

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 1% 1-mo incidence of panic attacks.

TABLE 1 Criteria for Diagnosis of a Panic Attack

A discrete period of intense fear or discomfort, in which ≥4 of the following symptoms developed abruptly and reached a peak within 10 min:
- Palpitations, pounding heart, or accelerated heart rate
- Sweating
- Trembling or shaking
- Sensations of shortness of breath or being smothered
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy, unsteady, light-headed, or faint
- Derealization (feelings of unreality) or depersonalization (being detached from oneself)
- Fear of losing control or going crazy
- Paresthesias (numbness or tingling sensations)
- Chills or hot flashes

From Kliegman RM et al: *Nelson essentials of pediatrics,* ed 5, Philadelphia, 2006, Saunders.

PREVALENCE (IN U.S.):
- 15% to 20% lifetime prevalence of one or more panic attacks.
- Panic disorder is much more uncommon, with a lifetime prevalence of 1.5% to 3.5%; chronicity of condition reflected by a similar 1-yr prevalence rate of 1% to 2%.
- Agoraphobia is relatively rare; 0.3% to 1% lifetime prevalence; 30% to 50% of patients diagnosed with panic disorder also have agoraphobia.
- Lower rates of panic disorder are reported among Latinos, African Americans, Caribbean blacks, and Asian Americans (DSM-5).
- Lower estimates for Asian, African, and Latin American countries (0.1% to 0.8%) (DSM-5).

PEAK INCIDENCE:
- Chronic condition with a waxing and waning course.
- Bimodal incidence peaks noted, with the first peak between ages 15 and 24 yr and second peak between ages 35 and 44 yr.

PREDOMINANT SEX:
- Women more commonly affected (>85% of clinical population).
- Panic disorder twice as common in women.
- Panic disorder with agoraphobia three times as common in women.

PREDOMINANT AGE:
- Age of onset is typically late adolescence to mid-30s. Onset earlier in males (24 yr) than females (28 yr).
- Onset after age 45 yr is rare and should raise suspicion of different etiology.

GENETICS:
- Risk of developing panic disorder in first-degree relatives of individuals with panic disorder is four to seven times that of general population.
- Findings in twin studies: Approximately 60% of contributing factors to panic are genetic.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Panic disorder:
- Present either with a panic attack or with fear and anxiety related to anticipation of a future panic attack or its implications.
- Typical presentation: Unexpected, untriggered periods of intense anxiety and fear with associated physiologic changes (e.g., palpitations, sweating, tremulousness, shortness of breath, chest pain, gastrointestinal distress, faintness, derealization, paresthesia). This is accompanied by associated fears of dying, heart attack, stroke, passing out, losing control, or losing one's mind. Panic attacks are often described as "the most terrifying" episode an individual has experienced.

TABLE 2 Criteria for Diagnosis of Panic Disorder

1. Recurrent unexpected panic attacks with associated worry or behavior change
2. Not due to effects of a drug, medication, or medical condition

- Emergency or physician visits often occasioned by physical symptoms such as chest pain, dizziness, or difficulty breathing. Thirty percent of patients presenting with chest pain have panic disorder.
- In a recent study of 1327 patients reporting noncardiac chest pain, 77.1% had visited the emergency department.
- Patients reporting a fear of dying from a panic attack tend to have more symptomatic panic attacks and agoraphobia.

Agoraphobia:
- Rare complaints to physician. May manifest in missed office visits or tardiness. Patients may request home visits or telephone care.
- Activities usually self-limited by avoiding public situations where the patient believes he or she might experience a panic attack and would be unable to exit readily, such as the following:
  1. Crowded public areas (stores, public transportation, flying, church)
  2. Individual interactions (hairdresser, dentist, neighborhood meetings)
  3. Driving (especially if alone, far from home, over bridges, through tunnels, on highways, or on isolated roads)
- On exposure to or anticipation of exposure to feared situations, significant anxiety occurs. Anxiety may generate somatic symptoms that trigger a full-blown panic attack. Patients believe that escape from these situations reduces the alarming symptoms, thus reinforcing future avoidance. In actuality, symptom relief stems from adrenaline breaking down in the body after approximately 20 minutes.

ETIOLOGY

Hypotheses (NOTE: There are sufficient data to support each model. Models are not mutually exclusive.):
- Central dyscontrol of autonomic arousal (typically localized to the locus ceruleus); similar symptoms may be chemically induced with yohimbine, caffeine, or cholecystokinin.
- Cognitive overreaction (i.e., "catastrophic misinterpretation") to relatively mild or benign physiologic cues that then triggers a genuine autonomic cascade and further misinterpretations.
- Dysfunction of a central suffocation alarm mechanism; some signs of compensated respiratory alkalosis. Can be experimentally induced with sodium lactate or carbon dioxide.

RISK FACTORS

- Temperamental: Negative affect and anxiety sensitivity are risk factors for the onset of panic attacks. Severe separation anxiety in childhood may precede the panic disorder.
- Environmental: Sexual and physical abuse in childhood is common in panic disorder. Most panic sufferers are able to identify a coalescence of stressors preceding their first panic attack.
- Genetic and physiological: Although the exact genes are unknown, it is believed that multiple genes contribute to the vulnerability to panic attacks.

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Medical conditions:

- Endocrinopathies:
  1. Hyperthyroidism
  2. Hyperparathyroidism
  3. Pheochromocytoma
  4. Carcinoid tumor
- Cardiac and respiratory diseases:
  1. Arrhythmias
  2. Myocardial infarction
  3. Chronic obstructive pulmonary disease
  4. Asthma
  5. Mitral valve prolapse
- Metabolic:
  1. Hypoglycemia
  2. Electrolyte imbalances
  3. Porphyria
- Seizure disorders: Complex partial seizures can present with ictal panic attacks.
- Psychiatric disorders (NOTE: Panic attacks are common in a variety of psychiatric disorders. Panic disorder could be conceptualized as a phobia of the somatic sensations or situations that have become paired with panic attacks.)
  1. Phobias (e.g., specific phobia or social phobia). Note that fear of going on a plane because of crashing would be a specific phobia, whereas fear of going on a plane because one is then trapped and worries about panic is more suggestive of panic disorder with agoraphobia
  2. Obsessive-compulsive disorder (cued by exposure to the object of the obsession)
  3. Posttraumatic stress disorder (cued by recall of a stressor)
  4. Generalized anxiety disorder (cued by excessive worry)
- Therapeutic (theophylline, steroids) and recreational (cocaine, amphetamine, caffeine, diet pills) drugs and drug withdrawal (alcohol, cannabis, barbiturates, benzodiazepines)

WORKUP

- Emergency presentation: Cardiac, respiratory, or neurologic symptoms
- History and physical examination to rule out a concomitant medical or substance-related condition

NOTE: Panic disorder and agoraphobia are not diagnoses of exclusion, but exclusion of other conditions is usually required.

LABORATORY TESTS

- Thyroid profile
- Electrolyte measures, including calcium
- Toxicology screen
- ECG
- Acute cases: Possible monitoring and cardiac enzymes to rule out arrhythmia or ischemia

IMAGING STUDIES

- For temporal lobe dysfunction (e.g., temporal lesions or as ictal or interictal manifestation of temporal lobe complex partial seizures): Brain CT scan or MRI or an electroencephalogram in some patients
- Holter monitor to rule out occult or episodic arrhythmias
- Chest x-ray, arterial blood gases, or pulmonary function tests if respiratory compromise suspected

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Cognitive-behavioral therapy (CBT), in particular Panic Controlled Treatment, is generally very effective, with strongest results for cognitive restructuring (i.e., challenging catastrophic misinterpretations of somatic symptoms), in vivo or imaginal exposures (i.e., exposure to panic triggers in a controlled graded hierarchical fashion from least to most difficult with the goal of habituation and extinction of the fear response), and interoceptive exposures (i.e., repeated recreation and management of feared somatic sensations via activities such as chair spinning, straw breathing, and hyperventilation).
- CBT effect sizes are equal to or larger than for pharmacotherapy, attrition rates are lower, and relapse rates are lower. Treatment may take several sessions spread over weeks and may require referral to a behavioral specialist. CBT has been shown to be the most effective intervention for panic disorder with or without agoraphobia across treatment sites.
- A recent dismantling study of cognitive-behavioral therapy components for panic disorder suggests that interoceptive exposure and a face-to-face setting were associated with better treatment efficacy whereas muscle relaxation and virtual reality exposure were associated with significantly lower efficacy.

ACUTE GENERAL Rx

- Benzodiazepines, particularly clonazepam and alprazolam: Highly effective in the acute setting, although long-term use is contraindicated for effective outcome and due to addictive potential.
- Low-dose clonazepam for patients with rare panic attacks and asymptomatic periods (0.25-0.5 mg PO or sublingually prn).
- Start patient on selective serotonin reuptake inhibitor (SSRI) or similar agent and taper patient off benzodiazepine by wk 2 to 3.

CHRONIC Rx

- Preferred pharmacologic agents: Antidepressants with a significant serotonin reuptake inhibitory action. Generally, start at low dose and titrate upward. Minimum treatment duration is 6 to 8 mo, but many patients need to take medications indefinitely. These medications should not be discontinued abruptly; they should be tapered due to withdrawal effects including rebound anxiety.
  1. SSRIs: Sertraline (50-200 mg/day), citalopram (20-60 mg/day), escitalopram (5-30 mg/day), and fluoxetine (5-60 mg/day)
  2. Imipramine (100-300 mg/day)
  3. SNRIs: Venlafaxine (75-225 mg/day)
- Combination CBT plus SSRI has shown good long-term effects and is somewhat better than antidepressants or CBT alone. Combination CBT plus benzodiazepine does not provide any added benefit and may undermine CBT (interoceptive and in vivo exposures may be less effective if the benzodiazepine is completely controlling the anxiety).

DISPOSITION

- Typical course is chronic but with significant waxing and waning (common to have long periods of remission).
- Presence of agoraphobia associated with a more chronic course.
- Findings with long-term follow-up studies: 6 to 10 yr after treatment some 30% are in remission, 40% to 50% have improved with residual symptoms, and the remainder are either unchanged or worse.

REFERRAL

- If patients do not respond to an SSRI.
- Cognitive-behavioral therapy is the preferred treatment.

PEARLS & CONSIDERATIONS

- Patient and family education is an important first step in the management of panic disorder. Education provides more adaptive explanations for the benign somatic sensations paired with panic. Presentation of genetic information and explanation of the benign nature of the physiology of each of the symptoms the patient experiences serve as a good start to allay fears and reduce stigma.
- Resumption of avoided activities or situations is a positive prognostic sign and may promote further therapeutic gains.
- The therapist's adherence to the treatment protocol and the therapeutic alliance established during the first session predict a better outcome for the long-term success of CBT for panic disorder with or without agoraphobia.

BASIC INFORMATION

DEFINITION

Panniculitis refers to inflammation of subcutaneous fat. Most cases are found in association with a systemic disease. Panniculitis can be separated into groups based on histopathologic characteristics. Panniculitis is classified into lobular or septal panniculitis based on whether the inflammation is seen in the fat lobules or septae, respectively. It can be further classified based on whether the inflammation is found with or without vasculitis (Table 1) and by predominant cell type. A classification of the panniculitides is summarized in Box 1.

ICD-10CM CODES

M79.3	Unspecified panniculitis
M5400	Panniculitis affecting regions of neck and back, site unspecified
M5401	Panniculitis affecting regions of neck and back, occipito-atlanto-axial region
M5402	Panniculitis affecting regions of neck and back, cervical region
M54.03	Panniculitis affecting regions of neck and back, cervicothoracic region
M54.04	Panniculitis affecting regions of neck and back, thoracic region
M54.05	Panniculitis affecting regions of neck and back, thoracolumbar region
M54.06	Panniculitis affecting regions of neck and back, lumbar region
M54.07	Panniculitis affecting regions of neck and back, lumbosacral region
M54.08	Panniculitis affecting regions of neck and back, sacral and sacrococcygeal region
M54.09	Panniculitis affecting regions, neck and back, multiple sites in spine

EPIDEMIOLOGY & DEMOGRAPHICS

The epidemiology of the various panniculitides varies with each disease process. The most common panniculitis is erythema nodosum (refer to topic "Erythema Nodosum"). Another common panniculitis seen in the clinical setting is lipodermatosclerosis (LDS), which is usually seen in young, overweight females with associated venous insufficiency.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Skin lesions can appear as nonspecific areas of erythema or erythematous nodules and/or plaques. The nodules can be palpated beneath the dermis. Ulceration, atrophy, and sclerosis can be associated clinical features of these lesions.
- The lesions are frequently painful and tender to palpation.
- Associated constitutional symptoms such as low-grade fevers, malaise, fatigue, myalgias, and arthralgias may be present.
- These skin findings usually are found on the lower limbs; however, the location of these lesions can vary with each specific panniculitis, that is, erythema nodosum is found on the pretibial areas of the lower extremities (Fig. E1), erythema induratum occurs on the calf, and lupus panniculitis occurs on the upper arms, shoulders, and face.
- Skin findings tend to evolve as the types of inflammatory cells change over the course of a few days.

ETIOLOGY

Panniculitis can be either primary/idiopathic or secondary. Common secondary etiologies can be classified into the following broad categories:

- Infections: Bacterial (streptococci), mycobacterial, fungal, parasitic, and viral
- Inflammatory/connective tissue disease: Erythema nodosum, erythema induratum, lipodermatosclerosis, lupus panniculitis, cutaneous polyarteritis nodosa, dermatomyositis-associated panniculitis
- Malignancy: Subcutaneous panniculitis-like type T-cell lymphoma
- Pancreatic disease: Pancreatic panniculitis, which is associated with pancreatitis or pancreatic carcinoma
- Immunodeficiency states: Alpha-1 antitrypsin deficiency panniculitis, which is associated with pulmonary and hepatic disease
- Trauma: Cold panniculitis (due to exposure to the cold), traumatic panniculitis, and factitial panniculitis (due to injection of medication or foreign substances into the subcutaneous fat)
- Deposition: Calciphylaxis, gout

Panniculitis can be a sign of an underlying systemic disease. Lupus panniculitis can occur alone or may present before or after the onset of either discoid lupus erythematosus or systemic lupus erythematosus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- The skin lesions of panniculitis need to be distinguished from other skin lesions that may manifest similarly, such as insect bites, thrombophlebitis, and cellulitis.
- Disorders affecting the deep dermis or fascia (i.e., plaque morphea, eosinophilic fasciitis), benign or malignant tumors manifesting as subcutaneous nodules, and nodules with deep bruising may have similar clinical findings and be difficult to distinguish from panniculitis.

WORKUP

- Diagnosis of panniculitis depends on a thorough history and physical examination, evaluation of patient's risk factors, skin lesion appearance and distribution, as well as any associated clinical findings.
- If the diagnosis is unclear or needs to be confirmed, a deep skin biopsy should be performed. The preferred biopsy is an excisional biopsy, but a large 6- to 8-mm punch biopsy may be sufficient.

Although the above often establishes a diagnosis, there are times when it is difficult to accurately diagnose a specific panniculitis. Different forms of panniculitides have similar clinical findings while others are rare, complicating the presentation. Biopsy specimens may be too superficial to assess

TABLE 1 Classification of Panniculitis

I. Without prominent vasculitis
  A. Septal inflammation
    1. Lymphocytic and mixed: Erythema nodosum and variants
    2. Granulomatous: Palisaded granulomatous diseases, sarcoidosis, subcutaneous infection: Tuberculosis, syphilis
    3. Sclerotic: Scleroderma, eosinophilic fasciitis, lipodermatosclerosis, toxins
  B. Lobular inflammation
    1. Neutrophilic: Infection, ruptured folliculitis and cysts, pancreatic fat necrosis
    2. Lymphocytic: Lupus panniculitis, post-steroid panniculitis, lymphoma/leukemia
    3. Macrophagic: Histiocytic cytophagic panniculitis
    4. Granulomatous: Erythema induratum/nodular vasculitis, palisaded granulomatous diseases, sarcoidosis, Crohn disease
    5. Mixed inflammation with many foam cells: α1-antitrypsin deficiency, traumatic fat necrosis
    6. Eosinophilic: Eosinophilic panniculitis, arthropod bites, parasites
    7. Enzymatic fat necrosis: Pancreatic enzyme panniculitis
    8. Crystal deposits: Scleredema neonatorum, subcutaneous fat necrosis of the newborn, gout, oxalosis
    9. Embryonic fat pattern: Lipoatrophy, lipodystrophy
II. With prominent vasculitis (septal or lobular)
  A. Neutrophilic: Leukocytoclastic vasculitis, subcutaneous polyarteritis nodosa, thrombophlebitis, ENL
  B. Lymphocytic: Nodular vasculitis, perniosis, angiocentric lymphomas
  C. Granulomatous: Nodular vasculitis/erythema induratum, ENL, granulomatosis with polyangiitis, Churg-Strauss allergic granulomatosis
III. Mixed patterns

ENL, Erythema nodosum leprosum.

From Lee L, Werth V: The skin and rheumatic diseases: panniculitis, In Firestein G et al [eds]: *Kelley's textbook of rheumatology,* ed 9, Philadelphia, 2013, Elsevier Saunders, p. 611.

BOX 1 Classification of the Panniculitides

Mostly septal panniculitis without vasculitis
- Erythema nodosum
- Vilanova disease: Subacute nodular migratory panniculitis

Mostly lobular panniculitis without vasculitis
- Idiopathic neutrophilic panniculitis
- Subcutaneous fat necrosis of the newborn
- Postcorticosteroid panniculitis
- Calcifying panniculitis
- Pancreatic panniculitis
- α_1-Antitrypsin deficiency
- Physical or factitial panniculitis
- Histiocytic cytophagic panniculitis
- Lipodystrophy syndromes
- Connective tissue panniculitis
- Subcutaneous panniculitis–like T-cell lymphoma
- Sclerosing panniculitis: Lipodermatosclerosis

Mixed panniculitis
- Lupus profundus: Lupus erythematosus panniculitis
- Erythema nodosum–like lesions of Behçet syndrome

Panniculitis with vasculitis
- Small-vessel vasculitis (postcapillary venule), also known as *leukocytoclastic vasculitis*
- Medium-sized-vessel vasculitis (arterioles or small arteries): Polyarteritis nodosa
- Erythema induratum, also known as *nodular vasculitis*

From Hochberg MC: *Rheumatology*, ed 7, Philadelphia, 2019, Elsevier.

for the involvement of the subcutaneous fat or to assess for the presence of vasculitis. Inflammation of the subcutaneous fat is a changing process, with varying histologic findings as well as physical characteristics of skin lesions based on the stage of evolution. Cellular infiltrates may not be confined to one location in the subcutaneous fat, and may overlap between septa and lobules (Fig. E2).

LABORATORY TESTS

Depending on the suspected underlying disorder, the following workup may be considered:
- Throat swab for rapid streptococcal screen, ASO titer, CBC, PPD, chest radiograph, tissue cultures, and histologic stains for organisms
- Amylase, lipase
- Serum alpha-1 antitrypsin level
- ESR, CRP
- Laboratory evaluation for possible connective tissue disease
- Further special studies of biopsy sample if malignancy is suspected

IMAGING STUDIES

- Chest radiography
- Ankle-brachial index for assessment of peripheral vascular disease
- Further imaging based on clinical suspicion (i.e., CT scan of abdomen for pancreatitis)

Rx TREATMENT

Treatment of panniculitis is toward treatment of the underlying etiology. Any suspected medications should be discontinued. Appropriate antibiotics to treat underlying infections should be prescribed.

NONPHARMACOLOGIC THERAPY

- Leg elevation, bed rest
- Support stockings

ACUTE GENERAL Rx

- Nonsteroidal antiinflammatory medications (NSAIDs)
- Oral corticosteroids

CHRONIC Rx

- Oral potassium iodide (300 to 900 mg per day)
- Oral corticosteroids
- Colchicine
- Hydroxychloroquine
- Immunosuppressive medications

REFERRAL

- Dermatology for biopsy of skin lesions
- Specific specialists based on underlying etiology

BASIC INFORMATION

DEFINITION

Paralytic shellfish poisoning (PSP) is caused by the consumption of molluscan shellfish contaminated with a marine toxin produced by dinoflagellates (algae) that has a rapid onset of neurological symptoms and can be severe and even life-threatening.

SYNONYMS

Neurotoxic Shellfish Poisoning
PSP

ICD-10CM CODE
T61.78 Other shellfish poisoning

EPIDEMIOLOGY & DEMOGRAPHICS

- In the U.S., there are about 30 cases a yr reported.
- About 1 person dies every 4 yr from this toxic seafood poisoning.

INCIDENCE: Toxin-containing shellfish are generally found in the cold-water regions of the coast of northwestern and northeastern U.S., southern Chile, Japan and the North Sea.

PEAK INCIDENCE: PSP has been associated with algal blooms known as "red tides," but cases can occur even without red tides. Cases are more common in the summer as dinoflagellates grow better in warmer seasons.

RISK FACTORS: Shellfish including mussels; scallops; clams; and, at times, crustaceans (Dungeness crabs, shrimp, or lobsters), gastropod mollusks (e.g., whelk, moon snails or abalone), and fish that ingest zooplankton (Atlantic salmon, herring, mackerel). Most common are mussels or clams.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Symptoms usually occur within 30 minutes (few minutes to 4 hours) after exposure. Symptoms include:
  1. Tingling and numbness periorally spreading to neck and face
  2. Headache, nausea, vomiting, and diarrhea
  3. Ataxia, difficulty swallowing
  4. Weakness to paralysis and respiratory failure
- Death can occur within 2 to 12 hours of ingestion of contaminated seafood. Case fatality rate: 12%
- Neurotoxic symptoms improve after 12 hours and resolve completely within a few days

ETIOLOGY

- The illness is caused by marine toxins: Saxitoxin produced by algae, especially dinoflagellates and possibly other algae and bacteria. The toxin is not destroyed by heat or freezing, and the contaminated fish will smell and look normal.
- Saxitoxin blocks voltage-gated sodium channels in nerve and muscle cell membranes thus blocking nerve signal transmission.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Ciguatera fish poisoning: Caused by ingesting tropical reef fish such as barracuda, grouper, sea bass, and snapper containing ciguatoxin, which is produced by dinoflagellates. Presents with a clinical picture of nausea/vomiting, diarrhea, cramps, muscle aches, itching, and dizziness.
- Pufferfish poisoning (tetrodotoxin): Pufferfish, porcupine, and sun fish may become highly poisonous at certain times of the yr. The toxin tetrodotoxin derives from Pseudomonas bacteria and is cardio- and neurotoxic and can cause death in 2 to 6 hours of ingestion by blocking voltage-gated sodium ion channels.
- Scombroid fish poisoning (histamine fish poisoning): Caused by improper fish storage and bacterial overgrowth that converts high levels of histidine in the fish flesh to histamine. Patients will present with rash and facial and upper body flushing, vomiting, burning, or metallic taste in the mouth.
- Botulism.

WORKUP

Should be considered when a history is elicited of consumption of a known seafood that can serve as a vector for PSP followed by onset of neurological symptoms including paralysis

LABORATORY TESTS

Assay for the detection of saxitoxin in urine of affected patients through health departments and assays on samples of food

TREATMENT

Supportive treatment including mechanical ventilation, may be necessary.

PEARLS & CONSIDERATIONS

COMMENTS

Saxitoxin is a potent neurotoxin three orders of magnitude more toxic than sodium cyanide

PREVENTION

Monitoring of shellfish beds by health departments and avoidance of shellfish that have been harvested from areas deemed contaminated

BASIC INFORMATION

DEFINITION

Paraneoplastic syndromes are a large group of disorders caused by either an abnormal immune response to a malignancy or as a result of hormonal or other soluble factors produced by these malignancies. They often affect areas of the body away from the site of the original tumor or metastases, which is in contrast to syndromes that are direct complications of tumor invasion, compression, or metastasis (e.g., superior vena cava syndrome). Findings and symptoms are specific to each syndrome. Paraneoplastic syndromes affect multiple organ systems and remain a challenging diagnostic entity.

ICD-10CM CODES

E22.2	Syndrome of inappropriate secretion of antidiuretic hormone
E83.5	Disorders of calcium metabolism
G13.0	Paraneoplastic neuromyopathy and neuropathy
G13.1	Other systemic atrophy primarily affecting central nervous system in neoplastic disease
G73.1	Lambert-Eaton syndrome in neoplastic disease
G73.3	Myasthenic syndromes in other diseases classified elsewhere

EPIDEMIOLOGY & DEMOGRAPHICS

- Paraneoplastic syndromes may affect as many as 8% of cancer patients.
- See Table 1 for epidemiology of each syndrome.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Hypercalcemia of malignancy:
- Nausea/vomiting
- Constipation
- Abdominal pain
- Anorexia
- Hypertension
- Fatigue
- Altered mental status (from confusion to coma)
- Depression/anxiety
- Polyuria
- Acute kidney injury
- Bone pain

Syndrome of inappropriate antidiuretic hormone (SIADH):
- Headache
- Weakness
- Anorexia
- Nausea, vomiting
- Memory impairment, irritability, restlessness, seizures
- Obtundation or coma may be seen with hyponatremia <125 mEq/L

Cushing syndrome:
- Muscle weakness
- Rapid weight gain
- Centripetal fat distribution, progressing to obesity; limbs are often spared or wasted
- Characteristic "moon facies" due to accumulation of fat deposition in the cheeks
- Skin atrophy, easy bruising, and purple abdominal striae due to skin fragility
- Hyperpigmentation, notably in sun-exposed areas
- Menstrual irregularity, mild hirsutism in women
- Hypertension
- Depression, anxiety, irritability

Paraneoplastic thrombocytosis:
- Thrombosis
- Nausea, vomiting
- Paresthesias, visual disturbances, head ache

Paraneoplastic erythrocytosis:
- Erythroderma
- Post-shower (aquagenic) pruritus
- Plethora

Paraneoplastic glomerulonephritis:
- Renal failure: Oliguric or anuric
- Malaise
- Nausea, vomiting

Paraneoplastic Neurological Syndromes: (Table 2 and Table 3)

Paraneoplastic cerebellar degeneration (PCD):
- May develop prodrome of dizziness, nausea, vomiting
- Ataxia
- Diplopia
- Dysphagia, dysarthria

Lambert-Eaton myasthenic syndrome (LEMS):
- Gradual onset of symmetric proximal muscle weakness and fatiguability; lower extremity involvement is more common
- Hyporeflexia
- Mild bulbar dysfunction, although respiratory failure can occur late in the disease process
- Dysautonomia, especially erectile dysfunction

Myasthenia gravis (MG):
- Ocular symptoms: Ptosis and diplopia
- Weakness of facial muscles, notably with fatigable chewing
- Weakness of neck extensor and flexor muscles; proximal and distal extremities may also be involved
- May progress to involve muscles of respiration and respiratory crisis

Opsoclonus myoclonus syndrome (OMS):
- Truncal ataxia and unsteady gait
- Involuntary and conjugate gaze rapid eye movements (opsoclonus)
- Muscle twitching (myoclonus)
- Other symptoms: Irritability, sleep disturbance, dysarthria or mutism

Limbic encephalitis (LE):
- Insidious mood or psychiatric changes; hallucinations
- Short-term memory loss
- Hyperthermia or somnolence if hypothalamic involvement
- Seizures occur in up to half of patients

Paraneoplastic dermatologic and rheumatologic syndromes:
- Acanthosis nigricans
- Dermatomyositis (DM)
- Necrolytic migratory erythema
- Hypertrophic osteoarthropathy

TABLE 1 Epidemiology of Each Paraneoplastic Syndrome

Condition	Prevalence	Risk Factors
Hypercalcemia of malignancy	Up to 20% of all cancer patients	Squamous cell cancers (lung, head, and neck), breast, kidney, bladder, and ovarian cancers, lymphoma
Syndrome of inappropriate antidiuretic hormone (SIADH)	Up to 2% of all cancer patients Found in 10%-45% of SCLC patients	SCLC
Cushing syndrome	Approximately 2% of all cancer patients (50% of these are SCLC)	SCLC Pituitary adenoma, benign and malignant adrenal tumors, carcinoid tumors
Limbic encephalitis (LE)	Less than 1%	SCLC Testicular germ cell tumor Breast cancer Ovarian teratoma
Paraneoplastic cerebellar degeneration	Less than 1%	SCLC Hodgkin lymphoma Breast cancer
Lambert-Eaton myasthenic syndrome (LEMS)	3% of SCLC patients	SCLC, prostate cancer, lymphoma
Paraneoplastic thrombocytosis	5%-20% of patients with solid tumors	Lung, colorectal, mesothelioma
Paraneoplastic erythrocytosis	4% of patients	Renal cell carcinoma, hepatocellular carcinoma
Paraneoplastic glomerulonephritis	2%-4% of patients	Hodgkin lymphoma, thymoma, prostate cancer
Myasthenia gravis (MG)	15% of thymoma patients	Thymoma
Opsoclonus myoclonus syndrome (OMS)	Less than 1%	SCLC, breast cancer, ovarian teratoma in adults; neuroblastoma in children

SCLC, Small cell lung cancer.

TABLE 2 Paraneoplastic Syndromes

Syndrome	Tumor	Associated Antibodies
Cerebellar degeneration	SCLC Gynecologic Breast Lymphoma Thymoma	Anti-Hu Anti-Yo Anti-Ri Anti-CV2 Anti-TR
Limbic encephalitis	SCLC Testes Breast Ovarian teratoma Thymoma	Anti-Hu Anti-Ma Anti-Amphiphysin Anti-NMDA receptor Anti-VGKC Anti-GAD
Lambert–Eaton myasthenic syndrome	SCLC	Anti-VGCC
Sensory neuronopathy	SCLC	Anti-Hu
Stiff-person syndrome	SCLC Breast Thymoma	Anti-GAD Anti-Amphiphysin
Opsoclonus-myoclonus	Neuroblastoma SCLC Gynecologic Breast	Anti-Ri
Dermatomyositis/ polymyositis	Ovary Pancreas Stomach Colorectal Non-Hodgkin lymphoma	Variety of antibodies have been associated, including anti-TIF1

GAD, Glutamic acid decarboxylase*; NMDA,* N-methyl-D-aspartate*; SCLC*, small cell lung cancer*; VGCC,* voltage-gated calcium channel*; VGKC,* voltage-gated potassium channel.
Adapted from Kaufman DM et al: *Kaufman's clinical neurology for psychiatrists*, ed 8, Philadelphia, 2017, Elsevier.

TABLE 3 Paraneoplastic Syndromes of the Nervous System

Classical

Limbic encephalitis
Encephalomyelitis
Cerebellar degeneration
Opsoclonus-myoclonus
Sensory neuronopathy
Gastrointestinal pseudoobstruction/autonomic neuropathy
Lambert–Eaton myasthenic syndrome
Inflammatory myopathy

Nonclassical

Brainstem encephalitis
Stiff-person syndrome
Motor neuron disease
Necrotizing myelopathy
Optic neuropathy/retinopathy
Acute sensorimotor neuropathy
Chronic sensorimotor neuropathy
Myasthenia gravis

Autoimmune Encephalitides

NMDAR encephalitis
AMPAR encephalitis

AMPAR, Alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor; *NMDAR,* anti-*N*-methyl-D-aspartate receptor.
From Swaiman KF: *Swaiman's Pediatric Neurology, Principles and Practice*, ed 6, 2017, Elsevier.

- Leukocytoclastic vasculitis
- Paraneoplastic pemphigus (PNP)
- Polymyalgia rheumatica (PMR)
- Sweet syndrome (acute febrile neutrophilic dermatosis)
- Sign of Leser-Trélat (explosive onset of multiple seborrheic keratoses)

ETIOLOGY

Paraneoplastic endocrine syndromes (PES) are due to ectopic production of bioactive substances (e.g., hormones or peptides) that lead to metabolic derangements:

- **Hypercalcemia of malignancy:**
  1. *Humoral hypercalcemia of malignancy (HHM):* Due to production of parathyroid hormone-related peptide (PTHrP). Accounts for 80% of hypercalcemia of malignancy cases. Most common in lung (Table 4) and breast cancer (also seen in renal, bladder, and ovarian cancer).
  2. *Other etiologies of hypercalcemia of malignancy:* 1,25-dihydroxyvitamin D production from increased 1α-hydroxylase activity causes hypercalcemia in most Hodgkin and some non-Hodgkin lymphomas. Tumors can also produce ectopic parathyroid hormone (PTH).
  3. *Osteolytic activity:* 20% of hypercalcemia of malignancy cases. Tumor cells produce local factors that stimulate osteoclast activation, resulting in increased bone resorption.
- **SIADH:** Ectopic production of antidiuretic hormone (ADH) (arginine vasopressin, atrial natriuretic peptide) by tumor cells leads to inappropriately concentrated urine and natriuresis.
- **Cushing syndrome:** Ectopic ACTH promotes excess production of cortisol and other glucocorticoids from the adrenal glands, which do not respond to normal HPA feedback.
- **Paraneoplastic erythrocytosis**: Mediated by inappropriate production of erythropoietin (EPO) and is associated most commonly with renal cell carcinoma and hepatocellular carcinoma.
- **Paraneoplastic thrombocytosis**: Overproduction of inflammatory cytokines, especially IL-6, which induces thrombopoietin (TPO) mRNA expression and protein synthesis in the liver. Unlike secondary (reactive) thrombocytosis, TPO levels are not elevated.
- **Paraneoplastic glomerulonephritis**: Acute renal failure in the setting of newly diagnosed malignancy that is not explained by direct tumor involvement of the kidneys or genitourinary system. Diseases include minimal change disease, rapidly progressive glomerulonephritis, focal segmental glomerulonephritis, IgA nephropathy, and membranous nephropathy.
- **Paraneoplastic neurologic syndromes (PNS):** Due to immune cross-reactivity between tumor cells and components of the nervous system. Tumor-directed antibodies (onconeural antibodies) are produced by the patient in response to a developing cancer. These onconeural antibodies and associated onconeural antigen-specific T lymphocytes attack components of the nervous system because of antigenic similarity (molecular mimicry). Diagnostic criteria for paraneoplastic neurologic syndromes is summarized in Table 5.

TABLE 4 Hypercalcemia of Malignancy

Cancer	Frequency (%)	Mechanism
Lung	35	PTHrP Local osteolysis
Breast	25	PTHrP Local osteolysis
Head and neck	6	PTHrP
Renal	3	PTHrP Local osteolysis
Multiple myeloma	15	PTHrP (rare) Local osteolysis 1,25-Dihydroxyvitamin D
Prostate	7	Local osteolysis
Lymphoma	15	1,25-Dihydroxyvitamin D PTHrP

PTHrP, Parathyroid hormone-related protein.
From Skorecki K et al: *Brenner and Rector's the kidney*, ed 10, Philadelphia, 2016, Elsevier.

TABLE 5 Diagnostic Criteria for Paraneoplastic Neurologic Syndromes

Definite Paraneoplastic Neurologic Syndromes

- A classical syndrome and cancer that develops within 5 yr of the diagnosis of the neurologic disorder
- A nonclassical syndrome that resolves significantly after cancer treatment without concomitant immunotherapy provided that the syndrome is not susceptible to spontaneous remission
- A nonclassical syndrome with onconeural antibodies (well characterized or not) and cancer that develops within 5 yr of the diagnosis of the neurologic disorder
- A neurologic syndrome (classical or not) with well-characterized onconeural antibodies (anti-Hu, Yo, CV2, Ri, Ma2, or amphiphysin) and no cancer

Possible Paraneoplastic Neurologic Syndromes

- A classical syndrome, no onconeural antibodies, no cancer, but at high risk to have an underlying tumor
- A neurologic syndrome (classical or not) with partially characterized onconeural antibodies and no cancer
- A nonclassical syndrome, no onconeural antibodies, and cancer present within 2 yr of diagnosis

From Swaiman KF et al: *Swaiman's pediatric neurology: principles and practice*, ed 6, Philadelphia, 2017, Elsevier.

BOX 1 Evaluation and Diagnosis of Paraneoplastic Syndromes

- Characterize abnormality; obtain laboratory studies, imaging, and biopsy as necessary.
- Carefully elicit any additional symptoms and signs.
- Eliminate common causes.
- If there is no obvious etiology, consider a paraneoplastic syndrome.
- If signs and symptoms are consistent with a paraneoplastic syndrome, undertake a search for an unknown primary cancer or recurrence or progression of a known primary tumor.
- Screening should include a careful physical examination with breast, gynecologic, and prostate evaluations; basic hematology, chemistry, and urine studies; chest radiograph; and mammography.
- Computed tomography (CT) of the chest, abdomen and pelvis, or positron emission tomography/CT is indicated if there are any suspicious symptoms, signs, or laboratory abnormalities. Antibody testing for paraneoplastic neurologic syndromes and/or skin biopsy should be performed as indicated.
- Consider treatment of cancer and/or appropriate palliative treatment, including immunosuppressive therapy for paraneoplastic symptoms when possible.

- **LE, PCD, LEMS, MG, OMS:** Cross-reactive autoantibodies against various components of the central and peripheral nervous system.

DX DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- **Hypercalcemia of malignancy:** Primary hyperparathyroidism, familial hypocalciuric hypercalcemia, excess calcium intake, vitamin D toxicity, chronic granulomatous disorders, thiazide diuretics. It is important to differentiate between HHM and osteolytic causes of malignancy-associated hypercalcemia because prognosis and response to treatment differ
- **SIADH:** Hypovolemic hyponatremia, volume overload, reset osmostat, adrenal insufficiency, hypothyroidism, psychogenic polydipsia
- **Cushing syndrome:** Excess glucocorticoid administration, pituitary adenoma, benign or malignant adrenal tumors
- **Paraneoplastic thrombocytosis**: Reactive thrombocytosis from iron deficiency anemia, infection, inflammation, essential thrombocythemia
- **Paraneoplastic erythrocytosis**: Polycythemia vera, secondary polycythemia from smoking, high-affinity hemoglobinopathies, or chronic hypoxia (e.g., obstructive sleep apnea)
- **Paraneoplastic glomerulonephritis**: Renal failure from intrinsic injury from nephrotoxic agents (e.g., chemotherapy), postrenal failure from bladder obstruction, or rarely direct metastatic invasion from a primary tumor
- **LE, PCD, LEMS, MG, OMS:** Multiple sclerosis, stroke, meningitis, encephalitis, neurodegenerative diseases, myelitis, mixed connective tissue disease

WORKUP

- History and physical examination. Box 1 summarizes the evaluation and diagnosis of paraneoplastic syndromes.
- Age-appropriate cancer screening
- Chest-abdomen-pelvis CT
- Paraneoplastic neurologic syndromes: Lumbar puncture, PET, EEG, EMG

LABORATORY TESTS

Hypercalcemia of malignancy

- Serum calcium and albumin levels to measure corrected calcium (HHM more common when serum Ca^{2+} >13 mg/dl)
- Ionized serum calcium
- PTH (low to normal)
- PTHrP (elevated)
- $1,25(OH)_2D$ levels (if the above values are inconclusive)

SIADH

- Serum (corrected for glucose) and urine sodium (serum sodium <135 mEq/L or urine sodium >40 mEq/L)
- Serum and urine osmolality (serum osm <280 mOsm/kg of water and/or urine osm >100 mOsm/kg of water)

Cushing syndrome

- Initial testing: Low-dose dexamethasone suppression test, late-night salivary cortisol, 24-hour urinary free cortisol excretion.
- Once diagnosis is confirmed: High-dose dexamethasone suppression tests can help to distinguish Cushing syndrome (pituitary hypersecretion of ACTH) from patients with ectopic ACTH production.
- Potassium and glucose should be monitored closely due to increased risk of hypokalemia and hyperglycemia.

LE: Anti-Hu, Anti-Ma2, Anti-CRMP5, Anti-LGI1, Anti-AMPAR, Anti-mGluR5, CSF analysis, Anti-NMDAR, Anti-GABA-AR, Anti-GABA-BR

PCD: Anti-Yo, Anti-Tr Anti-Hu, Anti-Ma, Anti-Ri, Anti-CV2, Anti-VGCC, Anti-mGluR1, CSF analysis

LEMS: Anti-VGCC (P/Q), CSF analysis

MG: Anti-AChR, Anti-MuSK, CSF analysis

Paraneoplastic thrombocytosis: CBC, liver panel, iron panel, *JAK2* mutation, *CALR* mutation, *MPL* mutation

Paraneoplastic erythrocytosis: CBC, EPO level, *JAK2* mutation, peripheral blood smear

Paraneoplastic glomerulonephritis: BMP, urinalysis, urine protein to creatinine ratio, 24-hour urine protein collection, urine sediment analysis

IMAGING STUDIES

- **Hypercalcemia of malignancy:** CT imaging to evaluate for breast lesion, lung mass, or lymphadenopathy
- **SIADH:** CT imaging to evaluate for brain or lung mass
- **Cushing syndrome:** CT scan, MRI, or octreotide scan
- **LE, PCD, LEMS, MG:** CT chest, FDG-PET scan, MRI
- **Paraneoplastic erythrocytosis**: CT renal mass protocol or renal ultrasound to evaluate for renal cell carcinoma

RX TREATMENT

NONPHARMACOLOGIC THERAPY

Hypercalcemia of malignancy

- Treatment of underlying malignancy, either surgical resection or chemotherapy/radiation of identified tumors
- Fluid resuscitation, typically with initial 1 L bolus of isotonic saline followed by 200 to 300 ml/hr to achieve euvolemia, followed by maintenance hydration

SIADH

- Surgical resection of identified tumors
- Fluid restriction

- Maintain adequate dietary protein and salt intake

Cushing syndrome: Surgical resection of identified tumors

LE, PCD, LEMS, MG

- IVIG
- Plasma exchange

ACUTE GENERAL Rx

Hypercalcemia of malignancy

- Aggressive fluid hydration with normal saline (0.9%) to promote renal calcium excretion
- Bisphosphonates, either pamidronate or zoledronic acid intravenous infusions (treatment side effects are renal dysfunction and osteonecrosis of the jaw)
- Calcitonin weight-based dosing, although tachyphylaxis occurs after 48 hours of administration
- Loop diuretics if concurrent heart failure or renal failure
- Corticosteroids in cases of myeloma and lymphoma
- Hemodialysis in severe cases

SIADH

- If patient develops seizure or obtundation in cases of severe hyponatremia, then sodium replacement with hypertonic saline (3%) is indicated
- Sodium should not be corrected at a rate faster than 8 mEq/L in any 24-hour period to decrease chances of osmotic demyelination syndrome. Desmopressin, free water, and/or nephrology consultation may be required for an overly rapid correction.

Cushing syndrome

- Diuretics and antihypertensive agents for blood pressure and volume status management

CHRONIC Rx

- Chronic treatment is centered on treatment of the underlying malignancy
- **Hypercalcemia of malignancy**
  1. Bisphosphonate therapy every 4 wk in cases of bone metastasis
  2. Chronic calcitonin use can be considered
  3. Denosumab, a monoclonal antibody that inhibits osteoclastic bone resorption by blocking RANKL from binding to osteoclastic RANK receptors, can be used in patients refractory to bisphosphonate therapy
- **SIADH**
  1. Demeclocycline and vasopressin receptor antagonists (vaptans: Conivaptan and tolvaptan, although tolvaptan should not be used for longer than 30 days and should be avoided in patients with liver disease)
  2. Cessation of any possible causative medications
  3. Oral salt tablets if dietary salt intake insufficient
- **Cushing syndrome:** If surgery contraindicated, consider inhibition of adrenal enzymes with ketoconazole, mitotane, metyrapone
- **LE/PCD:** Glucocorticoids, cyclophosphamide, rituximab
- **LEMS:** Pyridostigmine, azathioprine, glucocorticoids
- **MG:** Pyridostigmine, azathioprine, cyclosporine, mycophenolate, rituximab
- **Paraneoplastic thrombocytosis**: Consider prophylactic low-molecular-weight heparin or aspirin if no contraindications exist, siltuximab (antibody against IL-6)

DISPOSITION

Specific to each condition; however, humoral hypercalcemia of malignancy carries a poor overall prognosis with 30-day mortality of 50%.

REFERRAL

Oncology, endocrinology, neurology, nephrology

PEARLS & CONSIDERATIONS

COMMENTS

- Signs or symptoms of a paraneoplastic syndrome may manifest prior to the identification of a malignancy.
- If paraneoplastic syndrome is suspected, a thorough workup for a tumor is indicated.
- With treatment of the primary tumor, the clinical effects of hypercalcemia of malignancy, SIADH, and Cushing syndrome may improve or resolve.
- Neurologic paraneoplastic syndromes can have long-term effects due to permanent CNS or PNS damage. Tumor detection can also be difficult as these immune-mediated syndromes may also be keeping the tumor in check.
- New neurologic deficits after starting a checkpoint inhibitor (e.g., PD-1 inhibitor) may indicate drug-induced autoimmunity rather than a paraneoplastic syndrome.

PREVENTION

- Smoking cessation
- Age-appropriate cancer screening

PATIENT & FAMILY EDUCATION

In conditions with autoimmune etiology (LE, PCD, LEMS, MG, OMS), symptoms may not improve even if the tumor is identified and treated, as damage to the nervous system may be sustained or permanent.

Paranoid Personality Disorder (PTG)

BASIC INFORMATION

DEFINITION

Paranoid personality disorder (PPD) is characterized by a pattern of pervasive distrust and suspiciousness that leads the person to assign malevolence to the motives of others. PPD begins by early adulthood and causes significant distress or impairment in multiple domains of functioning. Individuals must meet four or more of the following criteria, each of which should be enduring and inflexible across contexts:

- Suspect, without justification, that others are exploiting, harming, or deceiving them.
- Preoccupied with unwarranted doubts about the loyalty or trustworthiness of friends or associates.
- Reluctant to confide in others because of unjustified fear that the information will be used against them in a malicious fashion.
- Infer demeaning or threatening statements from benign remarks or events.
- Bear grudges for extended periods. For example, PPD patients are unforgiving of perceived or real insults and slights.
- Perceive attacks on their character that are not apparent to others. Quick to react angrily or to counterattack.
- Recurrent suspicions, without justification, regarding fidelity of spouse or partner.

SYNONYM

PPD

ICD-10CM CODE
F60.0 Paranoid personality disorder
DSM-5 CODE
301.0 Paranoid personality disorder

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Epidemiologic studies report a prevalence of 2.3% to 4.4% in the general U.S. population.
PREDOMINANT SEX: More commonly diagnosed in males in clinical samples.
GENETICS: Increased prevalence of PPD in relatives of patients with schizophrenia and delusional disorder, paranoid type.

CLINICAL PRESENTATION

- These patients are highly suspicious and hypervigilant to interpersonal threats.
- They may present as cold, guarded, and resistant, as if the clinical interviewer were inappropriately prying.
- Alternatively, they may be oppositional and argumentative, defending against perceived attacks, and they may threaten litigation.
- They may be rigid and controlling in relationships, constantly questioning and criticizing the behavior and motives of others, including romantic partners (pathologic jealousy).
- Because they do not easily trust in other people, patients with PPD seek to be self-sufficient and autonomous, and therefore any vulnerability (such as medical illness) can feel dangerous to them.
- In response to stress, they may experience very brief psychotic episodes (minutes to hours). However, they do not have persistent, bizarre delusions.

ETIOLOGY

- Genetic influence is suggested by increased prevalence of PPD in families with schizophrenia and delusional disorder, paranoid type.
- Childhood maltreatment, bullying, and trauma are associated with the development of paranoid traits.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Schizophrenia or delusional disorder, paranoid type, each of which requires the presence of persistent positive psychotic symptoms such as delusions or hallucinations
- Substance-induced paranoia, especially in the context of cocaine, PCP, or methamphetamine use disorder
- Personality changes caused by a general medical condition that affects the central nervous system
- Paranoid traits associated with a sensory disability (e.g., hearing impairment)
- Other personality disorders:
  1. Schizotypal personality disorder includes magical thinking and unusual perceptual experiences.
  2. Schizoid and borderline personality disorders do not have prominent paranoid ideation.
  3. Avoidant personality disorder includes fear of embarrassment.
  4. Narcissistic personality disorder includes the fear that hidden "flaws" or "inferiority" may be revealed.
- Common comorbid disorders include major depressive disorder, obsessive-compulsive disorder, agoraphobia, and substance use disorders
- The most common co-occurring personality disorders are schizotypal, schizoid, narcissistic, avoidant, and borderline
- Consider whether the behaviors and attitudes are not pathologic but instead adaptive responses to a particular sociocultural context, such as chronic stress due to minority or immigrant status that results in a cycle of anger and mistrust. For a diagnosis of PPD, the traits should be inflexible, maladaptive, and persistent

WORKUP

- History: Collateral information is essential to establishing the presence of longstanding interpersonal pattern in multiple domains of the patient's life.
- Physical examination
- Mental status examination

LABORATORY TESTS

Those necessary to rule out medical causes of personality changes

IMAGING STUDIES

Those necessary to rule out medical causes of personality changes

TREATMENT

NONPHARMACOLOGIC THERAPY

- Cognitive-behavioral therapy to help patients control rage, manage perceived criticism, and develop social skills
- Psychodynamic psychotherapy to help patient develop capacity to trust and improve interpersonal functioning.
- Guidelines for general management of the patient with PPD:
  1. Convey your intent to "do no harm."
  2. Address the patient's fears and concerns, no matter how irrational, in a clear, direct, and detailed manner.
  3. Remember that behind the patient's hostility lies fears that are real to him or her.
  4. Maintain a professional and neutral stance.
  5. Avoid responding with too much warmth and friendliness, which can intensify paranoia.
  6. Give the patient detailed and factual information about the treatment plan.
  7. Give the patient as much control as possible over the treatment plan.
  8. Do not take the patient's hostility or suspicion personally, but understand it as an attempt to manage intense fear.
  9. Validate the patient's concerns about the diagnosis or treatment plan.

ACUTE GENERAL Rx

Benzodiazepines or low-dose antipsychotics to control hostility and paranoia

CHRONIC Rx

- Low-dose antipsychotic medication may have small benefit in treating suspiciousness. Increase dose in small increments to minimize risk of side effects.
- Treat comorbid symptoms, such as by using selective serotonin inhibitors for depression or agoraphobia.

COMPLEMENTARY & ALTERNATIVE MEDICINE

No evidence of efficacy in PPD.

DISPOSITION

- Severity is variable and course is chronic. Often patients have lifelong difficulty maintaining intimate relationships.
- In some cases, PPD is an antecedent of delusional disorder, paranoid type.

REFERRAL

- For pharmacotherapy or psychotherapy, if acceptable to patient

- If patient has acute worsening of functioning due to a stressor

PEARLS & CONSIDERATIONS

COMMENTS

- Medical illness exacerbates these patients' sense of vulnerability, which increases their fear and therefore their oppositional behaviors.
- Communicating personal information to the physician challenges the guarded, self-protective approach to others and will often heighten PPD patients' fear that the physician will harm them.
- The encounter with the physician intensifies hypervigilance. As a result, innocuous or even overtly helpful behaviors by the physician may be perceived as manipulating or threatening.
- With the perceived threat, these patients will often confront and challenge the physician on their motives and their rationale for diagnosis and treatment. Conflict and argument are common.
- Thus, establishing an alliance with the patient can be challenging.
- Faced with such a patient, physicians may understandably react defensively to unfounded suspicion or distance and not respond to the patient's concerns. Both responses increase the patient's anxiety and paranoia.

Paraphilic Disorders

BASIC INFORMATION

DEFINITION

It is important to distinguish between paraphilia and paraphilic disorders.

- The term *paraphilia* applies to sexual arousal that is repeatedly and intensely stimulated by thoughts and/or behavior elicited by stimuli other than that which is associated with consensual mature human partners. For example, sexual arousal that is repeatedly and intensely stimulated by **activity** such as rubbing up against an unsuspecting person or by a **target preference** such as shoes or diapers would be identified as paraphilia.
- To meet the DSM-5 criteria for a **paraphilic disorder,** there must be the presence of a paraphilia over at least a 6-mo period that is causing distress or impairment to an individual or harm or risk of harm to others. In addition, the intensity of the paraphilia sexual arousal must equal or exceed the intensity of an individual's normophiliac sexual arousal.
- Paraphilia that does not meet DSM-5 criteria is not considered a mental illness, but individuals with paraphilic thoughts and behavior may still present for treatment.
- It is not unusual for a person to express more than one paraphilic interest. Recent research has also identified the "wish to experience" and the "actual occurrence" of at least one lifetime paraphiliac act to be common in both men and women.

SYNONYMS

Atypical sexual behavior
Hypersexuality
Sexual impulsivity disorder

ICD-10CM CODES

F65	Paraphilias
F65.0	Fetishism
F65.1	Transvestic fetishism
F65.2	Exhibitionism
F65.3	Voyeurism
F65.4	Pedophilia
F65.5	Sadomasochism
F65.50	Unspecified
F65.51	Sexual masochism
F65.52	Sexual sadism
F65.8	Other paraphilias
F65.81	Frotteurism
F65.89	Other paraphilias
F65.9	Paraphilia, unspecified

DSM-5 CODE

Depends on specific diagnosis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Unknown due to: (1) the secretive nature of the behavior; (2) changes in criterion over time; and (3) differences between cultural definitions of abnormality. It is estimated, however, that only about 1% to 2% of men presenting with paraphilia behavior are distressed by their behavior and meet the criteria of paraphilic disorder.

PEAK INCIDENCE: Although prepubescent individuals can be diagnosed with a paraphilic disorder, diagnosis is usually made postpubescence during late adolescence and early adulthood.

PREVALENCE: Prevalence rates for paraphilia and paraphilic disorders are extremely difficult to report with any certainty. While the seemingly unlimited variety of sexually arousing material available on the Internet suggests a wide range of potentially sexually arousing stimulation that human males and females may be interested in, there are no data to accurately describe whether or not such interests are reflective of paraphilia prevalence rates.

PREDOMINANT SEX AND AGE:

- Males are at a much higher risk than females to experience paraphilias and paraphilic disorders. Although lacking in convincing research, studies estimate the male-to-female ratio to be 20:1 or greater.
- Paraphilia behavior can begin in early childhood but is manifested most commonly in late adolescence and early adulthood and may be expressed throughout the life cycle. Paraphilia behavior and paraphilic disorders tend to become less intense and less frequent in older age.

GENETICS: Although the literature points to some possible genetic influences on sexual interest in males and females, it is inconclusive that any genetic influences exist regarding the development of paraphilias or paraphilic disorders.

RISK FACTORS: Possible risk factors associated with paraphilia and paraphilic disorders include:

- Male gender
- Low self-esteem in childhood and adolescence
- Perceived lack of availability of consensual sexual partners
- Inhibition of normative sexual outlets often related to extreme religiosity or negative sexual messages from parents or caretakers
- Early exposure to paraphilia stimulation and opportunity for repeated exposure

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Usually diagnosed in late adolescence or early adulthood
- May be diagnosed in males as erectile dysfunction or delayed ejaculation during consensual sexual relations when paraphilic stimuli are absent
- May be identified as a result of illegal offenses in some cases such as pedophilia, voyeurism, exhibitionism, or stealing of clothing
- Paraphilic behavior may be so time consuming or obsessive compulsive that it interferes with work, education, relationships, and/or productivity
- Certain paraphilic behaviors may put an individual at risk for disease and/or physical harm (self-inflicted or from others)

ETIOLOGY

There are no conclusive theories that satisfactorily explain the etiology of paraphilias and paraphilic disorders. It is quite possible, however, that the combination of biologic vulnerability and a conditioned learning process lead to paraphilic interests. Males are more at risk for developing paraphilic behavior, perhaps because males are more easily aroused sexually and are more aware of their arousal because of their erectile response. A repeated association of an erection response with certain visual, auditory, olfactory, imagined, or tactile stimuli may condition paraphilia behavior.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Medical: Dementia, substance intoxication, seizures, dissociative fugue state, frontal parietal traumatic brain injury, sexsomnia
- Psychiatric: Manic episode, schizophrenia, dissociative disorder, posttraumatic stress disorder, erotomania delusion, nonparaphilic hypersexuality disorder (i.e., compulsive masturbation, protracted promiscuity, cybersex dependence, pornography dependence), obsessive compulsive disorder, adjustment disorder, impulse control disorder

WORKUP

- A very detailed psychosexual developmental history is necessary and must include a review of sexual experiences with others as well as fantasies and stimuli that accompany masturbation. Paraphilic interests are typically first manifested in childhood or adolescence and persist to a greater or lesser degree throughout life. Such interests are often essential for sexual arousal and must be intense and persistent to meet DSM-5 criteria.
- A detailed psychiatric assessment is necessary to make a differential diagnosis and to identify common comorbid conditions that often accompany paraphilic interests such as low self-esteem and deficits in social skills.
- A physical examination should be performed in cases in which possible physical injury may have resulted from paraphilic behavior such as in cases of masochism or unusual genital, breast, or anal stimulation.
- Information from sexual partners (if available) is helpful for diagnosis and treatment.
- Information regarding the impact of paraphilic behavior on relationships, finances, work productivity, and legal problems is necessary to determine the diagnosis of paraphilic disorder.

TREATMENT

Pharmacologic agents may be used to suppress sexual fantasies, sexual desire, sexual urges, and obsessive compulsive behavior associated with paraphilia. Pharmacologic therapy is used as an adjunct therapy to psychotherapy and not a monotherapy.

PHARMACOLOGIC THERAPY

- Long-acting gonadotropin-releasing hormones (used for dangerous sex offenders where there is a risk of harm to self or others):
  1. Triptorelin (Trelstar)
  2. Leuprolide (Lupron)

3. Goserelin (Zoladex)

- Antiandrogens: (used for dangerous sex offenders where there is a risk of harm to self or others):
  1. Medroxyprogesterone acetate (Depo-Provera)
  2. Spironolactone (Aldactone)
- Selective serotonin reuptake inhibitors (SSRIs): (used for treatment of less serious paraphilia behavior that has obsessive compulsive features)
  1. Fluvoxamine (Luvox)
  2. Fluoxetine (Prozac)

NONPHARMACOLOGIC THERAPY

Individually tailored therapy that addresses patient needs and comorbid mental health problems combined with a strong alliance with the therapist are important ingredients for successful treatment outcome with paraphilia and paraphilic disorders. Common psychotherapeutic interventions include the following:

- Cognitive behavior therapy
- Social skills training
- Relapse prevention

ACUTE GENERAL Rx

Acute therapy begins with a comprehensive assessment of the intensity, frequency, duration, and topography of the paraphilia and assessment of comorbid mental health problems. Paraphilic disorders will be determined by the distress level and risk of harm to self and to others. If it is determined that there is a risk of harm, then therapy should begin with a consideration of pharmacotherapy in conjunction with psychotherapy.

Psychotherapy involves building an alliance with the patient to increase motivation and encourage full disclosure of all aspects of the paraphilia thoughts and behaviors. Individual therapy tailored for each patient's needs and mental health issues is most effective. Punishment or shaming of a patient only serves to inhibit therapeutic progress and goals.

Therapy typically includes techniques and strategies to suppress and manage paraphilia thoughts and behaviors along with strategies to increase positive social skills, constructive use of time, challenging distortions in thinking, and managing comorbid mental health problems.

CHRONIC Rx

It is unlikely that paraphilia thoughts and desires will remit completely and, therefore, strategies for long-term management should be implemented. In cases of paraphilic disorders, lifetime management involves awareness of all personal risk factors for relapse, plans for managing risks of relapse, building positive support systems, building constructive competing behaviors that interfere with opportunities for expressing and acting on paraphilic behavior and commitment to long-term therapy.

Full remission of a paraphilic disorder is established if there is a 5-yr period without stress or impairment or harm to self or others related to paraphilic behavior.

REFERRAL

- Diagnosis complicated by untreated or poorly managed comorbid psychiatric conditions or active substance abuse.
- Consultation for individuals presenting with autism spectrum disorder, intellectual disability, or other cognitive impairments should be considered.

PEARLS & CONSIDERATIONS

- Since there is often a great deal of shame associated with paraphilic disorders, health care professionals must be especially sensitive, nonjudgmental, and supportive of patients presenting with problems in this area.
- Treatment of paraphilic disorders should focus on how the paraphilic behavior is impacting relationships, productivity, employment, education, and finances.
- If a significant other is available, he or she should be included in the assessment process in order to add to a comprehensive understanding of the problem and in order to correct any misunderstandings.

BASIC INFORMATION

DEFINITION

Idiopathic Parkinson disease (PD) is a progressive neurodegenerative disorder characterized clinically by rigidity, tremor, postural instability, and slowness of movement (bradykinesia).

SYNONYMS

PD
Paralysis agitans

ICD-10CM CODES

G20	Parkinson disease
G21.1	Other drug-induced secondary parkinsonism
G21.11	Neuroleptic induced parkinsonism
G21.2	Secondary parkinsonism due to other external agents
G21.3	Postencephalitic parkinsonism
G21.4	Vascular parkinsonism
G21.8	Other secondary parkinsonism
G21.9	Secondary parkinsonism, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE:

- It is the second most common neurodegenerative disease worldwide and is found in every country.
- Affects more than 1 million people in North America at 0.3% of the population and 1% of people over the age of 60. Prevalence increases with age.
- In those aged >70 yr, 700/100,000 are affected.
- Lifetime risk of Parkinson disease is 2% in men and 1.3% in women.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Tremor (Fig. E1)—typically a resting tremor with a frequency of 4 to 6 Hz that is often first noted in the hand as a pill-rolling tremor (thumb and forefinger). Can also involve the leg and lip. Tremor improves with purposeful movement. Usually starts asymmetrically.
- Rigidity—increased muscle tone that persists throughout the range of passive movement of a joint. Rigidity, like resting tremor, is usually asymmetric at onset.
- Akinesia/bradykinesia—slowness in initiating movement and decrement with repeated movements.
- Postural instability—tested by "pull test." Ask patient to stand in place with back to examiner. Examiner pulls patient back by the shoulders, and proper response would be to take no steps back or very few steps back without falling. Retropulsion is a positive test, as is falling straight back. Postural instability is not usually severe early on. If falls and postural reflexes are greatly impaired early on, then consider other disorders, such as progressive supranuclear palsy.
- Masked facies (hypomimia)—face seems expressionless, giving the appearance of depression. Decreased blink; often there is excess drooling.
- Gait disturbance.
- Stooped posture, decreased arm swing.
- Difficulty initiating the first step; small shuffling steps that increase in speed (festinating gait). Steps become progressively faster and shorter while the trunk inclines further forward.
- Other complaints and findings early on include handwriting becoming smaller (micrographia), and voice becoming softer and often "gruffer" (hypophonia).
- Nonmotor symptoms in Parkinson disease include neuropsychiatric (depression, apathy, impulse control disorders, hallucinations), cognitive, dysautonomia (especially orthostatic hypotension, sexual dysfunction, and anosmia), and sensory abnormalities. These symptoms also may be subject to fluctuations during "on" versus "off" states.
- Common premotor symptoms of Parkinson disease include constipation, anosmia, depression, and REM sleep behavior disorder.

ETIOLOGY

- Most cases are sporadic. Age is the most common risk factor, although a combination of both environmental and genetic factors likely contributes to disease expression.
- Approximately 5% to 10% have a genetic etiology. Several different genes have been identified; these include the parkin gene, a significant cause of early-onset autosomal recessive PD, and *LRRK2*, the most common cause of familial and sporadic parkinsonism.

DIAGNOSIS

- A clinical diagnosis can be made based on a comprehensive history and physical examination. The four cardinal signs used to diagnose PD are (mnemonic = TRAP):
  1. **T**remor (resting, typically 4-6 Hz)
  2. **R**igidity, of the cogwheel type
  3. **A**kinesia/bradykinesia—slowing and decrement of movement
  4. **P**ostural instability—failure of postural "righting" reflexes leading to poor balance and falls
- Bradykinesia plus at least one other sign are necessary, but all four cardinal signs do not need to be present to make a presumptive diagnosis of PD and begin treatment.

DIFFERENTIAL DIAGNOSIS

- Multiple system atrophy—distinguishing features include early autonomic dysfunction (including urinary incontinence, orthostatic hypotension, and erectile dysfunction), parkinsonism, cerebellar signs, and normal cognition
- Dementia with Lewy bodies—parkinsonism with concomitant dementia: Patients often have early hallucinations and fluctuations in level of alertness and mental status
- Corticobasal syndrome—often begins asymmetrically with apraxia, cortical sensory loss in one limb, and sometimes, alien limb phenomenon
- Progressive supranuclear palsy—tends to have axial rigidity greater than appendicular (limb) rigidity. These patients have early and severe postural instability. Hallmark is supranuclear gaze palsy that usually involves vertical gaze (especially downward) before horizontal
- Essential tremor—bilateral postural and action tremor
- Secondary (acquired) parkinsonism (Box 1):
  1. Iatrogenic—any of the neuroleptics and antipsychotics. The high-potency D_2-blocker neuroleptics are most likely to cause parkinsonism. Quetiapine is an atypical antipsychotic with lower risk of parkinsonism. Metoclopramide can also cause parkinsonism. Abuse of methamphetamine has been recently linked to risk of PD
  2. Postinfectious parkinsonism—von Economo encephalitis
  3. Dementia pugilistica—parkinsonism and dementia after repeated head trauma
  4. Toxins (e.g., MPTP, manganese, carbon monoxide)
  5. Cerebrovascular disease "vascular parkinsonism" (basal ganglia infarcts); often lower limbs (especially gait) affected more than upper extremities

WORKUP

- Identification of clinical signs and symptoms associated with PD (see "Physical Findings"), and elimination of conditions that may mimic it with a comprehensive history and physical examination.
- Routine genetic testing is not recommended.

IMAGING STUDIES

Computed tomographic (CT) scan has almost no role in investigations. Magnetic resonance imaging (MRI) of the head may sometimes distinguish between idiopathic PD and other conditions that present with signs of parkinsonism (see "Differential Diagnosis").

Dopamine transporter imaging (DaTscan with [^{123}I]β-CIT SPECT) evaluates the level of dopamine in the striatum and can be used to confirm parkinsonism in atypical cases. DaTscan is approved to distinguish essential tremor from parkinsonism but cannot distinguish between different causes of parkinsonism. Interpretation can be tricky, and routine use is not recommended at this time.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Physical therapy, patient education and reassurance, treatment of associated conditions (e.g., depression) are important. A safe, practical, and reasonable exercise regimen must be encouraged.
- Avoidance of drugs that can induce or worsen parkinsonism: neuroleptics (especially high potency), certain antiemetics (prochlorperazine, trimethobenzamide), metoclopramide, nonselective MAO inhibitors (may induce hypertensive crisis), reserpine, methyldopa.

BOX 1 Causes of Parkinsonism

Primary Parkinsonism
- Parkinson disease (idiopathic/sporadic parkinsonism)

Secondary Parkinsonism
- Drug-induced parkinsonism
  - Neuroleptic drugs
  - Calcium blocker cinnarizine
- Vascular parkinsonism (pseudoparkinsonism)
  - Multi-infarct states
  - Single basal ganglia/thalamic infarct
  - Binswanger disease
- Multisystem degenerative diseases
  - Progressive supranuclear palsy
  - Multiple system atrophy (striatonigral type)
  - Corticobasal degeneration
  - Alzheimer disease
  - Wilson disease (young-onset parkinsonism)
  - Dementia with Lewy bodies
  - Neurofibrillary tangle parkinsonism
- Toxins
  - MPTP
  - Manganese
- Familial parkinsonism
- Postinfectious parkinsonism
  - Creutzfeldt-Jakob disease
  - AIDS
  - Postencephalitis (encephalitis lethargica)
- Miscellaneous causes
  - Hydrocephalus
  - Posttraumatic
  - Tumors
- Metabolic causes (postanoxic)

AIDS, Acquired immunodeficiency syndrome; *MPTP,* 1-methyl-4-phenyl-1,2,2,6-tetrahydropyridine.
From Fillit HM: *Brocklehurst's textbook of geriatric medicine and gerontology,* ed 8, Philadelphia, 2017, Elsevier.

ACUTE GENERAL Rx

- There continues to be controversy whether levodopa or dopamine agonists should be the initial treatment. In younger patients, agonists may be favored; in patients >65 yr, levodopa is typically the preferred initial therapy.
- It is appropriate to initiate pharmacotherapy when required by symptoms; prior practice of waiting for limitation of ADLs is now outdated. Fig. 2 describes an approach to patients with parkinsonism.
- Motor complications do develop during the course of the disease and likely reflect the combination of disease progression together with the side effects of dopaminergic medications.

CHRONIC Rx

- Levodopa therapy:
  1. The most efficacious treatment and cornerstone of symptomatic therapy—should be used with a peripheral dopa decarboxylase inhibitor (carbidopa) to minimize side effects (nausea, lightheadedness, postural hypotension). The combination of the two drugs is marketed under the trade name Sinemet. Levodopa therapy has been found to reduce morbidity and mortality in PD patients.
  2. Usual starting dose is 25/100 mg (carbidopa/levodopa) tid 1 hr before (or after) meals.

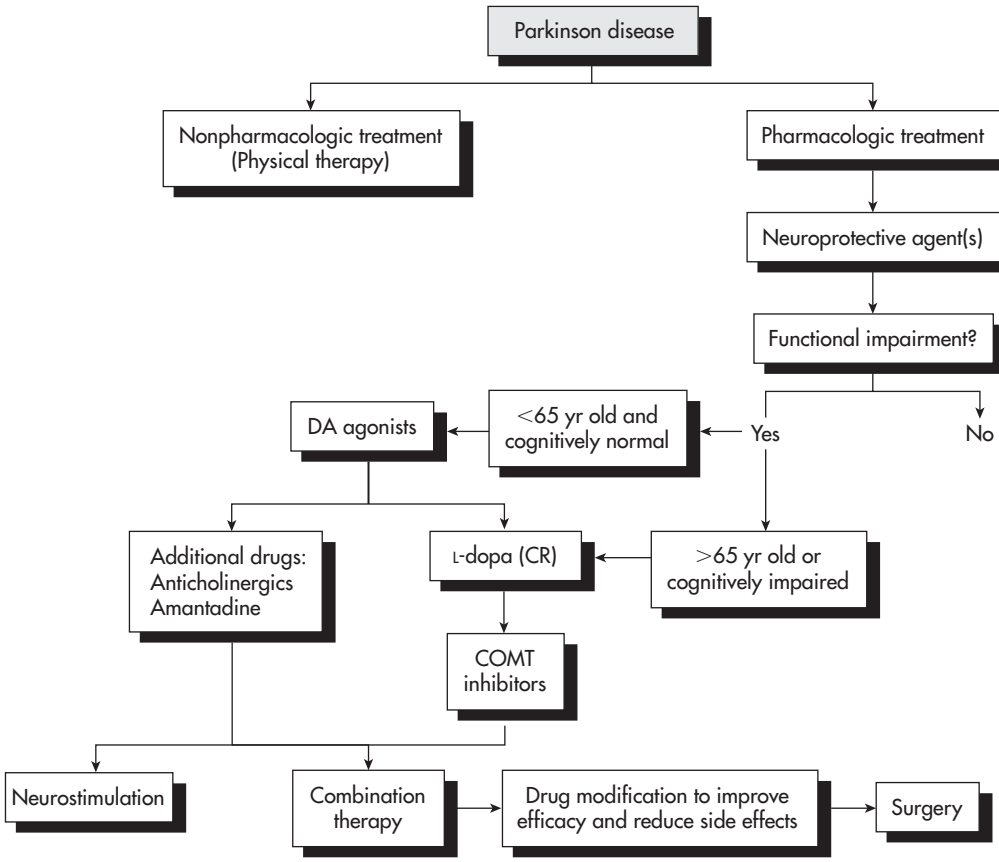

FIG. 2 Diagrammatic representation of a therapeutic approach to patients with parkinsonism. *COMT,* Catechol-O-methyl transferase; *CR,* controlled release; *DA,* dopamine. (Modified from Goldman L, Ausiello D [eds]: *Cecil textbook of medicine,* ed 24, Philadelphia, 2012, WB Saunders.)

3. Controlled-release (Sinemet CR) and extended-release (Rytary) preparations are also available, but their use should be supervised by a neurologist.
4. Stalevo (combination Sinemet and entacapone, a COMT inhibitor). Useful for patients with motor fluctuations (wearing off); has no role in treating early patients with PD.
5. Duopa (carbidopa/levodopa), administered via a 16-hour infusion to the jejunum through either a nasojejunal tube (short-term) or PEG-J tube (long-term), is used for treating motor fluctuations in patients with advanced PD.

- Dopamine receptor agonists (ropinirole, pramipexole, rotigotine) are not as potent as levodopa, but they are often used as initial treatment in younger patients to attempt to delay the onset of complications (dyskinesias, motor fluctuations) associated with levodopa therapy. These medications are more expensive than levodopa. In general, they cause more side effects than levodopa, including nausea, vomiting, light-headedness, peripheral edema, confusion, and somnolence. They can also cause impulse control behaviors such as hypersexuality, binge eating, and compulsive shopping and gambling. Presence of these must be assessed at each visit as the appearance of these side effects is often under-reported and their consequences can be severe. Dopamine agonists also can be associated with a prolonged withdrawal syndrome.
  1. Ropinirole: Initial dose is 0.25 mg tid but must be titrated over the course of 4 weeks to 1 mg tid and then may be increased by 1.5 mg/week to a maximum of 24 mg/day. An extended-release formulation is also available.
  2. Pramipexole: Initial dose is 0.125 mg tid but must be titrated over the course of weeks to 1.5 to 4.5 mg/day in three doses. An extended-release formulation is also available.
  3. Rotigotine: 2 mg to 6 mg/24 hour transdermal patch.
  4. Apomorphine: A dopamine agonist used for acute, intermittent treatment of unpredictable "off" episodes with advanced Parkinson disease.
- COMT inhibitors (entacapone and tolcapone) are used as adjunct to levodopa therapy to treat end-of-dose wearing off.
- MAO-B inhibitors can be used as monotherapy early in the disease or as adjunctive therapy in later stages; they have been shown to have milder symptomatic benefit than dopamine agonists or levodopa. They are well tolerated and easy to titrate. Concurrent use of stimulants and sympathomimetics should be avoided. Certain food restrictions may apply.
  1. Rasagiline: Initial dose is 0.5 mg qd, then 1 mg daily. The ADAGIO study suggests that 1 mg rasagiline may have disease-modifying benefits, but results must be interpreted with caution.
  2. Selegiline: Usual dose, 5 mg bid with breakfast and lunch. Has amphetamine byproduct so has mild stimulant-like effects, which can be beneficial in some patients.
  3. Safinamide: FDA approved as add-on therapy for carbidopa-levodopa that reduces "off time" and increases "on time" with fewer dyskinesias. Starting dose is 50 mg daily for 2 weeks, which can be increased if needed to 100 mg daily.
  4. Istradefylline is the first FDA-approved adenosine A 2A receptor agonist for use as an adjunct to carbidopa/levodopa in adults with Parkinson disease experiencing "off" episodes.
- Amantadine (unclear mechanism of action, but reported to modulate the dopamine and glutamate systems in the CNS) can be used alone early in the disease. Later in the disease, it is especially useful in the treatment of dyskinesias. Dosage is 100 mg tid (titrate q week from 100 mg qd). Must adjust for elderly and renal impairment. The most notable side effect, especially in the elderly, is confusion. An extended-release version is now FDA approved for the treatment of dyskinesia.
- Anticholinergic agents are only helpful in treating tremor but may be more effective than levodopa for tremor in some circumstances. They can also be used to treat drooling in patients with PD. Potential side effects include constipation, urinary retention, memory impairment, and hallucinations. They should be avoided in the elderly.
  1. Trihexyphenidyl: Initial dose, 1 mg PO tid.
  2. Benztropine: Usual dose, 0.5 to 1 mg qd or bid.
- Treatment of nonmotor symptoms: Nonmotor symptoms such as depression, anxiety, irritability, dementia, psychosis, urinary and sexual dysfunction, sleep disturbances such as REM behavior disorder, decreased sense of smell, and impulsive behavior among others often cause a great deal of distress for patients and caretakers alike. Treatable symptoms should be addressed pharmacologically using medications appropriate for elderly patients sensitive to antidopaminergic medications. In addition, two medications are specifically indicated for nonmotor symptoms associated with PD.
- Psychosis: Pimavanserin (Nuplazid) is FDA approved for the treatment of Parkinson disease psychosis and has been shown effective for the treatment of hallucinations and delusions associated with Parkinson disease psychosis. The medication is an inverse agonist of 5-HT2A and 5-HT2C receptors without any evidence of dopamine blockade.
- Parkinson disease dementia: Rivastigmine (Exelon), a cholinesterase inhibitor available both orally and transdermally as a patch (with few GI side effects), is approved to treat not only Alzheimer disease but also Parkinson disease dementia.

SURGICAL OPTIONS

- Pallidal (globus pallidus interna) and subthalamic deep-brain stimulation (subthalamic nucleus) are currently the surgical options of choice for patients with advanced PD; similar improvement in motor function and adverse effects have been reported after either procedure. Compared with ablative procedures, DBS has the advantage of being reversible and adjustable. Thalamic DBS may be useful for refractory tremor. It improves the cardinal motor symptoms, extends medication "on" time, and reduces motor fluctuations during the day. In general, patients are likely to benefit from this therapy if they show a clear response to levodopa. Therefore, when considering DBS, patients should be evaluated for motor response to levodopa by stopping levodopa overnight and evaluating motor response before and after a dose of levodopa.
- Surgery is often limited to patients with disabling, medically refractory problems, and patients must still have a good response to L-dopa to undergo surgery. Yet for many patients, earlier stimulation might provide an improved motor benefit before disability from other symptoms has occurred and should be considered at an earlier stage of PD. DBS results in decreased dyskinesias, fluctuations, rigidity, and tremor.

DISPOSITION

PD usually follows a slowly progressive course leading to disability over the course of several yr. However, every patient will progress individually, and patients should be reassured that this diagnosis does not, by definition, result in being either wheelchair- or bed-bound.

REFERRAL

- Neurology consultation is recommended at initial diagnosis of PD.
- Exercise is important for all patients with PD.
- Participation in outpatient physical therapy program is recommended for patients with moderate to advanced disease.

PEARLS & CONSIDERATIONS

- Asymmetry of symptoms at onset is typical of PD and therefore very useful in distinguishing PD from other causes of parkinsonism.
- Although resting tremor is a common presenting symptom, up to 25% of patients with idiopathic PD do not have classic resting tremor.

Paronychia

BASIC INFORMATION

DEFINITION

Paronychia is a localized superficial infection or abscess of the lateral and proximal nail fold. Paronychia may be acute or chronic.

SYNONYMS

Nail bed infection
Nail bed abscess

ICD-10CM CODES

B37.2	Candidiasis of skin and nail
L03.019	Cellulitis of unspecified finger

EPIDEMIOLOGY & DEMOGRAPHICS

- Acute paronychia affects males and females equally.
- Chronic paronychia is more common in females than males (9:1).
- Acute paronychia most often occurs in children.
- Chronic paronychia usually presents in the fifth or sixth decade of life.
- Paronychia is the most common infection of the hand.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Acute paronychia usually presents with the sudden onset of redness, swelling, and pain with abscess or cellulitis formation in the nail fold. Fluid with purulence is often present (Fig. E1).
- Chronic paronychia is insidious, presenting with mild swelling and erythema of the nail folds.
- Acute paronychia usually involves only one finger.
- Chronic paronychia may involve more than one finger.
- Acute paronychia usually involves the thumb.
- Chronic paronychia commonly involves the middle finger.

ETIOLOGY

- Any disruption of the seal between the proximal nail fold and the nail plate can cause paronychial infections.
- Acute paronychia is almost always bacterial in origin (e.g., methicillin-sensitive *Staphylococcus aureus* [most common, but also consider MRSA], *Streptococcus pyogenes, Enterococcus faecalis, Proteus* and *Pseudomonas* species, and anaerobes).
- Paronychia can also be associated with use of lamivudine and indinavir, which are used in HIV therapy.
- Chronic paronychia is commonly caused by *Candida albicans* (70%), with bacterial organisms accounting for the remaining 30%.
- Trauma, nail biting, hangnails, diabetes, and long-term exposure to water are common predisposing features of paronychia.

DIAGNOSIS

The diagnosis of paronychia is self-evident on physical examination.

DIFFERENTIAL DIAGNOSIS

- Herpetic whitlow caused by herpes simplex
- Pyogenic granuloma
- Viral warts
- Ganglions
- Squamous cell carcinoma

WORKUP

A workup is usually not pursued unless there is treatment failure.

LABORATORY TESTS

- Gram stain and culture any purulent drainage.
- Potassium hydroxide (KOH) mount may show pseudohyphae.

IMAGING STUDIES

Radiographs of the digit if concerned about osteomyelitis

TREATMENT

NONPHARMACOLOGIC THERAPY

- For acute paronychia without purulent drainage, warm soaks tid or qid are helpful. If pus is present, surgical drainage is required (Fig. E2).
- For chronic paronychia, avoid frequent immersion in water or exposure to moisture.

ACUTE GENERAL Rx

- Trimethoprim-sulfamethoxazole DS 1 PO bid for 7 days is usually the antibiotic of choice for acute paronychia as it covers methicillin-susceptible *Staphylococcus aureus* strains (MSSA) and methicillin-resistant *S. aureus* (MRSA) strains.
- Alternative antibiotic choices include dicloxacillin 500 mg qid, cephalexin 500 mg qid, clindamycin, and amoxicillin-clavulanate.
- Surgical drainage is indicated if purulent discharge is noted.
- Use local anesthesia such as digital block or ethyl chloride spray.
- A No. 11 blade scalpel is used to lift the lateral perionychium and proximal eponychium off the nail, facilitating drainage.
- If the pus is located beneath the nail, the lateral edge of the nail can be lifted off the nail bed and excised.

FIG. E1 Paronychia with pus visible at the paronychial fold and a collection extending below the eponychial fold. (From Cameron JL, Cameron AM: *Current surgical therapy*, ed 12, Philadelphia, 2017, Elsevier.)

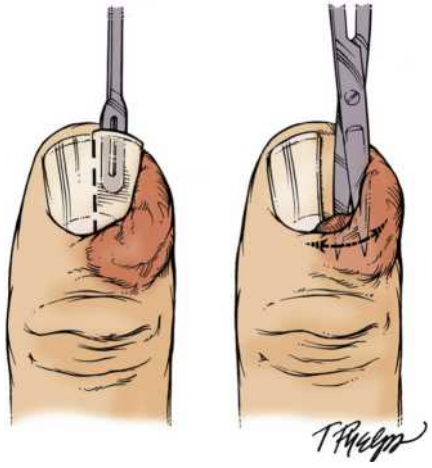

FIG. E2 Surgical drainage of acute paronychia. The lateral nail on the affected side is elevated gently from the nail bed, and a longitudinal strip of nail is removed. If this does not decompress the infection adequately, the margins of the nail fold are opened gently to drain the adjacent soft tissues. (From Cameron JL, Cameron AM: *Current surgical therapy*, ed 12, Philadelphia, 2017, Elsevier.)

CHRONIC Rx

- If no fungal organism is found, tincture of iodine (2 drops bid) helps keep the nail and skin dry.
- Chronic paronychia caused by *Candida albicans* is treated with topical antifungal agents (e.g., miconazole or ketoconazole applied tid).
- Unresponsive cases may be treated with oral itraconazole, fluconazole, or terbinafine, but this should be done in consultation with dermatology and/or infectious disease as it requires prolonged therapy and has significant drug-to-drug interactions.
- One study suggested that topical steroids such as methylprednisolone aceponate were more effective than antifungals, implying that the origin is chronic dermatitis, not fungus. Topical tacrolimus ointment 0.1% has also been found effective.
- Surgery may be needed in refractory cases.

DISPOSITION

- Most acute paronychias with appropriate treatment resolve within 7 to 10 days.
- Osteomyelitis is a potential complication of paronychia.
- Untreated chronic paronychia leads to thickening and discoloration with eventual nail loss.

REFERRAL

Chronic paronychia refractory to topical medical therapy is best referred to dermatology and/or infectious disease. A hand surgeon is consulted if abscess drainage or surgery is being considered.

PEARLS & CONSIDERATIONS

COMMENTS

The gastrointestinal tract, including the mouth and bowel, and the genitourinary tract in women are the usual sources of *C. albicans* in chronic paronychia.

Paroxysmal Cold Hemoglobinuria

BASIC INFORMATION

DEFINITION

Paroxysmal cold hemoglobinuria (PCH) was the first, albeit rarest, autoimmune hemolytic anemia to be identified. It is characterized by transient or episodic massive intravascular hemolysis after exposure to cold temperatures and was first described in patients with secondary or tertiary syphilis. In modern times, chronic PCH is very rare, usually occurs in the elderly, and is associated with malignancy. Most cases are of the acute transient type, which is usually idiopathic in adults and secondary to a viral syndrome or immunization in children.

SYNONYMS

PCH
Donath-Landsteiner hemoglobinuria

ICD-10CM CODE

D59.6	Hemoglobinuria due to hemolysis from other external causes

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Estimated at 0.4 cases per 100,000 people
PREVALENCE: Accounts for up to 5% of all adult hemolytic anemias and 30% to 40% of childhood cases
PREDOMINANT SEX AND AGE: Mild male sex predilection with reported male-to-female ratio of 2:1 to 5:1. PCH affects both young children (acute form) and the elderly (chronic form).
GENETICS: None
RISK FACTORS: Age (most common in young population), infections, and neoplasms have been associated with the development of Donath-Landsteiner antibody.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Within min to a few hours after cold exposure, there is a sudden onset of fever, rigors, and chills followed by red to brown urination.
- Associated symptoms include back, leg, and abdominal pain.
- Headaches, nausea, vomiting, diarrhea, and esophageal spasm are common.
- Oliguria and anuria can develop following renal dysfunction.
- May be associated with Raynaud phenomenon.
- Associated with cold urticaria.
- Transient splenomegaly and hepatomegaly with jaundice may occur.
- Symptoms and gross hemoglobinuria usually resolve within hours.
- Symptoms believed to be mediated by smooth muscle dysfunction as a result of nitric oxide deficiency associated with hemoglobinemia.

ETIOLOGY

- The Donath-Landsteiner antibody is a biphasic, usually polyclonal, immunoglobulin G (IgG). It is known to bind to various antigens such as I-, i-, p-, Pr-, which are normally present on the red blood cell (RBC) surface, yet the glycosphingolipid P antigen is considered its primary target. The antibody in PCH also has thermal properties. It sensitizes RBCs in peripheral circulation (where typical thermal range for RBC binding is <20° C [<68° F]). As blood warms to 37° C [98.6° F] in the central circulation, the antibodies dissociate upon rewarming, but complement remains attached to the RBCs and ensures hemolysis.
- In children, the appearance of the antibody usually follows the onset of a viral respiratory illness by 1 to 3 wk. Symptoms may persist for several wks.
- PCH has been associated with multiple infectious pathogens, including syphilis, *Haemophilus influenzae,* Epstein-Barr virus (EBV), cytomegalovirus (CMV), influenza A, varicella, measles, mumps, adenovirus, parvovirus B19, coxsackie A9, *Mycoplasma pneumoniae,* and *Klebsiella pneumoniae.*
- Chronic PCH has also been associated with hematologic and solid organ malignancy such as small cell lung cancer, Hodgkin and non-Hodgkin lymphoma, primary myelofibrosis, myelodysplastic syndrome, and chronic lymphocytic lymphoma.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cold agglutinin disease, paroxysmal nocturnal hemoglobinuria, malaria, drug-induced hemolytic anemia, and hemolytic transfusion reaction
- Other causes of acute massive intravascular hemolysis and myoglobinuria secondary to rhabdomyolysis
- Table E1 differentiates various types of autoimmune hemolytic anemias

WORKUP

CBC, U/A, peripheral blood smear, hemolysis labs (LDH, total bilirubin, haptoglobin, reticulocyte count), iron studies, indirect and direct Coombs, complement levels, flow cytometry for PNH testing for CD55 or CD59 on the RBC membrane if clinically indicated, viral studies (if clinically warranted with thick and thin smear to rule out malaria)

LABORATORY TESTS

- The presence of IgG that reacts with the RBC at reduced temperatures but not at body temperature. In the Donath-Landsteiner test, a patient's serum is incubated with papainized pooled donated RBCs and complement at 4° C (39.2° F), and then warmed to 37° C (98.6° F). Lysis is observed in a positive test.
- A more sensitive test involves using radiolabeled monoclonal anti-IgG. This is incubated at 4° C (39.2° F) with the patient's serum and donor RBCs. The degree of radioactivity on the separated RBCs will be elevated in PCH compared with a control run at 37° C (98.6° F).
- Elevated bilirubin and lactate dehydrogenase, free plasma hemoglobin, low haptoglobin, low complement (C2, C3, C4).
- Abnormal RBC forms on the peripheral blood smear such as poikilocytosis, spherocytosis, anisocytosis, and nucleated RBCs.
- Erythrophagocytosis by neutrophils and monocytes may be seen.

IMAGING STUDIES

If chronic PCH, imaging could be considered to rule out underlying malignancy as the etiology when clinically warranted.

TREATMENT

NONPHARMACOLOGIC THERAPY

The mainstay of treatment is the avoidance of exposure to cold and presence of supportive care.

ACUTE GENERAL Rx

- In children in particular, warmed, packed RBC transfusion may be necessary because the anemia may become life threatening and hemolysis may be ongoing for several wk.
- Testing and treatment for underlying secondary condition.
- Hydration and alkalinization of the urine may be necessary to prevent renal failure.
- Plasma exchange therapy with 5% albumin fluid replacement has been successfully employed.
- Treatment with rituximab has resulted in termination of hemolysis in a case report.
- Azathioprine and cyclophosphamide have also been suggested in case reports.
- Steroids, although commonly used, have not been shown to be beneficial.
- Splenectomy is not indicated, as it plays no role in the pathogenesis of the hemolysis in PCH.
- Folic acid supplementation to prevent consumptive folate deficiency.

CHRONIC Rx

Several case reports suggest that rituximab and immunosuppressants such as azathioprine may be effective. Treatment of the underlying cause such as infection or malignancy may also help in chronic disease. In addition, cold avoidance is appropriate for all patients.

COMPLEMENTARY & ALTERNATIVE MEDICINE

None

DISPOSITION

- Postinfectious varieties are self-limited.
- Adult idiopathic form is generally manageable by avoiding cold exposure.

REFERRAL

To hematologist to aid in diagnosis and management

TABLE E1 Characteristics of Autoimmune Hemolytic Anemia

Characteristic	Type of Autoimmune Hemolytic Anemia		
	Warm Autoimmune Hemolytic Anemia	Cold Agglutinin Disease	Paroxysmal Cold Hemoglobinuria
Antibody isotope	IgG, rare IgA, IgM	IgM	IgG
Direct antiglobulin test (DAT) result	IgG and/or C3	C3	C3
Antigen specificity	Multiple, primarily Rh	i/I, Pr	P
Hemolysis	Primarily extravascular	Primarily extravascular	Intravascular
Common disease associations	B-cell neoplasia/ lymphoproliferative, collagen-vascular	Viral, neoplasia	Syphilis, viral

From Hoffman R et al: *Hematology: Basic principles and practice,* ed 5, Philadelphia, 2009, Churchill Livingstone.

SUGGESTED READINGS

Shanbhag S et al: Paroxysmal cold hemoglobinuria, *Hematol Oncol Clin North Am* 29(3):473-478, 2015.

PEARLS & CONSIDERATIONS

COMMENTS

- PCH is associated with brown or red discoloration of urine after cold exposure in adults or after a viral infection in children.
- PCH can be associated with viral or bacterial infections, including syphilis, *H. influenzae*, EBV, CMV, influenza A, varicella, measles, mumps, and adenovirus, or malignancy, especially in adults.
- PCH can cause life-threatening hemolysis in children.

PREVENTION

None

AUTHORS: **Hussain Mohammad H. Naseri, MD,** and **Donny V. Huynh, MD**

Paroxysmal Nocturnal Hemoglobinuria

BASIC INFORMATION

DEFINITION

Paroxysmal nocturnal hemoglobinuria (PNH) is an acquired clonal stem disorder characterized by episodes of bone marrow failure, hemolytic anemia, and recurrent venous thrombosis.

SYNONYM

PNH

ICD-10CM CODE

D59.5 Paroxysmal nocturnal hemoglobinuria [Marchiafava-Micheli]

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence: 2 to 5 per million in the U.S.
- Affects patients of any age (reported spectrum 6 to 82 yr) but most common in patients aged 30 to 50 yr
- Affects both sexes (slight female predominance) and all races

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The initial manifestations in PNH are as follows:

- Hemoglobinuria: Typically the first morning void reveals dark urine, with progressive clearing during the day. Hemolysis occurs at night as the P_{CO_2} level rises during sleep, lowering pH levels and facilitating complement-mediated lysis.
- Hemolysis: In addition to the circadian hemolysis and resulting hemoglobinuria, episodes of hemolytic exacerbations can accompany infections, menstruation, transfusion, surgery, iron therapy, and vaccinations. Symptoms of severe hemolysis include chest, back, or abdominal pain, headache, fever, malaise, and fatigue.
- Aplastic anemia: This may be the presenting manifestation of PNH (therefore PNH must be in the differential diagnosis of aplastic anemia) or may develop as a later complication of PNH.
- Thrombosis: This is a leading cause of death in PNH and occurs in 40% of patients. It can occur as deep vein thrombosis in the lower extremities, subclavian vein, portal or mesenteric vein, hepatic vein (Budd-Chiari syndrome), or cerebrovascular thromboses.
- Renal failure: Acute renal failure associated with massive hemoglobinuria (acute tubular necrosis) or progressive renal failure associated with thrombosis within renal small veins.
- Dysphagia.
- Infections (associated with leukopenia or immunosuppressive therapy).
- Physical findings include:
  1. Pallor (anemia)
  2. Jaundice (hemolysis)
  3. Splenomegaly
  4. Unilateral extremity swelling (DVT)
  5. Ascites (Budd-Chiari syndrome)

ETIOLOGY & PATHOGENESIS

- Hemolysis in PNH is complement mediated and is a direct result of PNH cells acquiring a deficiency of complement regulatory proteins; the erythrocytes are abnormally sensitive to acidified serum.
- Patients have two populations of red blood cells (RBCs): Some sensitive to hemolysis (PNH III cells) and others not (PNH I cells), in variable proportions (10% to 75% PNH III cells). Approximately 20% PNH III are required for hemoglobinuria to be detectable.
- The RBC defects in PNH are in the membrane proteins as follows:
  1. Decay-accelerating factor deficiency
  2. Membrane inhibitor of reactive lysis deficiency
  3. C-8 binding protein deficiency
- Protein deficiencies are the result of an acquired mutation located in the X chromosome, which regulates glycosyl phosphatidyl inositol (GPI). GPI anchors the above-mentioned proteins in the RBC membrane; GPI-deficient RBCs proliferate as an abnormal clone. Hemolysis is caused by the absence of decay-accelerating factor (CD55) and the membrane inhibitor of reactive lysis (CD59), which are glycosylphosphatidylinositol-dependent complement regulatory proteins.
- Hemolysis in PNH is chronic because of a continuous state of complement activation, but paroxysms resulting in brisk hemolysis coincide with increases in complement activation triggered by surgery, infection, or inflammation.
- The pathophysiology of the relation of PNH and aplastic anemia is unknown. The leading hypothesis is that PNH stem cells have a conditional survival advantage in the setting of an autoimmune attack (e.g., aplastic anemia) that targets the bone marrow.

DIAGNOSIS

It is useful to classify PNH patients as either "classical" or "hypoplastic." This can usually be accomplished by ordering a complete blood count, reticulocyte count, LDH level, peripheral blood flow cytometry for PNH, and BM aspirate, biopsy, and cytogenetics. Most, but not all, patients can be readily subdivided into classical or hypoplastic PNH, a distinction that aids with therapeutic decisions.

Patients with classical PNH tend to have mild to moderate cytopenias, a normocellular to hypercellular BM, an elevated reticulocyte count, a markedly elevated LDH level, and a relatively large PNH granulocyte population (>30%).

In contrast, hypoplastic PNH patients present with manifestations similar to that of aplastic anemia or hypoplastic MDS. These patients typically present with moderate to severe cytopenias, a hypocellular BM (<25% cellularity), a decreased corrected reticulocyte count, a normal or mildly elevated LDH level, and a relatively small (<20%) PNH granulocyte population.

Clinical situations:

- Intravascular hemolysis
- Hemoglobinuria
- Pancytopenia associated with hemolysis
- Iron deficiency associated with hemolysis
- Recurrent venous thrombosis
- Recurrent episodes of abdominal pain, headache, or back pain associated with hemolysis

DIFFERENTIAL DIAGNOSIS

- See "Anemia, Autoimmune Hemolytic" in Section I.
- See "Anemia, Aplastic" in Section I.
- See "Anemia" algorithm in Section III.

LABORATORY TESTS

- Complete blood count: Anemia, leukopenia, thrombocytopenia
- Bone marrow aspiration and biopsy
- RBC smear: Reticulocytosis, spherocytosis (Fig. E1)
- Negative Coombs test
- Elevated lactate dehydrogenase
- Low serum haptoglobin
- Low serum iron saturation, low ferritin
- Elevated urine hemoglobin, urine urobilinogen, urine hemosiderin
- Positive Ham test (acidified serum RBC lysis)
- Assaying granulocytes is the most reliable method of diagnosing PNH because they are not affected by blood transfusions. Identification of GPI-anchored protein deficiency on hematopoietic cells by using monoclonal antibodies or flow cytometry; flow cytometric analysis of granulocytes is the best way to diagnose PNH. Most hematologists prefer to use FLAER over monoclonal antibodies on granulocytes and monocytes because of improved sensitivity and specificity; anti-CD59 is the most reliable marker on erythrocytes
- Cytogenetic studies are not diagnostic

TREATMENT

- Eculizumab, a humanized antibody that inhibits the activation of terminal complement components, is an effective approved therapy for PNH; it reduces intravascular hemolysis, hemoglobinuria, and need for transfusion in patients with PNH. It is very expensive and requires lifelong administration. Vaccination against meningococcus is mandatory before eculizumab administration due to increased susceptibility to neisserial infection.
- Prednisone (0.5 to 1.0 mg/day) for 6 to 8 wk is helpful to reduce complement activation if eculizumab is unavailable.
- Danazol 400 mg/day can also decrease hemolysis.

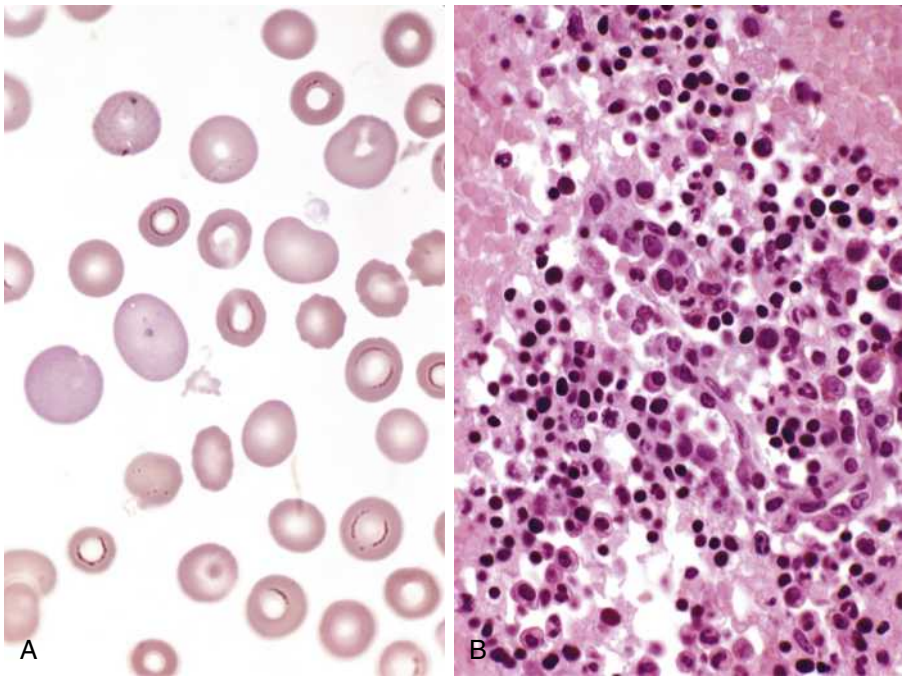

FIG. E1 Paroxysmal nocturnal hemoglobinuria. A, Large polychromatophilic red cells (shift cells) are seen following an episode of hemolysis. **B,** The bone marrow biopsy shows marked erythroid hyperplasia. (From Jaffe ES et al: *Hematopathology,* Philadelphia, 2011, Saunders.)

- Iron replacement, folic acid supplementation: All patients with classical PNH should be prescribed folic acid (1 to 2 mg/day). Iron supplementation is recommended in those with absent iron stores.
- Packed red blood cell transfusions.
- Treatment and prevention of thrombosis (heparin, warfarin).
- Avoidance of oral contraceptives.
- Allogeneic bone marrow transplantation is a therapeutic option that is offered in cases of eculizumab failure.

REFERRAL

To hematologist

PROGNOSIS

- Median survival is 10 to 15 yr.
- 25% survive up to 25 yr.
- With thrombosis at presentation, only 40% survival to 4 yr.
- 1% incidence of leukemia.
- 5% incidence of myelodysplastic syndrome.
- Death often results from thrombosis or progressive pancytopenia.

Patellofemoral Pain Syndrome PTG ALG

BASIC INFORMATION

DEFINITION

Patellofemoral pain syndrome is overuse or overload of the patellofemoral region leading to anterior knee pain.

SYNONYMS

PFPS
Retropatellar pain syndrome
Runner's knee
Lateral facet compression syndrome
Idiopathic anterior knee pain

ICD-10CM CODES

M22.2	Patellofemoral disorders
M25.569	Pain in unspecified knee

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Estimated >20% of adolescents. Patellofemoral pain syndrome (PFPS) is the most common diagnosis in outpatients presenting with knee pain. PFPS also constitutes 16% to 25% of all injuries to runners.
PREDOMINANT SEX AND AGE: Nearly 2:1 female predominance; disproportionately affects active adolescents and adults in the second and third decades of life.
RISK FACTORS: Increase in physical activity intensity or duration, overuse, joint overload, trauma, anatomic abnormalities, malalignment, patellar hypermobility, quadriceps weakness.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Gradual or acute onset of anterior knee pain
- Sometimes localized under or around the patella
- Also described as a catching sensation under the patella
- Worsened pain with squatting, running, prolonged sitting, or ascending or descending steps
- Effusion implies intraarticular pathology not explained by PFPS
- Pain may be elicited by compression of the patella into the trochlear groove while the leg is extended

ETIOLOGY

No clear consensus; likely multifactorial, including muscle overuse or joint overload with malalignment and/or trauma potentially contributing, resulting in imbalances in the forces controlling patellar tracking during knee flexion and extension.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Patellofemoral arthritis
- Patellar instability
- Patellar stress fracture
- Osgood-Schlatter disease (osteochondritis of the tibial tubercle)
- Articular cartilage injury
- Prepatellar bursitis
- Pes anserine bursitis
- Iliotibial band syndrome
- Plica synovitis (also called plica syndrome)
- Chondromalacia
- Bony abnormalities
- Bone tumors
- Patellar tendinopathy
- Other: Referred pain from lumbar spine or hip joint pathology, osteochondritis dissecans, Sinding-Larsen-Johansson syndrome (patellar apophysitis), symptomatic bipartite patella

WORKUP

- PFPS is a clinical diagnosis of exclusion; evaluate and rule out other possibilities on the differential.
- Physical exam should include:
  1. Dynamic patellar tracking
     a. Can be assessed by having the patient perform a single leg squat and stand.
     b. Positive "J" sign—lateral tracking of the patella when knee is moved from flexion to extension.
  2. Patellar mobility testing
     a. Displace patella medially; displacement >3 quadrants is considered hypermobile.
  3. Patellar grind (or inhibition) test
     a. With knee extended, push patella inferiorly into the trochlear groove.
     b. Ask patient to contract quadriceps muscle while maintaining gentle pressure on the patella to prevent movement of the patella superiorly.
     c. Positive test if pain is produced.
  4. Patellar tilt test
     a. Assesses for tightness of the lateral structures, which predisposes to PFPS.
     b. Extend knee and grasp patella between thumb and forefinger.
     c. Compress medial aspect of patella posteriorly while elevating lateral aspect.
     d. Positive test if lateral aspect is fixed and cannot be raised to a horizontal position (0 degrees).

IMAGING STUDIES

- No imaging is necessary in the initial workup.
- Consider plain films if symptoms do not improve after 1 to 2 mo of therapy.

TREATMENT

There is a general lack of consensus. Management should focus on the implementation of a comprehensive rehabilitation program.

NONPHARMACOLOGIC THERAPY

- Physical therapy
  1. Quadriceps, hamstring, iliotibial band, and calf-stretching exercises
  2. Quadriceps and hip abductor strengthening
  3. Core muscle strengthening might improve pain and dynamic balance

ACUTE GENERAL Rx

- Short-term (2 to 3 wk) nonsteroidal anti-inflammatory drugs or acetaminophen for pain relief
- Activity modification
- Ice for 10 to 20 min after activity

CHRONIC Rx

- Physical therapy: Strengthening and flexibility exercises.
- Consider arch supports or evaluation for custom orthotics.
- Spontaneous resolution may occur in some cases, although 50% of individuals with PFPS will have long-term symptoms (>5 yr after diagnosis).

DISPOSITION

Outpatient management

REFERRAL

Consider referral to orthopedics for surgical evaluation as a last resort if conservative therapies fail. Surgical options include release of the lateral retinaculum, articular cartilage procedures, and proximal realignment, usually with anteromedialization of the tibial tubercle.

PEARLS & CONSIDERATIONS

PATIENT & FAMILY EDUCATION

BASIC INFORMATION

DEFINITION

The ductus arteriosus (DA) is a fetal vascular communication between the proximal descending aorta and main pulmonary artery. It derives from the left sixth aortic arch. During development, this connection allows right ventricular blood to bypass the increased pulmonary vascular resistance of the nonfunctional fetal lungs into the low resistance system of aortic and placental circulation. Closure typically occurs first functionally within hours of delivery, then anatomically within the first few days, though this may take longer in premature infants. If a ductus fails to close within 72 hours of birth in a full-term infant, diagnosis of a patent ductus arteriosus (PDA) can be made. Postnatal DA closure and obliteration are driven by multiple mechanisms, including increased oxygen saturation, decreased levels of endogenous prostaglandins and nitric oxide, and intimal proliferation and fibrosis. Failure of complete closure results in PDA, which may have hemodynamic consequences, the severity of which depends on the size and length of the defect.

SYNONYM

PDA

ICD-10CM CODE
Q25.0 Patent ductus arteriosus

EPIDEMIOLOGY & DEMOGRAPHICS

- PDA is the third most common congenital abnormality.
- Prevalence is 2.9 per 10,000 live births. Incidence has increased due to improved survival of premature infants (especially those born <30 wk gestation).
- Female predominance 2:1.
- Genetics play a role in PDA, with sibling recurrence risk of approximately 5%.
- Risk factors include first trimester rubella infection, high altitude birth, chromosomal abnormalities such as Down syndrome, and associated cyanotic congenital heart disease.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Continuous, "machinery-like" murmur, appreciated over the left scapula and in the left infraclavicular area in patients with left-to-right shunting (Fig. E1). The murmur intensity increases during systole and peaks at the second heart sound. Oftentimes, the increase in flow through the aortic valve produces a flow murmur at the right upper sternal border.
- The apical impulse may be hyperdynamic if there is significant left-to-right shunting.
- Widened pulse pressure.
- S1 is normal, but S2 may be split with an accentuated P2 component if there is pulmonary hypertension. An S3 may be appreciated if shunt volume is significant.
- Increased jugular venous pressure (with RV failure):
  1. When the defect has resulted in irreversible pulmonary hypertension, no murmur may be present due to minimal shunt. However, cyanosis and clubbing, particularly of the feet (differential cyanosis), may develop.
- Exertional dyspnea, fatigue, and signs of volume overload or congestive heart failure.
- Atrial fibrillation due to progressive left atrial enlargement.
- Small defects are generally asymptomatic and may be diagnosed later in life.
- Fig. E2 shows the anatomy of patent ductus arteriosus.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Rule out other causes of continuous murmurs such as aortopulmonary shunts or window, coronary fistula, ruptured sinus of Valsalva aneurysm, aortic-cameral fistula, and mixed aortic stenosis and regurgitation.
- Coarctation of the aorta also will have a murmur over the scapula, but has an arm-leg blood pressure gradient and hypertension.
  1. In patients with Eisenmenger syndrome, consider ASD and VSD in the differential diagnosis.

WORKUP

- ECG:
  1. When the defect is large enough to cause left-sided volume overload, there may be LA enlargement, LV hypertrophy.
  2. When pulmonary hypertension has occurred, right-axis deviation, RVH and P pulmonale may be present.
- Chest x-ray
- Echocardiography (Fig. E3)
- Cardiac magnetic resonance imaging (MRI) or CT
- Cardiac catheterization
- Adults with PDA should have oxygen saturation measured in feet and hands to rule out right-to-left shunting

IMAGING STUDIES

- Chest x-ray may be normal. In moderate to large shunts, cardiomegaly, left heart enlargement, and increased pulmonary vascular markings may be present.
- Echocardiography with Doppler flow studies is generally diagnostic. The parasternal short-axis and suprasternal views can show the presence of the PDA, the size of the defect, and the direction of shunting. Color flow Doppler may be useful to view even tiny ductus flow. Echocardiography can also estimate the degree of shunt by the effects of the PDA on left heart chamber sizes and may be used to determine the pulmonary: Systemic shunt ratio (Qp:Qs), which describes shunt size. Lastly, echocardiography can measure pulmonary artery pressures to determine if pulmonary hypertension has developed.

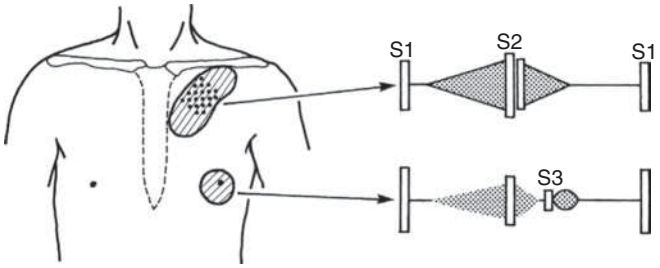

FIG. E1 Cardiac findings of patent ductus arteriosus. A systolic thrill may be present in the area shown by dots. (From Park MK: *Park's pediatric cardiology for practitioners,* ed 6, Philadelphia, 2014, WB Saunders.)

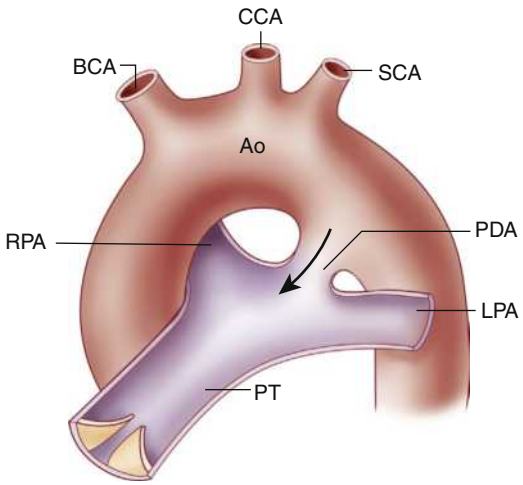

FIG. E2 Anatomy of a patent ductus arteriosus. Note the relationships among the position of the ductus, left subclavian artery, and pulmonary artery bifurcation. *Ao,* Aorta; *BCA,* brachiocephalic; *CCA,* common carotid artery; *LPA,* left pulmonary artery; *PDA,* patent ductus arteriosus; *PT,* pulmonary trunk; *RPA,* right pulmonary artery; *SCA,* subclavian artery. (From Perloff JK [ed]: *Clinical recognition of congenital heart disease,* ed 4, Philadelphia, 1994, WB Saunders.)

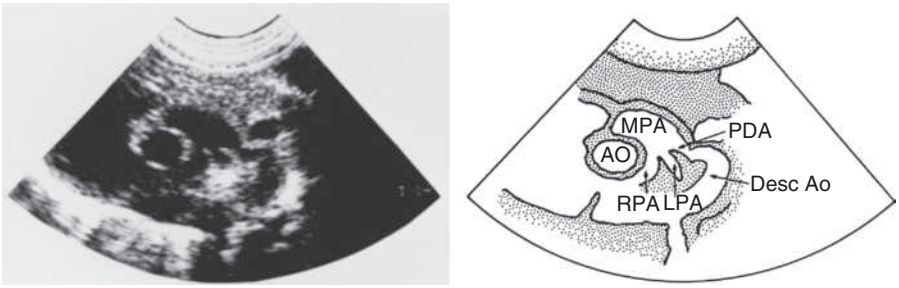

FIG. E3 Parasternal short-axis view demonstrating patent ductus arteriosus *(PDA)* that connects the main pulmonary artery *(MPA)* and the descending aorta *(Desc Ao).* *AO*, Aorta; *LPA*, left pulmonary artery; *RPA*, right pulmonary artery. (From Park MK: *Park's pediatric cardiology for practitioners,* ed 6, Philadelphia, 2014, WB Saunders.)

- Transesophageal echocardiography is modestly helpful, especially when patients have poor acoustic windows.
- Cardiac MRI and CT: May be useful if echo is not diagnostic; the PDA may be directly visualized and its morphology described with either technique. MRI is gold standard for assessing LV size and function. It can determine whether the left-sided chambers are enlarged and establish the degree of shunting using phase contrast imaging to determine the Qp:Qs noninvasively. MRI is also useful to assess for associated lesions; cardiac CT can offer similar information at the price of radiation exposure.
- Cardiac catheterization: Left- and right-heart catheterization can be used when the diagnosis remains unclear. It can also help to estimate the degree of left-to-right shunting, demonstrate PDA morphology, establish right-sided pressures and, if elevated, assess the response to vasodilators, and attempt closure where technically feasible.
- PDAs are classified based on the ratio of left-to-right shunting:
  1. Small: Qp:Qs <1.5:1
  2. Moderate: Qp:Qs 1.5 to 2.2:1
  3. Large: Qp:Qs >2.2:1
- "Silent" PDA refers to a very small PDA with minimal shunt and no audible murmur, discovered incidentally by imaging studies.

Rx TREATMENT

PHARMACOLOGIC THERAPY

- Cyclooxygenase inhibitors (e.g., indomethacin, ibuprofen) are useful agents for PDA closure in the premature infant. These inhibit local prostaglandin synthesis, which is often necessary for the duct to remain open. These are ineffective in term infants and older patients.
- Antibiotic prophylaxis is recommended only in patients with a history of endocarditis, or within 6 mo of closure device placement.
- In patients with signs and symptoms of volume overload, diuretics and digoxin may be used until formal device or surgical closure can be performed.
- In older patients with secondary pulmonary hypertension, pulmonary vasodilators can be extremely helpful in improving symptoms and mortality, as well as potentially allowing safe closure of the defect.
- In the absence of indications for closure, timing and treatment for PDA vary among physicians and are not well standardized.

SURGICAL Rx

- Device closure is the preferred PDA closure method when technically suitable. Closure of a PDA is considered if the following are present:
  1. Signs of left ventricular volume overload.
  2. Patients with pulmonary arterial hypertension and pulmonary arterial pressure <2/3 of systemic pressure, or pulmonary vascular resistance <2/3 of systemic vascular resistance.
  3. Either pulmonary arterial hypertension and pulmonary artery pressure >2/3 of systemic pressure or pulmonary vascular resistance >2/3 of systemic vascular resistance when one of the following is present:
     a. Net left to right shunt (Qp:Qs >1.5)
     b. Pulmonary vascular reactivity to testing (preferred with nitric oxide)
  4. Consider closure in patients with small PDAs with continuous murmur.
- Avoid PDA closure in patients with Eisenmenger syndrome or exercise-induced lower limb desaturation.
- Closure of PDA should not be performed in patients with a very small PDA without murmur.
- More than 95% of PDAs can successfully be closed percutaneously with a low rate of complications. Various occlusion devices may be used, depending on the underlying morphology.
- In patients with pulmonary hypertension, treatment with pulmonary vasodilators should be considered prior to closure.
- Surgical closure may be performed when a patient is undergoing cardiac surgery for other reasons or when the PDA is not suitable for device closure, such as in the case of very large defects, distorted ductal anatomy (e.g., aneurysm, endarteritis), or when the child is too small (<6 kg).
- Patients with severe, irreversible pulmonary hypertension are not recommended for PDA repair as they may require right-to-left shunting to maintain cardiac output.

DISPOSITION

- Long-term outcome depends on the size of the lesion and the associated degree of left-to-right shunting. Defects with a small shunt generally have good outcomes, except in rare instances of endarteritis (<0.25% annually). Patients with moderate shunts may develop left atrial and left ventricular volume overload and shortness of breath or arrhythmias. Very large shunts may lead to early heart failure, with subsequent Eisenmenger syndrome (fixed pulmonary hypertension with reversal of shunt causing cyanosis) if unrepaired.
- Infective endarteritis is uncommon and can generally be treated medically. Vegetations usually develop at the site where the high-velocity jet lesion enters the PA, and there are rare cases of septic embolization to the lung. Staphylococcal and streptococcal species are commonly implicated.
- Aneurysm of the DA has an unclear incidence and often spontaneously resolves. Rarely, these aneurysms may clinically manifest as thoracic masses, causing compression of adjacent structures with subsequent hoarseness or left bronchial obstruction, prompting surgical resection.
- Basic preoperative assessment for patients with adult congenital heart disease (ACHD) should include systemic arterial oximetry, an ECG, chest radiograph, TTE, and blood tests for full blood count and coagulation screen.
- Intracardiac shunts are considered moderate risk in preoperative evaluation for noncardiac procedures. High-risk features include severe systolic dysfunction (EF <35%), severe pulmonary hypertension (either primary or secondary), cyanotic heart disease, or severe left-side outlet obstruction.
- Clinical follow-up is recommended for adult patients to exclude residual deficits, pulmonary hypertension and LV dilation and dysfunction, and atrial arrhythmias.
- Patients with small, hemodynamically insignificant PDA should be reexamined every 3 to 5 yr to assess for cardiopulmonary decompensation.
- Infective endocarditis prophylaxis for dental procedures:
  1. Prophylaxis is not indicated for an unrepaired PDA or for a repaired PDA with no residual shunt after 6 mo.
- Prophylaxis is indicated for a repaired PDA in the first 6 mo following the repair, or where prosthetic material is present and there is a residual defect.
- The estrogen-containing oral contraceptive pill is not recommended in ACHD patients at risk of thromboembolism, such as those with cyanosis related to an intracardiac shunt, atrial fibrillation, severe PAH, or Fontan repair.
- Women with a repaired PDA generally can undergo pregnancy and delivery normally. Those with an unrepaired defect of a size that would ordinarily be repaired are recommended to undergo repair before becoming pregnant.

Patent Foramen Ovale

BASIC INFORMATION

DEFINITION

- Patent foramen ovale (PFO) is a vestige of the fetal circulation, and results from failure of the primum and secundum septa to fuse postnatally. Persistence of the one-way flap valve overlying this foramen ovale allows right to left blood flow when right atrial pressure exceeds that of the left.
- Foramen ovale remains open during intrauterine life, in a valve-like manner, to allow highly oxygenated blood to reach the left atrium from the inferior vena cava. High right atrial pressure in the fetus keeps it open.
- Soon after birth, as the pulmonary circulation fills, the left atrial pressure rises higher than that of the right atrium. This pushes the septum primum against the septum secundum, closing the right-to-left pathway through the foramen ovale.

SYNONYM

PFO

ICD-10CM CODE

Q21.1 Atrial septal defect

EPIDEMIOLOGY & DEMOGRAPHICS

- PFO fails to close in as much as one fourth of the population.
- PFO has similar frequency among males and females.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most patients with isolated PFO are asymptomatic.
- It cannot be detected on clinical examination.

COMPLICATIONS:

- Cryptogenic stroke (particularly <55 yr)
- The proposed mechanism of stroke with PFO includes paradoxical embolization, in situ thrombosis within the canal of the PFO, associated atrial arrhythmia, and concomitant hypercoagulable state
- Migraine with aura
- Decompression sickness and air embolism
- Increases risk of hypoxemia during sleep in patients with obstructive sleep apnea
- Platypnea-orthodeoxia syndrome (characterized by both dyspnea and arterial desaturation in the upright position with improvement in supine position)
- Increased risk of postoperative atrial fibrillation and hypoxemia, in off-pump coronary artery bypass surgery

ETIOLOGY

Unknown

DIAGNOSIS

- Testing for PFO is primarily performed in patients with a cerebral ischemic event of uncertain origin.
- A variety of echocardiography modalities have been used to diagnose PFO. These include:
  1. Transthoracic echocardiography (TTE)
  2. Transesophageal echocardiogram (TEE) (Fig. E1)
  3. Transmitral Doppler (TMD)
  4. Transcranial Doppler (TCD) of middle cerebral artery after injection of agitated saline peripherally
- TEE, especially when performed with contrast injected during a cough or Valsalva, is the most sensitive and preferred test for diagnosing PFO.
- Essentially, a PFO is suggested by the presence of echo dropout in the atrial septum visualized in more than one plane during echocardiography. The appearance of microbubbles in the left atrium within three to five cardiac cycles after injection of agitated saline peripherally is considered diagnostic of PFO with associated right-to-left shunt (RLS).
- The diagnosis of PFO is enhanced with multiple intravenous contrast injections with maneuvers that cause transient elevations of right atrial pressure (cough or Valsalva) to enhance RLS.
- TCD has the advantage of being noninvasive and easy to perform at bedside. But it can only detect a right-to-left shunt, not the location of the shunt or other cardiac structural anomalies.

TREATMENT

- Management guidelines from professional societies are shown in Table E1.
- Most patients with a PFO as an isolated finding receive no special treatment. This is because the yearly risk of cryptogenic stroke in healthy persons with PFO may be as low as 0.1%.
- As it is not associated with increased risk for endocarditis, antibiotic prophylaxis is not indicated.

PHARMACOLOGIC TREATMENT

When PFO is associated with an otherwise unexplained neurologic event, traditional treatment has been antiplatelet treatment (e.g., aspirin) therapy alone in low-risk patients and combined with therapeutic anticoagulants (e.g., warfarin) in high-risk patients.

Risk factors associated with a higher risk of complications, particularly stroke, include:

- Coexisting atrial septal aneurysm
- Large PFO
- Spontaneous right-to-left shunting
- Major shunt (>50 bubbles)
- Valsalva-provoking activity preceding the onset of stroke
- Presence of Chiari network (a congenital remnant of the right valve of the sinus venosus)
- Eustachian valves
- Younger age (<55 yr)
- Multiple clinical events or infarcts
- Pulmonary hypertension
- Failure or contraindications to anticoagulants
- High risk for recurrent deep venous thrombosis
- Pulmonary embolism at time of initial event
- Hypercoagulable state

PERCUTANEOUS TRANSCATHETER CLOSURE OF PFO

Percutaneous method of closure is usually preferred over open surgical closure because of invasiveness, procedure time, and patient convenience.

- Indications:
  1. Recurrent cryptogenic stroke due to presumed paradoxical embolism through PFO while on adequate medical treatment with antiplatelets or anticoagulants.

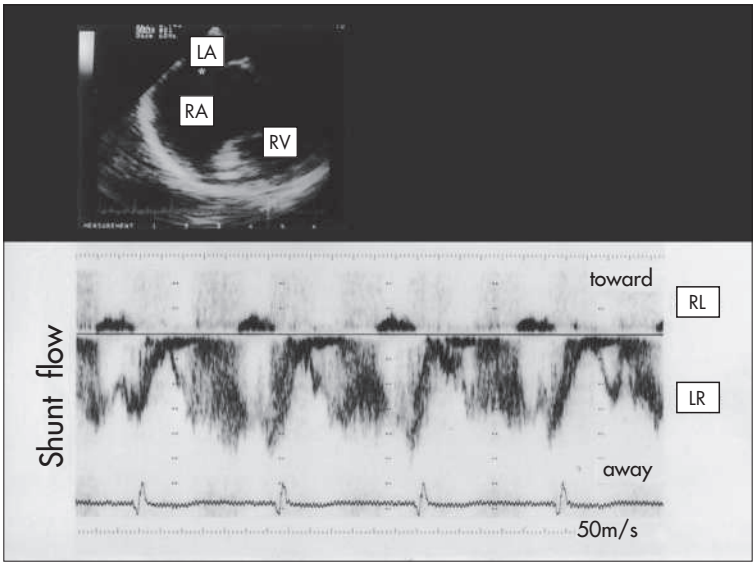

FIG. E1 Transesophageal echocardiography of an internal defect and pulsed Doppler flow signal. Pulsed Doppler echocardiographic signal is consistent with left-to-right level. *LA,* Left atrium; *LR,* left-to-right shunt signal; *RA,* right atrium; *RL,* right-to-left shunt signal; *RV,* right ventricle. (From Crawford MH et al [eds]: *Cardiology,* ed 2, St Louis, 2004, Mosby.)

TABLE E1 Management Guidelines from Professional Societies

	American Academy of Neurology	American College of Chest Physicians
PFO	Evidence is insufficient to determine whether warfarin or aspirin is superior in preventing recurrent strokes or death, but minor bleeding is more frequent with warfarin. There is insufficient evidence to evaluate the efficacy of surgical or endovascular closure.	
PFO alone		Antiplatelet therapy recommended over no therapy. Antiplatelet therapy suggested over warfarin
PFO with other risk factors		Inadequate data available to allow recommendation of optimal medical therapy vs. endovascular or surgical closure
PFO with concomitant deep vein thrombosis or pulmonary embolism	At least 3 mo of anticoagulation	Anticoagulation recommended

PFO, Patent foramen ovale.

The American Heart Association and American College of Cardiology have discouraged the use of devices to close a PFO as a means of preventing recurrent stroke. A recent trial (CLOSURE I) revealed that in patients with cryptogenic stroke or TIA who had a PFO, closure with a device did not offer a greater benefit than medical therapy alone for the prevention of recurrent stroke or TIA. More recent trials have shown that current guidelines may be too restrictive and it may be reasonable to consider a first embolic stroke and no other demonstrable cause as reason enough to close PFO.[1] Among adults who had a cryptogenic ischemic stroke, a recent multicenter trial found that closure of a PFO was associated with a lower rate of recurrent ischemic strokes than medical therapy alone during extended follow-up.[2]

2. In presence of contraindications to anticoagulants

- Contraindications:
  1. Presence of thrombus on the implant site or in the venous system used for access
  2. Active endocarditis or bacteremia
  3. Inadequate size of femoral vein for access
  4. Atrial septal anatomy without an adequate rim to hold the device
  5. Atrial septal anatomy that may result in the occluder obstructing an intracardiac structure
  6. Known hypercoagulable state
  7. Presence of an intracardiac mass or vegetation
- The CardioSEAL Septal Occlusion System and Amplatzer PFO Occluder devices are FDA approved.
- Requires SBE prophylaxis and antiplatelets (aspirin and clopidogrel for first 3 mo, followed by aspirin for another 3 mo) for 6 mo postprocedure. During this period of endothelialization, the risk of recurrent stroke is highest.
- The 1-yr rate of recurrent neurologic events ranged from 0% to 5% with percutaneous closure group vs. 4% to 12% with medical therapy group.
- MRI or metal detectors do not affect these implants, as they are not metallic.

SURGICAL CLOSURE (OPEN THORACOTOMY)

Indications:

- PFO >25 mm in size
- Inadequate rim of tissue around the defect
- Percutaneous device failure
- In presence of other indication for open heart surgery

PEARLS & CONSIDERATIONS

COMMENTS

- PFO is found on transesophageal echocardiography in about 50% of young survivors of stroke without clear cause for their stroke. In these patients, it is unclear whether the PFO was the cause of the stroke or whether it was an incidental finding.
- The frequency of ischemic stroke in patients in with symptomatic pulmonary embolism is higher in patients with PFO than in those without PFO. This finding supports the hypothesis that paradoxical embolism is a significant mechanism of ischemic stroke in patients with PFO.

Pediatric Medication Errors

BASIC INFORMATION

DEFINITION

A medication error is a preventable event that represents failure of intended prescription, dispensation, or administration of desired drug therapy. Medication errors may result in inappropriate medication use or an adverse drug event (ADE) (i.e., direct harm or injury to the patient).

SYNONYMS

Dosing errors or mistakes. Medication errors are not synonymous with ADEs because not all cause harm (a requirement of ADEs).

- Types of medication errors from the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) Index for Categorizing Medication:
  1. Category A: Circumstances or events that have the capacity to cause error.
  2. Category B: An error occurred that did not reach the patient.
  3. Category C: An error occurred that reached the patient but did not cause harm.
  4. Category D: An error occurred that reached the patient and required monitoring to confirm that it resulted in no harm to the patient and/or required intervention to preclude harm.
  5. Category E: An error occurred that may have contributed to or resulted in temporary harm to the patient and required intervention.
  6. Category F: An error occurred that may have contributed to or resulted in temporary harm to the patient and required initial or prolonged hospitalization.
  7. Category G: An error occurred that may have contributed to or resulted in permanent patient harm.
  8. Category H: An error occurred that required intervention necessary to sustain life.
  9. Category I: An error occurred that may have contributed to or resulted in the patient's death.

ICD-10CM CODE
NEC T50.9 Wrong drug (given in error)

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- 15% of pediatric outpatient prescriptions are either underdosed (7%) or overdosed (8%).
- Nearly 6% of medication orders for a hospitalized child contain an error. One percent of pediatric medication orders will result in a potential ADE. Less than 1% of medication orders for a child will contain an error that ultimately results in harm or injury.
- Potential for medication errors is three times higher in the pediatric inpatient population and eight times higher in the neonatal inpatient population than in hospitalized adult patients.
- A recent randomized controlled experiment found that 84.4% of parents made one or more dosing errors over nine attempts, especially when using medicine cups.

PEAK INCIDENCE: Among outpatient prescriptions, medication errors occur more frequently in children <4 yr compared with older children (20% vs. 13%).
PREVALENCE: Not applicable
PREDOMINANT SEX AND AGE: Children <4 yr
GENETICS: Not applicable
RISK FACTORS:

- Patient aged <4 yr
- Medications requiring calculation of individual doses based on weight (mg/kg), body surface area (mg/m^2), or age
- Off-label (non-FDA approved) medication use or lack of published information regarding dosing, pharmacokinetics, safety, efficacy, and clinical use
- Wide range of correct drug doses depending on indication
- Different and changing pharmacokinetic parameters between patients of various ages and stages of development
- Lack of computerized prescriber order entry (CPOE), standardized order sets, or alert systems
- Infants or children with multiple health care needs or those in intensive care or emergency department
- Limited ability of child to communicate to prevent error or signal that error has occurred
- Limited parental health literacy, the use of kitchen teaspoons or tablespoons for medication administration, and the use of medication dosing cups (instead of medication oral syringes)
- Limited reserve to withstand errors
- Errors of hospital medication administration and dispensing may be more common during evening, nighttime, and weekend shifts
- Most medications are prepared in concentrations and dosages intended for adult patients and requiring manipulation for administration to children

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Signs and symptoms of toxicity specific to the current drug regimen
- Lack of clinical efficacy of the current drug regimen

ETIOLOGY

Common sources of pediatric medication errors include:

- Prescribing errors: Lack of knowledge of medication; lack of recognition of the age-specific pharmacokinetics of a particular agent; use of medical abbreviations within the prescription or medication order; "look alike, sound alike" substitution errors; doses of liquid medications written as teaspoonfuls or tablespoonfuls
- Calculation errors: mg/kg/*dose* versus mg/kg/*day* dosing recommendations; "tenfold" decimal mistakes such as the use of trailing zeros (1 vs. 1.0) and naked decimals (0.1 vs. 1); patient weight in pounds versus kilograms
- Administration errors: Lack of patient or caregiver understanding; inappropriate medication administration tools; deviation from the "five rights" (i.e., the *right* drug at the *right* dose for the *right* patient by the *right* route at the *right* time)
- Dispensing errors: Inappropriate formulation recommended, prepared, or dispensed; nonstandardized intravenous and extemporaneous oral liquid concentrations; use of adult formulations for children

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Iatrogenic adverse drug reaction (unpreventable ADEs)
- Patient nonadherence

WORKUP

Alert from CPOE systems, deviation from standardized order set, or detection on review of prescription or medication order by pharmacist or nurse:

- Immediately discontinue medication order or prescription
- Determine if suspected error has reached the patient
- Assess harm to patient and intervene if necessary
- Determine source of error if possible
- Resume correct drug therapy with appropriate monitoring of efficacy and toxicity
- Report error to institution or facility for tracking and quality improvement purposes
- Report sentinel events to the Joint Commission

LABORATORY TESTS

Supratherapeutic or subtherapeutic serum drug concentrations (if applicable)

TREATMENT

Management of an ADE may include acute treatment of a toxic reaction or long-term management of a suboptimally treated condition. It should always include the workup described above.

ACUTE GENERAL Rx

If the medication error has reached the patient and resulted in an ADE, immediate intervention may be required. Disclosure to the patient or caregiver of an error resulting in harm to the patient is necessary.

CHRONIC Rx

Long-term management of injury or harm resulting from a medication error may be necessary.

DISPOSITION

- Reestablishing trust with the patient or caregiver after an error that resulted in harm to ensure optimal care in the future may be needed.
- The reporting of medication errors should be nonpunitive in nature and intent on individual education and correction of health systems–related flaws.

REFERRAL

Consultation with a pharmacist trained in pediatric pharmacotherapy may improve individual drug therapy and ensure age-specific drug dosing. Interpreters may be necessary to ensure drug information is accurately relayed to non–English-speaking patients or caregivers. Institutional bioethicists or legal counsel may be needed for significant or sentinel events.

PEARLS & CONSIDERATIONS

COMMENTS

- 20% of ADEs occurring in hospitalized children are preventable.
- The most common tenfold dosing errors in the home involve histamine H_2 antagonist medications and metoclopramide (in children ≤12 mo) and antibiotics or antihistamine-decongestant combination products (in children >12 mo). The top 5 drug classes with tenfold pediatric dosing errors in a university-affiliated hospital setting included opioid analgesics, antimicrobials, anticoagulants, gastrointestinal drugs, and intravenous nutrition.
- Careful attention must always be focused on the impact growth and development has on the pharmacokinetic characteristics of drugs used in children. A child's dose should not exceed that of an adult. Equations that calculate proportionate doses based on body weight or body surface area do not take into consideration these age-related changes.

PREVENTION

- Health systems management: Medication reconciliation at a transition in care (i.e., admission, discharge, or transfer); independent verification of medication orders by pharmacists and administration by nurses; elimination of medical abbreviations within medication orders and prescriptions; use of milliliters as the standard unit of measure; use of oral syringes that only display the metric scale to measure accurate doses; storing pediatric medications separately from adult preparations; use of patient-specific, ready-to-administer or unit doses dispensed by pharmacy; ensuring concentration always appears on the label. Automated clinical decision supports can provide prompts or use of forced functions at the time of prescribing or ordering. Computerized provider order entry can provide standardized order sets and alerts if necessary information is missing. Development and maintenance of order sets, templates, and dose alerts should include a pediatric pharmacist. Medication orders should include a dose calculation requiring prescribers to double-check weight-based dosing. Hospitals should consider use of smart infusion pumps with medication libraries including standard concentrations and dose limits. Institutions should devise event reporting systems to track trends and use a systematic analysis (e.g., root cause analysis) to evaluate medication errors when they occur in practice.
- Communication: Interdisciplinary cooperation can prevent medication errors. Limit interruptions or use distraction-free zones during medication preparation. Ensure appropriate pediatric representation on committees responsible for medication management. Drug information must be presented and reinforced at a level and in a language understandable to patients or caregivers.
- Education: Health care professionals must remain knowledgeable of current standards of care and new drug therapy options. Integrate pharmacists into interdisciplinary rounds. Provide competency and training to all staff. Incorporate bar coding, smart infusion pump technology, standardized intravenous and extemporaneous oral liquid concentrations, and error tracking. Educate parents and caregivers to use oral metric syringes to draw up liquid medications in milliliters.
- Review of drug therapy: Reassess prescriptions for accurate age-appropriate dosing and the indication for drug therapy, monitor for efficacy and toxicity, and reconfirm a patient or caregiver's understanding of the drug regimen.

PATIENT & FAMILY EDUCATION

- Caregivers should always remind a child's doctor of any drug allergies or side effects the child has had in the past.
- Caregivers should be instructed on the correct method of measuring liquid medication doses in milliliters using appropriately gradated oral medication syringes or droppers and to not use common kitchen utensils.
- Do not use over-the-counter cough and cold medicines for children less than 4 yr.
- An up-to-date list of all the medicines, including over-the-counter products and herbal and dietary supplements, a child uses should be kept and shared with each provider the child sees.
- Parents or caregivers should ask questions about medications and voice any concerns. If medication is required during school hours, a registered nurse should administer it whenever possible. Emergency medications such as epinephrine auto-injectors and inhalers should be made available to school staff.
- Counsel child and caregivers, verifying understanding of drug name, purpose, route of administration, dose, dose frequency, potential adverse effects, and management of adverse effects if they occur.

BASIC INFORMATION

DEFINITION

Pediculosis is lice infestation. Human beings can be infested with three kinds of lice: *Pediculus capitis* (head louse, Fig. 1), *Pediculus corporis* (body louse), and *Phthirus pubis* (pubic, or crab, louse). Lice feed on human blood and deposit their eggs (nits) on the hair shafts (head lice and pubic lice) and along the seams of clothing (body lice). Nits generally hatch within 7 to 10 days. Lice are obligate human parasites and cannot survive away from their hosts for longer than 7 to 10 days. Fig. 2 illustrates the life cycle of the head louse.

SYNONYM

Lice

ICD-10CM CODES

B85.0	Pediculosis due to *Pediculus humanus capitis*
B85.1	Pediculosis due to *Pediculus humanus corporis*
B85.2	Pediculosis, unspecified
B85.4	Mixed pediculosis and phthiriasis
Z20.7	Contact with and (suspected) exposure to pediculosis, acariasis and other infestations

EPIDEMIOLOGY & DEMOGRAPHICS

- There are 6 to 12 million cases of head lice in the United States yearly. The estimated annual direct and indirect cost of head lice infestation in the United States is $1 billion.
- Lice infestation of the scalp is most common in children (girls affected more often than boys).
- Infestation of the eyelashes is most frequently seen in children and may indicate sexual abuse.
- The chance of acquiring pubic lice from one sexual exposure with an infested partner is >90% (most contagious sexually transmitted infection [STI] known).
- Body lice are most common in conditions of poor hygiene.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Pruritus with excoriation may be caused by hypersensitivity reaction, inflammation from saliva, and fecal material from the lice.
- Nits can be identified by examining hair shafts (Fig.E3).
- The presence of nits on clothes is indicative of body lice.
- Lymphadenopathy may be present (cervical adenopathy with head lice, inguinal lymphadenopathy with pubic lice).
- Head lice are most frequently found in the back of the head and neck, behind the ears.
- Scratching can result in pustules and crusting.
- Pubic lice may affect the hair around the anus.

ETIOLOGY

Lice are transmitted by close personal contact or use of contaminated objects (e.g., combs, clothing, bed linen, hats).

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Seborrheic dermatitis
- Scabies
- Eczema
- Other: Pilar casts, trichonodosis (knotted hair), monilethrix
- Table 1 describes the differential diagnosis of nits

WORKUP

Diagnosis is made by seeing the lice (Fig. 4) or their nits. Combing hair with a fine-toothed comb is recommended because visual inspection of the hair and scalp may miss more than 50% of infestations.

LABORATORY TESTS

Wood's light examination is useful to screen a large number of children: Live nits fluoresce, empty nits have a gray fluorescence, and nits with unborn lice reveal white fluorescence.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Patients with body lice should discard infested clothes and improve their hygiene. Items that cannot be washed can be sealed in a plastic bag for 48 hours.
- Combing out nits is a widely recommended but unproven adjunctive therapy.
- Personal items such as combs and brushes should be soaked in hot water for 15 to 30 min. Clothing and bed linens should be washed in hot water (>130 °F; 54.4 °C) and then dried for at least 10 min at the hottest setting.
- Close contacts and household members should also be examined for the presence of lice.

ACUTE GENERAL Rx

The following products are available for treatment of lice:

- Permethrin: Available over the counter (1% permethrin [Nix]) or by prescription (5% permethrin [Elimite]); should be applied to the hair and scalp and rinsed out after 10 min. A repeat application 7 days later is generally not necessary in patients with head lice. It can be applied to clean, dry hair and left on overnight (8-14 hours) under a shower cap. Resistance to permethrin is now widespread.
- Malathion, an organophosphate, is effective in head lice. It is available by prescription. Use should be avoided in children ≤2 yr. It is not commonly used because of its objectionable odor, fear of flammability, and prolonged application time (8-12 hours).
- Spinosad (Natroba) is a newer FDA-approved product for head lice. It is a topical suspension applied to dry hair for 10 min, then rinsed. It may be repeated 7 days later if necessary. It is more effective than permethrin but also much more expensive. It is safe in pregnancy (category B—no evidence of risk in humans).
- Benzyl alcohol lotion, 5% (Ulesfia) can be used for treatment of head lice in patients >6 mo old. The lotion is applied to dry hair and left on for 10 min. Treatment must be repeated after 7 days because the drug is not ovicidal.
- Eyelash infestation can be treated with the application of petroleum jelly rubbed into the eyelashes three times a day for 5 to 7 days. The application of baby shampoo to

FIG. 1 Head louse family. From left to right: Female, male, and nymph. (With permission from Taplin D, Meinking TL: Infestations. In Schachner LA, Hansen RC [eds]: *Pediatric dermatology*, ed 4, Edinburgh, 2011, Mosby, pp 1141–80; Bolognia JL et al: *Dermatology*, ed 4, Philadelphia, 2018, Elsevier.)

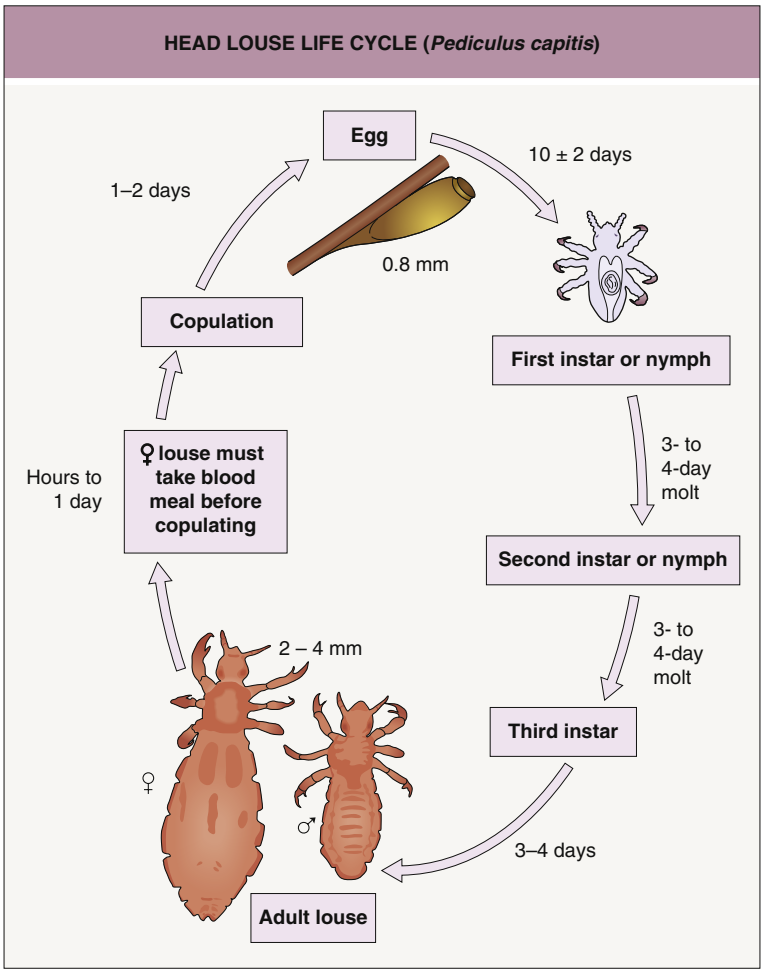

FIG. 2 Head louse life cycle (*Pediculus capitis*). (From Bolognia JL et al: *Dermatology*, ed 4, Philadelphia, 2018, Elsevier.)

the eyelashes and brows three or four times a day for 5 days is also effective. The use of fluorescein drops applied to the lids and eyelashes is also toxic to lice.

- In patients who have previously not responded to treatment or in whom resistance with 1% permethrin cream rinse occurs, a 10-day course of trimethoprim-sulfamethoxazole (TMP-SMX) 8 mg/kg/day in divided doses is an effective treatment for head lice infestation, especially for eyelash infestations with *Phthirus pubis.*
- Ivermectin, an antiparasitic drug, given as an oral dose of 400 mcg/kg of body weight on days 1 and 8, is effective for head lice resistant to other treatments (currently not FDA approved for pediculosis). Ivermectin 0.5% lotion is FDA approved as a single-use topical treatment for head lice in patients 6 mo or older. Cost is more than $200 for 4 oz.
- Fig. 5 summarizes treatments for head lice.

PEARLS & CONSIDERATIONS

COMMENTS

- Patients with pubic lice should notify their sexual contacts. Sex partners within the last month should be treated.

TABLE 1 Differential Diagnosis of Nits

Diagnosis	Comment
Nits	Firmly adherent to hair shaft; not easily removed with fingers
Seborrheic dermatitis (dandruff)	Diffuse scalp scaling; scales occasionally adhere to hair but easy to remove; scalp erythema may be present
Hair casts	Keratin protein that encircles hair shaft; easily removed
Piedra	Fungal infection of hair; firm nodules attached to hair shafts, white or black in color
Psoriasis	Thick silvery scales, often present overlying red plaques on the scalp
Hair products	Hairspray, mousse, gel

TREATMENTS FOR HEAD LICE				
Treatment	**Group**	**Administration on days 1 and 8**	**Concerns**	**Efficacy & resistance**
Pyrethrins (0.33%) synergized with piperonyl butoxide (4%), various formulations*	Natural botanicals	Topical application for 10 minutes to dry hair	Allergic reactions in individuals with sensitivity to chrysanthemums, ragweed, and related plants	Poor–fair; resistance common
Permethrin cream rinse or lotion (1%)*	Synthetic pyrethroid	Topical application for 10 minutes to clean, dry hair	None	Poor–fair; resistance common
Permethrin cream (5%)†	Synthetic pyrethroid	Topical overnight application to clean, dry hair	Allergic contact dermatitis in individuals with sensitivity to formaldehyde	Poor–fair; resistance common
Lindane shampoo (1%)	Organochlorine	Topical application for 4 minutes to clean, dry hair, then add water to lather and rinse	Potential CNS toxicity; not recommended for infants, children, breastfeeding mothers or pregnant women (category C)	Poor; resistance common
Carbaryl shampoo (0.5%)	Carbamate cholinesterase inhibitor	Topical application for 8–12 hours	Possible carcinogen	Poor–fair; resistance common (not approved in the U.S.)
Benzyl alcohol lotion (5%)§	Alcohol	Topical application for 10 minutes to dry hair	Potential skin irritation	Good; no resistance noted to date
Dimethicone (4%)	Silicone oil	Topical application for 15 minutes or overnight	None	Good
Spinosad cream rinse (0.9%)§	Bacterial fermentation product	Topical application for 10 minutes to dry hair	None	Good; no resistance noted to date
Malathion lotion or gel (0.5%)‡	Organophosphate cholinesterase inhibitor	Topical application for 8–12 hours to dry hair (Ovide® and gel products with isopropyl alcohol base are effective at 20 minutes)	Flammable isopropyl alcohol base; burning or stinging at sites of eroded skin	Excellent (in U.S.); resistance noted in Europe and Australia, but to date not in U.S.
Ivermectin solution (0.5%)§	Avermectin	Topical application for 10 minutes to dry hair	Potential skin and eye irritation	Excellent; no resistance noted to date
Oral ivermectin (available as 3 mg tablets)		Oral dose of 200–400 mcg/kg	Potential CNS toxicity; not recommended for children weighing <33 pounds (15 kg), breastfeeding mothers or pregnant women (category C)	

*Over-the-counter products.
†Approved for individuals ≥2 mo of age; pregnancy category B.
‡Approved for individuals ≥6 yr of age; pregnancy category B.
§Approved for individuals ≥6 mo of age; pregnancy category B.

FIG. 5 Treatments for head lice. In general, treatments should be given on two separate occasions, 1 wk apart. However, the FDA-approved regimen for treatment of head lice with 0.5% ivermectin solution is a single application. AirAllé ® is an FDA-cleared medical device that uses hot air to treat head lice via dehydration of their eggs and, to a lesser degree, hatched lice. Abametapir 0.74% lotion, an ovicidal metalloprotease inhibitor, has been shown in phase 3 clinical trials to have efficacy in the treatment of head lice. *CNS,* Central nervous system; *FDA,* U.S. Food and Drug Administration. Pedophilic Disorder

BASIC INFORMATION

DEFINITION

According to the DSM-5, pedophilic disorder (PD) is one of eight identified paraphilic disorders. A paraphilic disorder is described as "any intense and persistent sexual interest other than sexual interest in genital stimulation or preparatory fondling with phenotypically normal, physically mature, consenting human partners," that either causes distress or functional impairment to the individual or entails personal harm or risk of harm to others.

Diagnostic criteria for PD include the presence of recurrent, intense sexually arousing fantasies, sexual urges, or behaviors involving sexual activity with a prepubescent child or children (generally age 13 yr or younger) that occur over a period of at least 6 mo. The individual has acted on these urges or the urges have caused significant distress or interpersonal difficulty. The individual must be at least 16 yr and at least 5 yr older than the object of the sexual interest. DSM-5 subtypes pedophilic disorder into categories based on his/her victim gender preference (males, females, or both), on the exclusivity of the sexual urges (attracted only to children or not), and on his/her relationship with the victim ("limited to incest"). Individuals in late adolescence involved in ongoing sexual relationships with 12- or 13-yr-old children are not included for this disorder in DSM-5.

SYNONYM

Pedophilia

ICD-10CM CODE
F65.4 Pedophilia
DSM-5 CODE
302.2 Pedophilic disorder

EPIDEMIOLOGY & DEMOGRAPHICS

PREVALENCE: Unknown, with likely maximum of 5% in the male population and much smaller in the female population.
ONSET: Around the time of puberty, as adolescents begin to develop sexual interest.
PREDOMINANT SEX: The significant majority of pedophiles are men (females commit roughly 1%-6% of child sexual assault).

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Diagnosis is made by clinical interview and is often complicated by reluctance to disclose symptoms unless the behaviors have already been identified.
- Legal involvement is common and may be the reason for presentation for care.
- Sex offenders have higher rates of *general* crime recidivism than *sexual* crime recidivism. When known child molesters are rearrested, ~40% of their rearrests are for sexual offenses.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Antisocial personality disorder
- Conduct disorder
- Substance use disorder or intoxication
- Obsessive-compulsive disorder

WORKUP

Requires comprehensive data from multiple sources, including self-report, past sexual offense convictions, past and present partner report, psychophysiologic assessments, forensic computer analysis, and/or assessment tools. Deviant sexual preferences and lifestyle instability/criminality are strongly associated with general sexual recidivism. Therefore, clinical interview should explore sexual preferences (sex drive, paraphilic interests, victim characteristics), past sexual behaviors (including inquiry into the use of child pornography), and a history of rule violation, substance abuse, and risk taking. It is also important to explore opportunities that the individual has to be around children as well as exploring an individual's strengths and protective factors.

SCALES AND LABORATORY TESTS

- Penile plethysmography: The penile volume or circumference is measured in response to a variety of sexual materials. The result may be a predictor of sexual recidivism for individuals who have committed sexual offenses. However, ~20% to 30% of individuals tested are considered low or nonresponders. Further, in the U.S., possession of the viewing material (child pornography) presents a legal dilemma for researchers. Other limitations include its lack of applicability to females, lack of applicability to males with impotence, and ability of individuals to try to suppress sexual feelings via distraction. This form of testing is not currently admissible in court for the purpose of determining guilt.
- Viewing time: Viewing time is correlated with self-reported sexual interest and phallometric sexual arousal to children. No studies report that this measure predicts recidivism.
- Both of the above tests require the provider to show visual stimuli that may violate U.S. laws around possession of child pornography.
- Scales: For the prediction of general sexual recidivism, the most accurate approach appears to be the use of certain actuarial and mechanical measures. Some of the measures include the Static 99, MNSOST-3, Risk Matrix-2000, and the SVR 20 for adults, or the J-SOAP-II, ERASOR, and J-SORRAT-II for juveniles+. An individual's likelihood to recidivate is estimated based on the average risk of a group of individuals with similar characteristics.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Treatment for sexually aggressive behaviors in general typically incorporates multiple modalities, including individual, group, family, social skill, behavioral, and educational therapies.
- Key elements of treatment include taking responsibility for behaviors, developing empathy for victims, developing skills to prevent re-offending.
- General goals of treatment include improved control of deviant behaviors, impulse control, and coping; enhanced conflict resolution, anger management, and social skills; enhanced sense of empathy; understanding of cycle of thoughts, feelings, and events leading to inappropriate behaviors; respect within male-female relationships; and sexual education promoting healthy sexual behaviors (especially when working with juveniles).
- Community interventions might include the education of parents (re: high-risk situations, neighborhood sex offenders) and the education of children (re: assertiveness training, etc.).

PHARMACOLOGIC THERAPY

- *All used off-label in adults, adolescents, and children*
- Goals of treatment include suppression and elimination of deviant sexual fantasies, elimination of deviant sexual urges and behaviors, and reduction of risk for recidivism
- Selective serotonin reuptake inhibitors (SSRIs)
- Primary choice in adolescents, since few side effects (especially on adolescent physiological development)
- Case reports and small studies supporting use of fluoxetine, sertraline
- Antiandrogens and hormonal agents
- Medroxyprogesterone acetate (MPA):
  1. Most common hormonal agent in the U.S.
  2. Evidence mostly based on open trials
  3. Reduces sex drive, sexual fantasy, sexual activity
  4. Side effects include nausea, vomiting, feminization, weight gain, decreased sperm production, diabetes mellitus, headaches, deep vein thrombosis, hot flashes
  5. Induces testosterone-reductase in the liver, increasing metabolic clearance of testosterone and decreasing plasma testosterone
  6. Also has progestinic effect, leading to reduction of gonadotropin secretion
- Cyproterone acetate (CPA):
  1. Most common in Canada
  2. Antiandrogenic, antigonadotropic, progestinic effects

3. Principal effect at androgen receptors—blocks intracellular testosterone uptake and metabolism of androgen
4. Similar effects to MPA
5. Effects are dose dependent
6. Research indicates decrease in posttreatment recidivism rates for paraphilias
7. Side effects include decreased erections, masturbation, and sexual intercourse; liver dysfunction; adrenal suppression; osteoporosis; osteopenia

- Should be used only rarely by psychiatrists with experience in conjunction with pediatric endocrinologist for severe behaviors (short-term use)
- Luteinizing hormone-releasing hormone (LHRH) agonists
  - Leuprolide acetate most common in the United States
  - Goserelin acetate available, triptorelin acetate likely available soon
  - Specifically target paraphilias
  - Pharmacologic castration effect
  - Not recommended in children <18 yr, only indicated for severe symptoms in adults
  - Overstimulation of hypothalamic-pituitary axis leading to inhibition of gonadotropin secretion
  - Reduction or elimination of testosterone makes them useful in treating prostate cancer

REFERRAL

Refer to specialty mental health.

PEARLS & CONSIDERATIONS

- Individuals with pedophilia who have had no known risk of prior sexual contacts with children are at unknown risk to offend.
- Physicians must be aware of reporting requirements in their jurisdiction.

Pelvic Abscess PTG

BASIC INFORMATION

DEFINITION

Pelvic abscess is an acute or chronic infection, most commonly involving the pelvic viscera. Treatment requires directed therapy including broad-spectrum antimicrobials and, if medical therapy fails, surgical intervention. There are four categories based on etiologic factors:

- Ascending infection, spreading from cervix through endometrial cavity to adnexa, forming a tuboovarian complex
- Infection occurring in the puerperium, which spreads to the adnexa from the endometrium or myometrium by a hematogenous or lymphatic route
- Abscess complicating pelvic surgery
- Involvement of the pelvic viscera as a result of spread from contiguous organs, such as appendicitis or diverticulitis

SYNONYMS

Tuboovarian abscess (TOA)
Vaginal cuff abscess

ICD-10CM CODES	
K63.0	Abscess of intestine
K65.1	Peritoneal abscess
K68.11	Postprocedural retroperitoneal abscess
K68.12	Psoas muscle abscess
K68.19	Other retroperitoneal abscess
N70.93	Salpingitis and oophoritis, unspecified
N70.0	Acute salpingitis and oophoritis
N70.1	Chronic salpingitis and oophoritis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- 34% of hospitalized patients with pelvic inflammatory disease
- 1% to 2% of patients undergoing hysterectomy, most frequently with vaginal approach
- Peak incidence third to fourth decade

RISK FACTORS: Same risk factors as for pelvic inflammatory disease, although in 30% to 50% of patients there is no prior history of salpingitis before abscess forms.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Abdominal or pelvic pain (90%)
- Fever or chills (50%)
- Abnormal bleeding (21%)
- Vaginal discharge (28%)
- Nausea (26%)
- Up to 60% to 80% present without fever or leukocytosis; absence of these findings should not exclude diagnosis

ETIOLOGY

- Mixed flora of anaerobes, aerobes, and facultative anaerobes, such as *Escherichia coli, Bacteroides fragilis, Prevotella* spp., aerobic streptococci, and *Peptococcus* and *Peptostreptococcus* spp.
- *Neisseria gonorrhoeae* and *Chlamydia* are the major etiologic bacteria in cervicitis and salpingitis but are rarely found in abscess cavity cultures.
- In elderly patients consider diverticular disease.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Pelvic neoplasms, such as ovarian tumors and leiomyomas.
- Ovarian torsion.
- Inflammatory masses involving adjacent bowel or omentum, such as ruptured appendicitis or diverticulitis.
- Pelvic hematomas, as may occur after cesarean section or hysterectomy.

LABORATORY TESTS

- CBC with differential
- Aerobic as well as anaerobic cultures of cervix, blood, urine, sputum, peritoneal cavity (if entered), and abscess cavity before starting antibiotics
- Pregnancy test in patients of reproductive age

IMAGING STUDIES

- Sonogram: Noninvasive, inexpensive study to confirm diagnosis, estimate size of abscess, and monitor response to therapy; sensitivity >90%
- CT scan: Used for both diagnosis and therapy (CT-guided drainage) (Fig. E1)
  1. Useful where sonogram provides insufficient information, as with intraabdominal abscesses
  2. Success rate with CT-guided abscess drainage: Unilocular, 90%; multilocular, 40%

TREATMENT

Major concerns:

- Desire for future fertility
- Likelihood of rupture of abscess, with resulting peritonitis, septic shock, and morbid sequelae

ACUTE GENERAL Rx

- Clinical quandary is whether patient requires immediate laparoscopic surgery (uncertain diagnosis or suspicion of rupture) or management with IV antibiotics, reserving surgery for those with inadequate clinical response (e.g., 48 to 72 hr of therapy, with persistent fever or leukocytosis, increasing size of mass, or suspicion of rupture).
- Surgery indicated in poor response to medical therapy. Early surgery may be needed in those with large adnexal masses (>8 cm), or in immunocompromised patients.
- Antibiotic combinations:
  1. Clindamycin 900 mg IV q8h or metronidazole 500 mg IV q6 to 8h plus gentamicin either 5 to 7 mg/kg q24h or 1.5 mg/kg q8h
  2. Alternatives: Ampicillin-sulbactam 3 g IV q6h or cefoxitin 2 g IV q6h or cefotetan 2 g IV q12h plus doxycycline 100 mg IV q12h
- During medical management, high index of suspicion for acute rupture, such as acute worsening of abdominal pain or new-onset tachycardia and hypotension, mandating immediate surgical intervention after patient stabilization.
- Surgical options:
  1. Laparoscopy with drainage and irrigation
  2. CT-guided drainage (interventional radiology)
  3. Transvaginal colpotomy (abscess must be midline, dissect rectovaginal septum, and be adherent to vaginal fornix)
  4. Laparotomy, including total abdominal hysterectomy with bilateral salpingo-oophorectomy or unilateral salpingo-oophorectomy
  5. Evidence of ruptured tuboovarian abscess is a surgical emergency

DISPOSITION

- Of patients treated with medical therapy, response in 75%, with a 50% pregnancy rate. Pregnancy rate decreases with recurrent episodes.
- No response in 30% to 40%; can be treated with either CT-guided drainage or surgical intervention, keeping in mind that unilateral adnexectomy may give equal chance of cure versus hysterectomy, yet preserve reproductive potential.

REFERRAL

If patient has a tuboovarian abscess, refer to gynecologist.

PEARLS & CONSIDERATIONS

COMMENTS

- If *Actinomyces* species is isolated from culture, treatment with penicillin is required for an extended period (6 wk to 3 mo).
- Most common cause of preventable death: Physician delay in diagnosis.

Pelvic Congestion Syndrome

BASIC INFORMATION

DEFINITION

Pelvic congestion syndrome (PCS) is a poorly understood association between varicose or dilated pelvic veins and chronic pelvic pain (CPP).

SYNONYMS

PCS
Pelvic venous syndrome
Pelvic venous insufficiency
Pelvic varices
Pelvic vascular dysfunction

ICD-10CM CODE

N94.89 Other specified conditions associated with female genital organs and menstrual cycle

EPIDEMIOLOGY & DEMOGRAPHICS

- Reported in reproductive-age women. Incidence and prevalence are unclear. Pelvic varices are reported in 10% to 30% of CPP patients.
- Proposed risk factors include pregnancy, obesity, increased abdominal pressure, pelvic surgery, estrogen exposure, valvular insufficiency, and presence of other varicose veins (especially vulvar or perineal). Similar pain and dilation have also been reported in patients with mechanical compression in the setting of nutcracker syndrome, May-Thurner syndrome, thrombosis, or pelvic masses.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- There are no universally accepted or well-defined clinical criteria for the diagnosis of PCS. It is generally described as an association between CPP (at least 3 to 6 mo duration) and evidence of pelvic vascular insufficiency on imaging in the absence of other causes of pain.
- Common presenting features include sensation of a dull ache or heaviness, dysmenorrhea, dyspareunia, ovarian point tenderness on examination, and pain exacerbation with increases in abdominal pressure (such as pregnancy or standing position). Left-sided pathology is described more commonly, likely due to the anatomic course of the left ovarian vein into the renal vein as opposed to the inferior vena cava on the right side.

ETIOLOGY

Postulated mechanisms include the activation of pain receptors or release of nociceptive factors from local stasis and stretch of the venous walls.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for CPP is broad and includes gynecologic, urologic, gastrointestinal, musculoskeletal, neurologic, and psychologic disorders. Common causes of CPP include endometriosis, interstitial cystitis, irritable bowel syndrome, pelvic floor myalgia, and myofascial pain.

WORKUP

- Detailed history and physical examination, imaging, and evaluation for other causes of CPP are part of the workup. Evaluation often requires a multidisciplinary approach and may include trials of medical management for other common pain conditions.
- There are no specific laboratory tests for PCS.

IMAGING STUDIES

- Pelvic varices are seen in 10% to 38% of asymptomatic women and thus have low specificity for pelvic congestion syndrome. Similarly, there are no agreed-upon criteria for imaging findings. Pelvic ultrasound, mitral regurgitation (MR), CT, and catheter venography are all reasonable considerations for imaging workup.
- Pelvic ultrasound (Fig. E1) is considered first line for CPP, as it can be used to assess both pelvic anatomy and vasculature by evaluating Doppler flow. Common findings include:
  1. Slow (<3 cm/s), reversed, or retrograde blood flow
  2. Ovarian vein diameter >4 mm or >6 mm
  3. Pelvic congestion, tortuous venous plexuses, dilated arcuate pelvic veins
  4. Evidence of venous valvular incompetence
  5. Worsening findings with standing or Valsalva
- MR and CT venography have low specificity, are expensive, and may require radiation (CT), although they are less invasive than catheter venography.
  1. Suggested criteria include four or more tortuous parauterine veins, parauterine vein diameter >4 mm, and ovarian vein diameter >8 mm.
- Catheter venography is often reserved for cases in which intervention is planned. Findings suggestive of PCS include:
  1. Ovarian vein diameter >6 mm
  2. Pelvic vein diameter >5 to 10 mm
  3. Contrast retention >20, >40, or >60 sec or subjectively slow
  4. Tortuosity (absent/moderate/severe)
  5. Congestion of pelvic venous plexus, opacification of internal iliac vein, or filling of vulvovaginal/thigh varices
- Laparoscopy has been considered for the diagnosis and treatment of PCS, although this may be more beneficial for other causes of pelvic pain, such as endometriosis, ovarian cysts, or adhesive disease.

TREATMENT

- Referral to multidisciplinary teams, including gynecology, GI, pain specialists, physical therapy, and interventional radiology, may be indicated when the diagnosis is suspected to evaluate for other causes of pelvic pain.
- Clinical trials of oral medroxyprogesterone acetate, subcutaneous etonogestrel, and

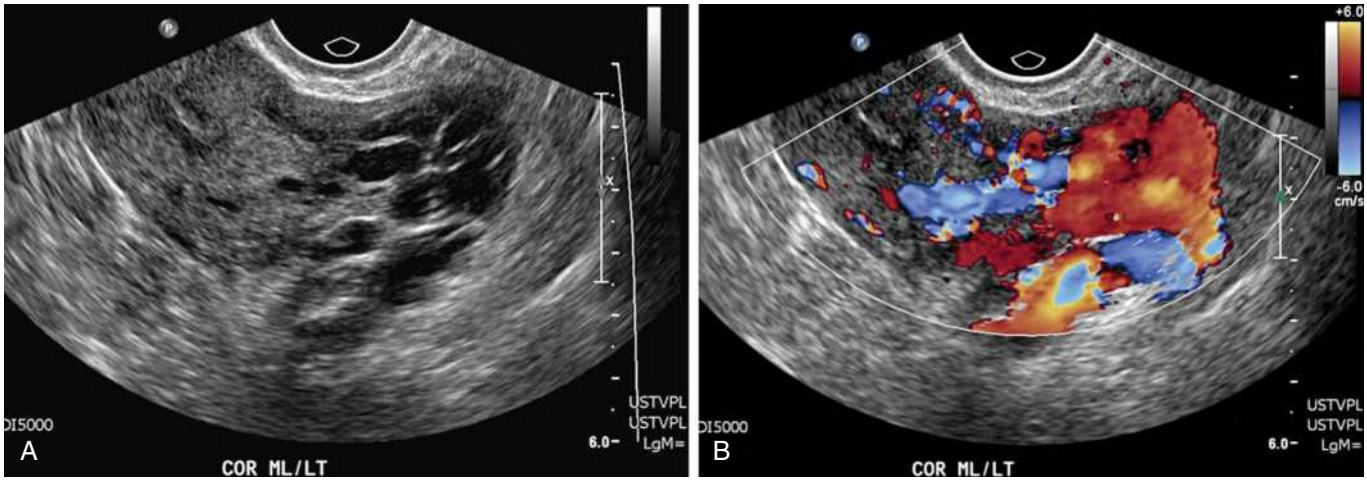

FIG. E1 Pelvic congestion syndrome. Transvaginal ultrasound without **(A)** and with **(B)** color Doppler imaging showing tortuous tubular anechoic structures in the adnexa that fill with color Doppler signal, compatible with dilated pelvic venous plexuses seen in pelvic congestion. (From Fielding JR et al: *Gynecologic imaging*, Philadelphia, 2011, WB Saunders.)

gonadotropin-releasing hormone agonists have shown a statistically significant decrease in pain for PCS patients. Other oral progesterones, danazol, and combined estrogen/progesterone contraceptives have also been suggested for medical treatment of PCS.

- Percutaneous endovascular embolization and sclerotherapy are the most common therapies studied with PCS. Symptomatic improvement is reported in 50% to 80% of patients and may increase with time. Complications were noted in approximately 2% of patients, including coil misplacement, coil migration, vein perforation, and phlebitis. Statistically significant decreases in pain scores are reported in most studies examining percutaneous treatment, although evidence is low quality and pooled from multiple small studies with inconsistent criteria for diagnosis and outcomes. Data on menses, fertility, and pregnancy are limited with no known complications.
- Laparoscopic ligation or excision of ovarian veins, hysterectomy, and salpingo-oophorectomy have been studied but have increased complications and similar efficacy to endovascular treatment.

PEARLS & CONSIDERATIONS

COMMENTS

- Pelvic congestion syndrome is a controversial condition describing the association between chronic pelvic pain and pelvic varices without clear diagnostic criteria.
- The differential diagnosis for CPP is broad, and medical treatment for PCS overlaps with methods that are effective for other common causes of CPP.
- Some low-quality evidence suggests symptom improvement with embolization or sclerotherapy.

BASIC INFORMATION

DEFINITION

Pelvic inflammatory disease (PID) is infection and inflammation of the upper female genital tract (including uterus, fallopian tubes, ovaries, and/or pelvic peritoneum) unrelated to pregnancy or surgical intervention. PID can be classified as acute (≤30 days duration), subclinical, or chronic (>30 days duration).

SYNONYMS

PID
Salpingitis
Oophoritis
Adnexitis
Pyosalpinx
Tubo-ovarian abscess
TOA

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE/PREVALENCE: Pelvic inflammatory disease is most often diagnosed in young, sexually active women. The incidence of PID is difficult to ascertain given its broad diagnostic criteria, its propensity to be missed as a diagnosis, and the challenges with follow-up due to patients seeking urgent or emergent care for this condition. The Centers for Disease Control and Prevention estimates 1 million new cases of PID are diagnosed yearly. The incidence may be rising given recent sharp increases in STDs associated with PID in the United States. PID has long-term health risks for women, including recurrent infection, chronic pelvic pain, pelvic adhesive disease, and tubal disease resulting in ectopic pregnancy and infertility.

RISK FACTORS:

- Sexually active adolescent and young women
- Previous episode of PID
- Prior chlamydial infection
- Multiple or new sexual partners within past 12 mo
- Sexual partner diagnosed with sexually transmitted infection (STI)
- Nonuse of barrier contraception

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Lower abdominal pain
- Abnormal vaginal discharge
- Abnormal uterine bleeding
- Postcoital bleeding
- Dysuria
- Dyspareunia
- Fever
- Nausea and vomiting (suggestive of peritonitis)

PHYSICAL FINDINGS

- Fever
- Abdominal tenderness
- Abnormal vaginal discharge
- Cervical friability
- Cervical motion tenderness
- Adnexal tenderness
- Adnexal mass
- Right upper quadrant tenderness (perihepatitis): 5% of PID cases

NOTE: Women with PID may be asymptomatic and/or have a benign physical examination.

ETIOLOGY

Pelvic inflammatory disease occurs as a result of ascending infection from the lower genital tract. Infections are often polymicrobial, and although gonorrheal and chlamydial infections are commonly implicated in the development of PID, fewer than 50% of women test positive for these organisms. This is likely due in part to increased STI screening efforts. PID may also arise in the setting of organisms associated with normal vaginal flora such as:

- *Bacteroides fragilis*
- *Escherichia coli* and other enteric gram-negative rods
- *Gardnerella vaginalis*
- *Haemophilus influenzae*

Rarer infectious causes include the following: *Mycoplasma hominis, Ureaplasma urealyticum, Mycoplasma genitalium* (a concern due to antibiotic resistance), *Mycobacterium tuberculosis* (an important cause in developing countries), and cytomegalovirus (CMV).

DIAGNOSIS

Diagnosis of PID is made when a patient has clinical or pathologic evidence of upper genital tract infection and inflammation. Although no single test or measure reliably diagnoses the spectrum of disorders that comprise PID:

- Providers should maintain a low threshold for diagnosis and treatment of PID given significant long-term health risks associated with the disease, especially if untreated
- Definitive criteria for diagnosis of PID include:
  1. Laparoscopic abnormalities consistent with PID
  2. Histopathologic evidence of endometritis in women with clinical suspicion for PID
  3. Transvaginal sonography or other imaging techniques showing thickened, fluid-filled tubes, with or without free pelvic fluid or tubo-ovarian complex
- The CDC suggests that women with risk factors, abdominal or pelvic pain, and any pelvic tenderness (cervical, uterine, and/or adnexal) be treated for PID

DIFFERENTIAL DIAGNOSIS

- Appendicitis
- Ectopic pregnancy
- Intrauterine/other pregnancy
- Ovarian cyst
- Adnexal torsion
- Endometriosis
- Urinary tract infection (cystitis or pyelonephritis)

WORKUP

- History—as in risk factors and clinical presentation, previously
- Physical examination—as in physical findings, previously

LABORATORY TESTS

- Wet mount: Clue cells, increased white cells
- Gram stain of endocervical exudate: >30 polymorphonuclear cells per high-power field correlates with chlamydial or gonococcal infection
- Endocervical cultures for *N. gonorrhoeae* and *C. trachomatis*
- Fallopian tube aspirate or peritoneal exudate culture if laparoscopy performed
- WBC: Leukocytosis
- Elevated acute phase reactants: ESR >15 mm/hr, C-reactive protein
- HCG to rule out intrauterine or ectopic pregnancy
- HIV, with consideration for other STI screening such as RPR, HBsAg, Hep C Ab (HIV increases incidence of TOA)

IMAGING STUDIES

Ultrasonography is commonly used to assess for PID and can be used to determine inpatient vs. outpatient treatment by presence or absence of TOA. Findings include:

- Thick-walled adnexal mass with heterogenous or cystic contents suggestive of abscess
- Dilated fallopian tubes (note that normal fallopian tubes are rarely identified on ultrasonography)
- "Cogwheel sign" indicating thickened fallopian tube walls
- Heterogenous fluid within the endometrium

CT scan or MRI may be useful to better characterize adnexal masses and/or rule out other pathology such as appendicitis or renal calculus. Choice of imaging modality will depend on clinical suspicion, logistical access, and associated cost.

PROCEDURES

Endometrial biopsy that reveals endometritis may support a diagnosis of PID. Laparoscopy has been utilized as a gold standard for diagnosing PID, but due to the invasive nature of this procedure and the risks, and costs associated, it is rarely indicated as a diagnostic tool.

Rx TREATMENT

Primary management of PID is medical, with broad-spectrum antibiotics administered in an outpatient setting. Inpatient treatment should be initiated when:

- Surgical emergency is not excluded
- Tubo-ovarian abscess is present
- Patient is unable or unwilling to complete outpatient treatment (including medication regimen and clinical follow-up)
- Outpatient treatment fails to improve symptoms in 48 to 72 hours
- Pregnancy, immunodeficiency, or other complicating medical condition exists

Evidence-based guidelines recommended by the CDC for acute PID are as follows:

INPATIENT REGIMENS

Recommended parenteral regimens

- Cefotetan 2 g IV q12h *PLUS* doxycycline 100 mg PO or IV q12h OR
- Cefoxitin 2 g IV q6h *PLUS* doxycycline 100 mg PO or IV q12hOR
- Clindamycin 900 mg IV q8h *PLUS* gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) q8h. Single daily dosing (3-5 mg/kg) can be substituted.

Alternative parenteral regimen

- Ampicillin/sulbactam 3 g IV q6h *PLUS* doxycycline 100 mg PO or IV q12h

When clinical improvement is apparent based on symptoms, physical exam, and laboratory criteria, antibiotics may be transitioned from IV to PO with doxycycline PO or clindamycin PO (depending on the regimen selected) administered to complete 14 days of total antibiotic therapy. If a patient does not improve despite use of a recommended antibiotic regimen, further workup and potential procedural intervention are warranted.

OUTPATIENT REGIMENS

Recommended intramuscular/oral regimens

- Ceftriaxone 250 mg IM in a single dose *PLUS* doxycycline 100 mg PO bid for 14 days
  WITH or WITHOUT metronidazole 500 mg PO bid for 14 days
  OR
- Cefoxitin 2 g IM in a single dose and probenecid, 1 g PO administered concurrently in a single dose *PLUS* doxycycline 100 mg PO bid for 14 days
  WITH or WITHOUT metronidazole 500 mg PO bid for 14 days
  OR
- Other third-generation cephalosporin (ceftizoxime or cefotaxime) *PLUS* doxycycline 100 mg orally bid for 14 days
  WITH or WITHOUT metronidazole 500 mg orally twice a day for 14 days

Alternative intramuscular/oral regimen

- Azithromycin 1 g PO once weekly for 2 wk PLUS ceftriaxone 250 mg IM in a single dose

TREATMENT CONSIDERATIONS

- Antimicrobials should include coverage against *N. gonorrhoeae* and *C. trachomatis* even if these organisms are not identified on culture.
- Due to increasing antibiotic resistance of *N. gonorrhoeae*, fluoroquinolones should be avoided in the treatment of PID. If gonorrhea is isolated in a woman with PID, addition of azithromycin 1 g orally one time should be considered in treatment.
- Women should avoid sexual activity until they and their sexual partners have been adequately treated and symptoms have resolved.
- TOA may require drainage, which may be accomplished by interventional radiology via aspiration or placement of a drain, or by a gynecologist via vaginal or laparoscopic means. Recurrent/persistent TOAs may be managed by total abdominal hysterectomy with bilateral salpingo-oophorectomy after acute treatment of infection.
- Treatment of PID in women with intrauterine devices (IUDs) does not include/require removal of the device unless there is no clinical improvement after 48 to 72 hours of treatment with an approved regimen. IUDs rarely serve as a source for PID, especially greater than 3 wk after insertion.
- Sexual partners of patients diagnosed with PID or other STIs should be evaluated and treated appropriately. In the setting of PID, treat all sexual partners within 60 days of onset of symptoms. Some states allow for expedited partner therapy (EPT), such that a woman's provider is able to supply her with enough medication to treat herself and her partner(s).
- Treatment of chronic PID may be aimed at a different spectrum of microbes and should be tailored appropriately.

DISPOSITION

- Given the risk of reinfection, all women should be retested for gonorrhea and chlamydia 3 to 6 mo after treatment.
- Follow-up includes confirmation of partner treatment, education on use of barrier contraception, and risks of PID and long-term sequelae, including:
  1. Recurrent PID.
  2. Chronic pelvic pain.
  3. Fallopian tubal damage that leads to infertility and/or ectopic pregnancy.
  4. Fitz-Hugh-Curtis syndrome.
  5. Potential risk for cancer: Limited studies have suggested a small association between PID and ovarian, endometrial, and colon cancer.

PEARLS & CONSIDERATIONS

COMMENTS

- Maintain a low threshold for the diagnosis and treatment of PID given the risks for progression to severe infection and to significant and chronic medical and reproductive complications.
- Most patients are candidates for outpatient therapy, but inpatient hospitalization is recommended in select cases.
- Use only CDC-recommended treatment regimens unless contraindicated due to severe patient allergy; in such cases, check local susceptibilities of suspected pathogen.
- Offer HIV and other STI screening to all women with suspected or diagnosed PID.
- IUDs may be retained unless women have failed to improve with 48 to 72 hours of treatment.
- Treat sexual partners of women with PID, with EPT if possible.
- Counsel patients on abstinence until they and their partners have completed treatment.
- Test for reinfection with gonorrhea and chlamydia 3 to 6 mo after treatment.

PREVENTION

Women aged <25 yr and/or participating in high-risk sexual behavior should be screened annually for chlamydia; studies have shown such screening to reduce cases of PID by >50%. The importance of minimizing partner exposures and using barrier contraception (either alone or in conjunction with another method) should also be emphasized.

BASIC INFORMATION

DEFINITION

Pelvic organ prolapse (POP) refers to descent of vaginal tissue and/or the uterus into the vaginal canal. It results from injury to or weakness in the connective tissue and muscles of the pelvic floor. Modern definitions of POP describe anterior and posterior vaginal wall defects, as well as apical defects in pelvic floor connective tissue. Synonyms for POP include cystocele (Fig. E1), rectocele, uterine prolapse (Fig. E2), enterocele (Fig. E3), and vaginal vault prolapse. Descriptions of this condition as a "dropped bladder," "dropped uterus," or defect in other pelvic organs should be avoided. These types of descriptions do not accurately reflect the pathophysiology of POP and often create confusion and unnecessary stress for patients. Table 1 describes the various types of POP affecting each vaginal compartment with corresponding ICD-10 codes.

SYNONYMS

Vaginal prolapse
Uterine prolapse
Genital prolapse
Uterine descensus
POP
Pelvic floor disorder
PFD

ICD-10CM CODES

N81.I8	Other female genital prolapse
N81.2	Incomplete uterovaginal prolapse
N81.4	Uterovaginal prolapse, unspecified
N81.5	Vaginal enterocele
N81.6	Rectocele
N81.82	Incompetence or weakening of pubocervical tissue

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE AND PREVALENCE: Exact prevalence estimates are difficult to determine due to varying definitions of POP and various diagnostic criteria. Based on self-reported symptoms in the National Health and Nutrition Examination Survey, the prevalence of POP is 3% to 4%. However, based on physical examination, the prevalence of POP is much higher. The incidence of POP surgery is 1.5 to 1.8 surgeries per 1000 women yrs. Annual direct health care costs are high, and repeat operations are common.

GENETICS: Data suggest a heritable component to POP; however, no specific genes or genetic factors outside of specific connective tissue diseases have been identified. Connective tissue disorders associated with an increased risk include Marfan syndrome and Ehlers-Danlos syndrome. In general, a genetic susceptibility exists in certain families, which is then affected by external factors to increase an individual woman's risk of POP.

RISK FACTORS: POP has a long latency and is multifactorial. Multiple risk factors have been identified. Some are modifiable, suggesting POP may be preventable; however, many risk factors are not. Some of the most common risk factors include:

- Pregnancy, labor, and vaginal childbirth
- Parity
- Age
- Chronic obstructive pulmonary disease (COPD) and chronic coughing
- Smoking
- Chronic constipation
- Chronic heavy lifting
- Chronic steroid use
- Connective tissue diseases (Marfan syndrome, Ehlers-Danlos syndrome)
- Pelvic surgery
- Menopause
- Family history
- Caucasian and Hispanic race

ETIOLOGY

- The cause of pelvic organ prolapse is usually multifactorial, but pregnancy is the most commonly associated risk factor.
- Muscle injury (levator ani) and connective tissue damage (pubocervical fascia) cause failure of pelvic floor support.
- Increased intraabdominal pressure results in strain on pelvic floor support structures.
- Injury to pelvic floor muscles or connective tissue supports results in uncompensated forces on pelvic floor, resulting in further injury to pelvic floor support structures.
  1. Acute (traumatic) injury to pelvic floor support can result from vaginal delivery, labor, or surgery.
  2. Chronic injury or strain on pelvic floor connective tissue and muscle can result from conditions such as COPD with chronic coughing or chronic constipation.
  3. Neurologic injury from acute or chronic strain on pelvic floor can result in denervation and subsequent muscular atrophy.
  4. Diseases or medications that weaken connective tissue (Marfan syndrome, corticosteroids) can predispose to injury.
  5. Hypoestrogenism may weaken pelvic floor tissue and impair ability to heal from injury.
- With injury to pelvic floor support structures, vaginal tissue becomes subjected to the forces from intraabdominal pressure and will stretch, allowing the bladder, uterus, or intestines to be displaced downward into the vaginal canal, resulting in clinical symptoms.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Bulge symptoms
  1. Vaginal pressure
  2. Protrusion from vagina (Fig. E4)
- Urinary symptoms
  1. Urinary hesitancy
  2. Urinary frequency or urgency
  3. Manual reduction of prolapse to complete urination
  4. Incomplete emptying
  5. Weak urinary stream
- Bowel symptoms
  1. Incomplete defecation
  2. Altered rectal sensation (urgency, lack of sensation)
  3. Splinting of vagina/perineum to defecate
- Sexual symptoms
  1. Dyspareunia
  2. Difficulty with vaginal penetration
- Other
  1. Vaginal bleeding from excoriated vaginal epithelium from chronic exteriorization
  2. Incarcerated prolapse with inability to be manually reduced

DIAGNOSIS

WORKUP

- Elicit specific symptoms. Determine the degree of bother with symptoms.
- Perform detailed pelvic exam. Examine anterior, posterior, and apical segments of vagina independently. Assess pelvic floor muscle tone.
  1. Exam is done in standard lithotomy position, and POP is assessed with Valsalva during exam.
  2. If symptoms are out of proportion to findings, repeat exam in standing position.
- Describe exam findings objectively (Boxes 1, 2, and 3).
  1. Quantitatively with POP-Q
  2. Descriptively with Baden-Walker halfway systems
- Urinary symptoms should be evaluated separately.
  1. POP is associated with urinary incontinence but *does not cause* urinary incontinence.

TABLE 1 Types of Genital Prolapse

Original Position of Organs	Prolapse	Symptoms (in addition to the general symptoms of discomfort, dragging, the feeling of a "lump," and, rarely, coital problems)
Anterior	Urethrocele Cystocele	Urinary symptoms (stress incontinence, urinary frequency)
Central	Cervix/uterus: 1st, 2nd, and 3rd degree Procidentia	Bleeding and/or discharge from ulceration in association with procidentia
Posterior	Rectocele Enterocele	Bowel symptoms, particularly the feeling of incomplete evacuation and sometimes having to press the posterior wall backward to pass stool

BOX 1 Points of Reference for POP-Q

Point	Description	Range of Values
Aa	3 cm above the hymen on anterior vaginal wall roughly corresponds with the urethrovesical junction.	–3 cm to +3 cm
Ba	The lowest extent of the segment of vagina between point Aa and the apex of the vagina. Unlike point Aa, it is not fixed but will be the same as Aa if point Aa is the most protruding point. In maximal prolapse, it will be the same as point C.	–3 cm to + TVL
C	Most distal edge of cervix (vaginal cuff if uterus/cervix absent).	
D	Posterior fornix (n/a if hysterectomy).	
Ap	3 cm above the hymen on posterior vaginal wall.	–3 cm to +3 cm
Bp	The lowest extent of the segment of vagina between point Ap and the apex of the vagina. Unlike point Ap, it is not fixed but will be the same as Ap if point Ap is the most protruding point. In maximal prolapse it will be the same as point D.	–3 cm to + TVL
GH (Genital Hiatus)	From urethral meatus to inferior hymenal ring.	
PB (Perineal Body)	From inferior hymenal ring to middle of anal orifice.	
TVL (Total Vaginal Length)	Without stretch or Valsalva.	

Key Points: Measure position of six points with respect to the position of the hymen. Points above the hymen (inside) are negative, points below the hymen are positive, and points at the hymen are 0.
Modified from Pemberton J (ed): *The pelvic floor,* Philadelphia, 2002, WB Saunders; and Bump RC et al: *Am J Obstet Gynecol* 175(1):13, 1996.

BOX 2 POP-Q Examination and Staging

Stage 0	No prolapse
Stage I	Leading edge ≥1 cm above hymenal ring
Stage II	Leading edge ≤1 cm above hymenal ring but ≤1 cm below hymenal ring
Stage III	Most distal point is >1 cm but < (TVL-2) cm below the hymenal ring
Stage IV	Leading edge ≥ (TVL-2) cm below hymenal ring

BOX 3 Baden Walker Halfway System

Grade 0	Normal position for each respective site
Grade 1	Descent halfway to the hymen
Grade 2	Descent to the hymen
Grade 3	Descent halfway past the hymen
Grade 4	Maximum possible descent for each site

- Evaluate postvoid residual urine volume in advanced POP (stage 3 and stage 4).
  1. Bladder ultrasound or catheterization at time of exam

LABORATORY TESTS

- Not indicated for routine evaluation of POP. Urine testing may be indicated based on presence or absence of urinary tract symptoms. Urodynamic testing may be performed for additional information and surgical planning.

IMAGING STUDIES

- Not indicated for routine evaluation of POP. Imaging studies for other gynecologic or urologic conditions may be indicated.
- Pelvic ultrasound may be considered in the *absence of POP* in patients with specific symptoms (i.e., pelvic pressure) (Fig. E5).

Rx TREATMENT

PRIMARY PREVENTION:

- Diagnosis and treatment of chronic cough
- Correction of constipation
- Weight control, nutrition, and smoking cessation counseling
- Pelvic muscle exercises
- Proper management of vaginal apex at time of hysterectomy in patients without POP
- McCall culdoplasty to prevent vaginal vault prolapse
- Cesarean delivery NOT indicated for prevention of POP
- Untreated urinary retention, even if asymptomatic, can cause bladder infection, reflux, and renal damage

POP TREATMENT OPTIONS:

- Expectant management: Can be appropriate, except in cases of incomplete bladder emptying.
- Pessaries (Fig. E6):
  1. Support device
  2. Silicone, not latex
  3. Exists in various shapes and sizes
     a. Use the simplest and smallest pessary that works
  4. 85% of women can be fitted successfully with a pessary (Fig. E7)
     a. Includes sexually active womena.
  5. Self-care can be learned by the majority of women
     a. Usually remove and clean once per mo; otherwise, office visit every 3 mo for cleaning and exam.
  6. Side effects/complications:
     a. Risk of UTI.
     b. Small vaginal erosions and very mild bleeding or spotting are common
        1) First episode of vaginal bleeding needs evaluation in postmenopausal patients
     c. Neglected pessaries can cause vaginitis, odor, severe vaginal erosion/bleeding, and fistula
     d. Vaginal estrogen may prevent or treat erosions and minimize risk of vaginitis and UTI
- Surgery:
  1. Indicated for bothersome POP and when patients fail or decline nonsurgical treatments.
  2. Goals of surgery are to eliminate vaginal bulge and improve associated symptoms.
     a. Most reliable symptom resolution is elimination of bulge/protrusion.
     b. Resolution of bladder and bowel symptoms is not routinely associated with surgical correction of POP.
     c. Choice of operation should be tailored to patient's presenting problems, lifestyle, and goals for the surgery.
  3. Evaluate and treat all defects present on exam.
     a. Combination defects are the most common presentation. Seen in 60% of patients.
     b. Anterior and apical combination is most common.
  4. There are multiple ways to classify operations for POP (Table 2).
     a. Obliterative:
        1) Narrow, shorten, or completely close off the vagina.
        2) High success rates with low morbidity.
        3) First-line treatment for women with significant medical comorbidities

TABLE 2 Surgical Approach to Pelvic Organ Prolapse

POP-Q Site	Vaginal	Abdominal
Aa	Anterior repair	Retropubic urethropexy
Urethra	Bladder neck suspension sling	
Ba	Anterior repair	Wedge colpectomy
Bladder	Paravaginal repair	Paravaginal repair
	Colpocleisis	Abdominal sacrocolpopexy
C	Uterosacral ligament suspension	Abdominal hysterectomy
Cervix/cuff	Iliococcygeus suspension	Uterosacral ligament suspension
	Sacrospinous fixation	Abdominal sacral colpopexy
	Manchester operation	Uterine suspension
	Hysteropexy	
	Vaginal hysterectomy	
	Colpocleisis	
D	McCall culdoplasty	Halban culdoplasty
Cul-de-sac		Moschcowitz culdoplasty
Ap	Rectovaginal plication (posterior repair)	Colpoperineopexy
	Site-specific repairs	

POP-Q, Pelvic Organ Prolapse Quantification System.

TABLE 3 Procedures for POP

Classification		Procedure	Compartment(s)
Obliterative		Le Fort colpocleisis	All
		Total colpocleisis	All
Reconstructive	Restorative	Uterosacral ligament suspension	Apex
		Hysteropexy	Apex
		Paravaginal defect repair	Anterior
		Anterior colporrhaphy	Anterior
		Posterior colporrhaphy	Posterior
		Defect-directed posterior repair	Posterior
		Perineorrhaphy	Posterior
	Compensatory		
	Mesh	Sacral colpopexy	All
		Sacral hysteropexy	Apex
		Transvaginal mesh	All
	Nonmesh	Sacrospinous ligament suspension	Apex
		Ileococcygeus suspension	Apex
		Enterocele repair	Posterior

who do not desire future vaginal intercourse.
4) Associated with high rates of postoperative incontinence; most surgeons offer antiincontinence procedure at the same setting.

b. Reconstructive:
1) Restorative procedures use normal anatomic relationships and structures.
2) Compensatory procedures utilize nonanatomic relationships and may or may not use synthetic meshes and graphs.

5. Table 3 categorizes various common procedures for POP.
6. Hysterectomy alone does not treat POP.
a. Often performed concomitantly with POP repair as necessary step to expose critical anatomy.
7. For symptomatic women who desire childbearing: Management with pessaries or pelvic muscle exercises is recommended; if surgical correction is required, uterosacral ligament hysteropexy is the preferred method.
a. Patients should be counseled that repair will likely break down with subsequent pregnancy.
8. Women without stress incontinence undergoing vaginal surgery for POP are at risk for postoperative urinary incontinence.
a. Use of a prophylactic midurethral sling inserted during vaginal prolapse surgery has been shown to result in a lower rate of urinary incontinence at 3 and 12 mo, but also in a higher rate of adverse events (UTIs, major bleeding complications, incomplete bladder emptying).
9. Abdominal mesh-based repairs and anterior vaginal mesh repairs have superior durability but higher risk and potential for unique complications.
a. Use of mesh with posterior repairs does not improve outcomes and is associated with increased complications.
10. Mesh erosion rates have been reported up to 10%, with similar incidence between biologic and synthetic graft. However, synthetic graft erosion often requires surgical revision.

DISPOSITION

- Surgical success rates range between 70% and 95%.
- Up to 30% of patients may require a second operation for POP.
- Untreated POP does not necessarily worsen.

REFERRAL

- To a urogynecologist/gynecologist if surgical intervention is needed or for complex cases involving bladder dysfunction.
- Treating physicians should have special training with synthetic mesh products, if they are used.

PEARLS & CONSIDERATIONS

- POP rarely, if ever, causes pain.
- Stage of POP does not dictate treatment or prognosis.
- Treatment for POP is based on symptoms and patient bother.
- Options for most patients are no treatment, pessary, or surgery.

BASIC INFORMATION

DEFINITION

The word "pemphigus" is derived from the Greek word *pemphix,* meaning blister. The pemphigus dermatoses encompass a group of rare, potentially fatal, chronic, autoimmune bullous diseases that are characterized by intraepidermal blisters of the skin and mucous membranes.

Pemphigus has four main subtypes:

- Pemphigus vulgaris (PV) (Fig. E1): The most common of the pemphigus diseases
  1. Pemphigus vegetans of Neumann, a rare clinical variant of PV in which healing is accompanied by vegetative proliferation of the epidermis
  2. Pemphigus vegetans of Hallopeau, a milder clinical variant of PV in which bullae do not precede vegetating plaques. Most common on intertriginous areas
- Pemphigus foliaceus (PF): A superficial form of pemphigus without oral mucosa involvement and a more favorable prognosis than that of PV.
  1. Pemphigus seborrhoicus, a rare clinical variety of PF in which lesions occur in a seborrheic distribution
  2. Pemphigus erythematosus, a localized variant of PF that mainly affects the elderly and can resemble cutaneous lupus erythematosus; the majority of cases will have positive antinuclear antibody (ANA) and negative anti–double-stranded DNA antibody (anti-dsDNA)
  3. Endemic pemphigus foliaceus (fogo selvagem), an endemic variant of PF that is seen mainly in endemic regions of Brazil and North Africa. The black fly (*Simulium nigrimanum)* may serve as a vector
  4. Pemphigus herpetiformis, pemphigus vulgaris or pemphigus foliaceus with urticarial plaques and vesicles in a herpetiform pattern
- Paraneoplastic pemphigus: Presents with hemorrhagic stomatitis and mucous membrane erosions; associated with malignancy (most commonly non-Hodgkin lymphoma and chronic lymphocytic leukemia [CLL]); complete neoplastic workup is required when diagnosis is suspected
- Immunoglobulin (Ig) A pemphigus: Fluid-filled blisters that progress to pustules and have a tendency to coalesce; mucosal involvement is rare
  1. Subcorneal pustular dermatosis-type IgA pemphigus
  2. Intraepidermal neutrophilic IgA dermatosis

SYNONYMS

Pemphigus
PV
Fogo selvagem: Endemic pemphigus foliaceus
Senear-Usher syndrome: Pemphigus erythematosus

ICD-10CM CODE
L10.0 Pemphigus vulgaris

EPIDEMIOLOGY & DEMOGRAPHICS

- Pemphigus vulgaris makes up 80% of all pemphigus cases
- Incidence is estimated at 1 to 5 cases per 1 million person-yr, but it is substantially higher in geographic regions with large populations of Ashkenazi Jewish or Mediterranean descent
- Typically occurs in the fourth to sixth decades of life, although range of ages affected is broad and may occur in the very young or the elderly
- Slight female predilection (1.5:1)

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- History:
  1. Multiple oropharyngeal ulcerations (Fig. E2) and erosions typically occur first (50% to 70% of cases), which can then be followed by a more generalized bullous eruption involving the skin within several weeks or months:
     a. Blisters are flaccid and rupture easily, leaving painful nonhealing erosions and ulcerations that may be the predominant clinical finding.
     b. Pain associated with oral mucosal blistering often results in dysphagia and hoarseness; nasal cavity involvement can lead to nasal congestion and mucus discharge.
     c. Skin bullae may occasionally be the initial manifestation of PV; most commonly involves the scalp (Fig. E3), upper chest, and back.
     d. Not commonly pruritic.

Physical findings:

1. Anatomic distribution:
   a. Oral mucosa: Most common sites are buccal, labial, and palatal mucosa, along with the tongue
   b. Can also involve the pharynx, larynx, vagina, penis, anus, and conjunctival mucosa; a recent study reported that 39% of patients with PV had pharyngoesophageal involvement as determined by upper gastrointestinal endoscopy
   c. Generalized cutaneous involvement (Fig. E4)
2. Other clinical findings:
   a. Nail dystrophy, paronychia, and subungual hematomas
   b. Ocular symptoms, though rare, may include conjunctival injection, pain, tearing, photophobia, and irritation; visual acuity is not affected; associated conjunctival papillomas and inflammatory masses have recently been reported

FIG. E1 Pemphigus vulgaris. (Courtesy Dr. Lawrence Lieblich. From James WD et al: *Andrews' diseases of the skin*, ed 12, Philadelphia, 2016, Elsevier.)

FIG. E2 Oral pemphigus vulgaris. (From James WD et al: *Andrews' diseases of the skin*, ed 12, Philadelphia, 2016, Elsevier.)

FIG. E3 Chronic pemphigus vulgaris of the scalp. (From James WD et al: *Andrews' diseases of the skin*, ed 12, Philadelphia, 2016, Elsevier.)

FIG. E4 Pemphigus vulgaris. (From James WD et al: *Andrews' diseases of the skin*, ed 12, Philadelphia, 2016, Elsevier.)

3. Lesion configuration:
   a. Mucosal membranes
   b. No preferential distribution
4. Lesion morphology:
   a. Flaccid bullae and vesicles progressing to ulcerations and erosions with a collarette of loose epidermis.
   b. Positive Nikolsky sign: When the clinician applies lateral pressure to normal-appearing skin at the periphery of active lesions, separation of the superficial epidermis occurs.
   c. Positive Asboe-Hansen sign: When gentle pressure is applied on intact bulla, the fluid spreads under the adjacent skin, thereby enlarging the blister.
   d. In the absence of treatment, healing with crusting followed by re-epithelialization may occur; scarring is rare, but some patients experience hyperpigmentation.
   e. Possibility for large areas of denuded skin with resulting bacterial superinfection.

ETIOLOGY

Autoimmune disease caused by autoantibodies against the cell surface of keratinocytes leading to separation of adjacent keratinocytes (called *acantholysis*). The predominant antibody in PV is directed against desmoglein 3 (Dsg-3) or both Dsg-3 and desmoglein 1 (Dsg-1; in PF it is directed against desmoglein 1. Desmoglein 1 is concentrated mainly in superficial epidermal layers, whereas desmoglein 3 is present mainly in the deeper epidermis layers, thus accounting for the differences in the sites of blister formation in PV versus PF.

Additional antibodies directed toward keratinocyte acetylcholine receptors have also been identified. Circulating antibodies are detected in approximately 80% of patients with active disease, and levels generally correlate with disease severity. Immunoglobulin (Ig) G, and rarely IgM, IgA, or complement protein C3, deposition occurs in lesional and healthy perilesional skin in 90% of patients.

Several drugs, including captopril, penicillamine, aspirin, calcium channel blockers, and rifampin, have been identified as potential triggers in the development of PV. Cessation of use generally leads to rapid resolution. Ultraviolet radiation, including phototherapy, may also exacerbate pemphigus vulgaris and foliaceus.

Dx DIAGNOSIS

The diagnosis of pemphigus vulgaris should be suspected in patients with painful oral erosions and flaccid bullae or erosions on the skin. The diagnosis is confirmed by histology, direct immunofluorescence (DIF) pattern of perilesional skin, indirect immunofluorescence (IIF) testing of serum, or ELISA testing for anti-desmoglein 1 and anti-desmoglein 3 autoantibodies.

DIFFERENTIAL DIAGNOSIS

- Herpetic stomatitis
- Aphthous stomatitis
- Erythema multiforme
- Stevens-Johnson syndrome
- Drug eruptions
- Lichen planus
- Systemic or bullous lupus erythematosus
- Mucous membrane or cicatricial pemphigoid
- Paraneoplastic pemphigus
- Pemphigus foliaceus
- Linear IgA bullous dermatosis
- Hailey-Hailey disease
- Grover disease
- Bullous pemphigoid (Table E1)
- Behçet syndrome
- Dermatitis herpetiformis
- Epidermolysis bullosa acquisita
- IgA pemphigus

WORKUP

Skin biopsy is diagnostic; specimens should be sent for routine histochemical staining and direct immunofluorescence. An upper endoscopy should be considered in patients with dysphagia to determine degree of esophageal involvement and check for esophageal Nikolsky sign. Airway evaluation is indicated for patients with any evidence of airway obstruction. DIF is positive in all patients with PV or PF. Alternative diagnosis should be considered if DIF is negative. DIF is negative in some patients with drug-induced pemphigus.

LABORATORY TESTS

- Light microscopy: Intraepithelial blisters with acantholysis; basal layer with single layer of intact cells (known as "tombstoning")
- DIF: Intercellular IgG and C3 deposition in "chicken-wire" lattice pattern
- IIF: Tests for presence and titer of antibodies; should be used in conjunction with clinical, histopathological, and DIF evaluation; estimated 90% positive predictive value and low negative predictive value; titers may correlate with disease state and can potentially be used for tracking progression and treatment response
- ELISA: Similar sensitivity but inferior specificity compared to IIF; antidesmoglein antibodies titers correlate with disease activity (however, there is a subset of patients with high anti-Dsg-3 antibodies but low disease activity)

Rx TREATMENT

A rating scale, such as the Pemphigus Disease Area Index (PDAI), can be used to assess disease severity. This scale correlates well with

TABLE E1 Differentiation of Pemphigus Vulgaris and Bullous Pemphigoid

Characteristics	Pemphigus Vulgaris	Bullous Pemphigoid
Age	Usually occurs in middle-aged persons	Usually occurs in elderly persons
Site	Oral mucosa, face, chest, groin	Flexural areas, groin, axilla; less often involving mucosal surfaces
Findings	Flaccid bullae and erosions, intraepidermal blisters, IgG autoantibodies against keratinocyte surfaces	Intact tense bullae, subepidermal blisters, IgG autoantibodies against hemidesmosomal antigens
Treatment	Prednisone 0.5-1.5 mg/kg/day with adjuvant immunosuppressant agents; refractory disease may require rituximab, intravenous immunoglobulin, immunoadsorption, plasmapheresis, or extracorporeal photochemotherapy	Prednisone 0.5-1 mg/kg/day with adjuvant immunosuppressant therapy as needed for refractory cases; localized disease may be controlled with topical steroids
Prognosis	>90% respond; steroid side effects significant; mortality rate under 5%	>90% respond; remissions and recurrences common; mortality rate up to 23%

IgG, Immunoglobulin G.

physician's assessment of disease severity and can be used for patients with even mild disease. Briefly, it requires quantitative measurement of the number and size of total skin and mucosal lesions and incorporates disease activity and damage. Similar to severe burns, PV can be fatal without adequate treatment due to secondary infections and metabolic disturbances. The mainstay of therapy is systemic corticosteroids with the goal of complete absence of, or only occasional, blistering.

NONPHARMACOLOGIC THERAPY

- Mild soaps and emollients to skin.
- Burow solution may be useful for weeping erosions.
- Avoid trauma to the skin.
- When there are extensive raw surfaces, daily baths are helpful in removing the thickened crusts and reducing foul odor; can be followed with nonstick bandaging (e.g., petrolatum gauzes).
- Soft diet and viscous lidocaine can be used in patients with oral lesions; flossing should be avoided in the presence of symptomatic lesions.
- A mixture of equal parts of simethicone (Maalox), elixir of diphenhydramine, and viscous lidocaine is also effective.

ACUTE GENERAL Rx

- For localized disease, topical steroids may be effective.
- For generalized disease, oral glucocorticoids are the mainstay of therapy and often work rapidly to halt blistering.
  1. Optimum dosing guidelines have not yet been established.
  2. Initial dose of prednisone is usually 0.5 to 1.5 mg/kg/day; if new lesions continue to form, the dose can be increased up to 2 mg/kg/day. Pulsed dosing may also be used.
  3. Adjuvant therapy with rituximab administered with prednisone as initial therapy may lead to improve mortality rates compared to prednisone alone.
  4. Alternative adjuvant therapies can also be initiated simultaneously with prednisone include azathioprine, mycophenolate mofetil (MMF), cyclophosphamide, cyclosporine, dapsone, infliximab, intravenous immunoglobulin, and plasma exchange. These agents help reduce the risk of relapse.
  5. Tumor necrosis factor (TNF)-α blockers should be avoided, given conflicting data regarding their efficacy in the treatment of PV.
  6. For patients with severe disease requiring initial prednisone dosing greater than 100 mg daily, treatment with pulse oral or intravenous (IV) steroids can be very effective; a common regimen is IV dexamethasone 100 mg for 3 days and repeated every 2 to 3 wk.
  7. Steroid tapering should begin once no new lesions have developed for at least 2 wk and approximately 80% of the existing lesions have healed. The steroid dose should be decreased by 25% at biweekly intervals, with slower reductions once a dose of 20 mg per day is reached. If fewer than three new lesions form during taper, increase steroid dose to last effective dose. If three or more new lesions form during taper, increase steroid dose back to prior doses.
  8. Ocular involvement in PV generally responds to prednisone and/or immunosuppressant therapy; lubricating artificial tears or topical ophthalmic corticosteroids can provide further symptomatic relief.

CHRONIC Rx

- Adjuvant therapy such as immunosuppressants, antiinflammatories, chemotherapeutic agents, and biologics are useful for disease control and to shorten the length of treatment with oral steroids. Azathioprine, MMF, dapsone, methotrexate, cyclophosphamide, and cyclosporine can also be used as monotherapy for patients with contraindications to corticosteroids. Treatment duration and dosing are determined by clinical response:
  1. Azathioprine: First-line adjuvant immunosuppressant. 1 to 3 mg/kg/day based on thiopurine methyltransferase (TPMT) activity; an initial dose of 50 mg daily can be started and increased after a week in the absence of adverse effects.
  2. Mycophenolate mofetil (MMF): Steroid-sparing agent. 2 g daily for average patient of 75 kg, or 1 g daily for elderly patients.
  3. Cyclophosphamide: Second-line immunosuppressant adjuvant agent. 500 mg IV infusion or 2 mg/kg/day PO. Use limited by potential long-term side effects, including infertility, infections, increased risk of cancers, and genitourinary complications.
  4. Methotrexate: Steroid-sparing agent. 10 to 20 mg/wk.
  5. Dapsone 100 mg daily or up to ≤1.5 mg/kg/day; serum G6PD activity should be checked prior to beginning therapy.
  6. Rituximab (anti-CD20 monoclonal antibody): Typical regimen is 1000 mg IV at baseline and 2 wk, then 500 mg every 6 mo.

Refractory disease:

- A relapse or flare is defined as the appearance of three or more lesions in a month without spontaneous resolution, or the extension of established lesions in a patient who has previously attained control of disease activity. A variety of treatment modalities are available:
  1. Intravenous immunoglobulin (IVIG): Refractory disease or for patients with contraindications to immunosuppressants. Dosing is 2 g/kg per cycle administered over 2 to 5 consecutive days each month. Contraindicated in IgA deficiency; can lead to aseptic meningitis in patients with history of chronic migraines.
  2. Immunoadsorption: Rapid removal of circulating antibodies. Indicated in PV patients who have failed corticosteroid therapy combined with azathioprine or MMF. Recommended schedule is four treatments on 4 consecutive days (2.5-fold plasma volume/day) repeated monthly. Can be combined with rituximab or cyclophosphamide therapy.
  3. Plasmapheresis: No standardized protocol. Four to five plasma exchanges of 1 to 1.5 plasma volumes over a period of 7 to 10 days is sufficient to remove 90% of total body initial immunoglobulin burden.

Should be used with caution in patients with cardiac dysfunction.

4. Extracorporeal photochemotherapy: Collection and reinfusion of mononuclear cells after extracorporeal irradiation with ultraviolet-A light in the presence of 8-metoxypsoralen. Case series have reported excellent clinical response with no adverse effects.

DISPOSITION

- Medication is continued until clinical disease is suppressed.
- Age of onset ≥65 yr, presence of coronary heart disease and/or cardiac arrhythmias at time of diagnosis, and level of anti-Dsg-1 autoantibodies ≥100 U/ml at diagnosis to be associated with greater mortality in PV patients.
- Before the use of oral corticosteroids, PV was usually a fatal disease with a mortality rate of greater than 73% and survival measured in months after diagnosis.
- Combined corticosteroids and adjuvant therapy have decreased mortality rates to less than 5%. However, patients with PV continue to have significantly increased mortality risks compared with the general population.
- The risk of all-cause mortality in PV patients is two to three times greater than expected for the general population. Death generally occurs from systemic and respiratory tract infections or complications related to medical therapy.

REFERRAL

- Dentistry
- Dermatology
- Ophthalmology
- Otolaryngology

PEARLS & CONSIDERATIONS

COMMENTS

- PV, unlike bullous pemphigoid, is generally a disease of middle-aged persons.
- Prednisone is the mainstay of treatment.
- Monitoring anti-Dsg-1 antibodies during treatment course may be helpful, as persistently high levels are a positive predictive marker for cutaneous relapse. In contrast, high levels of anti-Dsg-3 do not always correlate with a mucosal relapse.
- Because PV is mediated by IgG autoantibodies that can cross the placenta, neonates born to mothers with active PV can present with transient disease that self-resolves as the antibody is degraded.

BASIC INFORMATION

DEFINITION

Peptic ulcer disease (PUD) is an ulceration in the stomach or duodenum resulting from an imbalance between mucosal protective factors and various mucosal damaging mechanisms (see "Etiology").

SYNONYMS

PUD
Duodenal ulcer (DU)
Gastric ulcer (GU)

ICD-10CM CODES

K25.3	Acute gastric ulcer without hemorrhage or perforation
K25.7	Chronic gastric ulcer without hemorrhage or perforation
K26.3	Acute duodenal ulcer without hemorrhage or perforation
K26.7	Chronic duodenal ulcer without hemorrhage or perforation
K27.0	Acute peptic ulcer, site unspecified, with hemorrhage
K27.1	Acute peptic ulcer, site unspecified, with perforation
K27.2	Acute peptic ulcer, site unspecified, with both hemorrhage and perforation
K27.3	Acute peptic ulcer, site unspecified, without hemorrhage or perforation
K27.4	Chronic or unspecified peptic ulcer, site unspecified, with hemorrhage
K27.5	Chronic or unspecified peptic ulcer, site unspecified, with perforation
K27.6	Chronic or unspecified peptic ulcer, site unspecified, with both hemorrhage and perforation
K27.7	Chronic peptic ulcer, site unspecified, without hemorrhage or perforation
K27.9	Peptic ulcer, site unspecified, unspecified as acute or chronic, without hemorrhage or perforation
P78.82	Peptic ulcer of newborn
Z87.11	Personal history of peptic ulcer disease

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence: 250,000 to 500,000 (200,000 to 400,000 duodenal; 50,000 to 100,000 gastric) annually; duodenal ulcer/gastric ulcer ratio is 4:1.
- Anatomic location: <90% of duodenal ulcers occur in the first portion of the duodenum; gastric ulcers occur most frequently in the lesser curvature near the incisura angularis.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Epigastric pain is the most frequently reported symptom of PUD. The pain is typically improved with food or antacids and worsened by fasting.
- Physical examination is often unremarkable.
- Patient may have epigastric tenderness, tachycardia, pallor, hypotension (from acute or chronic blood loss), nausea and vomiting (if pyloric channel is obstructed), board-like abdomen and rebound tenderness (if perforated), and hematemesis or melena (with a bleeding ulcer). Box 1 describes key symptoms and signs of peptic ulcer.

ETIOLOGY

Often multifactorial. The following are common mucosal damaging factors:

- *Helicobacter pylori* infection. *H. pylori* is the major cause of PUD. It is found in more than 70% of patients with duodenal ulcers and gastric ulcers in the U.S. Rates are much higher (>90%) in other parts of the world. Eradication of *H. pylori* markedly reduces peptic ulcer recurrence
- Medications (NSAIDs, glucocorticoids). Risk factors for development of NSAID-related ulcers are described in Table 1
- Incompetent pylorus or lower esophageal sphincter
- Bile acids
- Impaired proximal duodenal bicarbonate secretion
- Decreased blood flow to gastric mucosa
- Acid secreted by parietal cells and pepsin secreted as pepsinogen by chief cells
- Cigarette smoking
- Alcohol

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Gastroesophageal reflux disease
- Cholelithiasis syndrome
- Pancreatitis
- Gastritis
- Nonulcer dyspepsia
- Neoplasm (gastric carcinoma, lymphoma, pancreatic carcinoma)
- Angina pectoris, myocardial infarction, pericarditis
- Dissecting aneurysm
- Other: High small-bowel obstruction, pneumonia, subphrenic abscess, early appendicitis

WORKUP

Comprehensive history and physical exam to exclude other diagnoses. Diagnostic modalities include endoscopy or upper GI series. Endoscopy is preferred and remains the gold standard for diagnosis of PUD. The presence of a mucosal break ≥5 mm in the stomach or duodenum confirms the diagnosis.

BOX 1 Key Symptoms and Signs of Peptic Ulcer

Uncomplicated Ulcer
No symptoms ("silent ulcer" in up to 40% of cases)
Epigastric pain
Pain may radiate to the back, thorax, other parts of abdomen (cephalad most likely, caudad least likely)
Pain may be nocturnal (most specific), "painful hunger" relieved by food, or continuous (least specific)
Nausea
Vomiting
Heartburn (mimics or associated with gastroesophageal reflux)

Complicated Ulcer
Acute perforation
Severe abdominal pain
Shock
Abdominal boardlike rigidity (and rebound and other signs of peritoneal irritation)
Free intraperitoneal air
Hemorrhage
Hematemesis and/or melena
Hemodynamic changes, anemia
Previous history of ulcer symptoms (80%)
Gastric outlet obstruction
Satiation, inability to ingest food, eructation
Nausea, vomiting (and related disturbances)
Weight loss

From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, Saunders.

TABLE 1 Risk Factors for Development of NSAID-Related Ulcers

Definite	Possible
Advanced age	Concomitant infection with *Helicobacter pylori*
History of ulcer	Cigarette smoking
Concomitant corticosteroid therapy	Consumption of alcohol
Concomitant anticoagulation therapy	
High doses of NSAIDs	
Serious systemic disorders	

NSAID, Nonsteroidal antiinflammatory drug.
From Andreoli TE et al: *Andreoli and Carpenter's Cecil essentials of medicine,* ed 8, Philadelphia, 2010, Saunders.

LABORATORY TESTS

- Routine laboratory evaluation is usually unremarkable.
- Anemia may be present in patients with significant GI bleeding.
- *H. pylori* testing by endoscopic biopsy, urea breath test or stool antigen test (*H. pylori* stool antigen) is recommended:
  1. The urea breath test documents active infection (sensitivity and specificity >90%). The patient ingests a small amount of urea labeled with carbon 13 or carbon 14. If urease is present (produced by the organism), the urea is hydrolyzed and the patient exhales labeled carbon dioxide that is then collected and measured. Use of proton pump inhibitors (PPI) within 2 wk of the urea breath test may interfere with test results.
  2. Stool antigen test is an ELISA that identifies *H. pylori* antigen in a stool specimen through a polyclonal anti–*H. pylori* antibody. It is as accurate as the urea breath test for diagnosis of active infection and follow-up evaluation of patients treated for *H. pylori.* A negative result on the stool antigen test 6 wk after completion of therapy identifies patients in whom eradication of *H. pylori* was successful.
  3. Serologic testing for antibodies to *H. pylori* is easy and inexpensive; however, the presence of antibodies demonstrates previous but not necessarily current infection. Antibodies to *H. pylori* can remain elevated for mos to yrs after infection has cleared; therefore antibody levels must be interpreted in light of the patient's symptoms and other test results (e.g., PUD seen on upper GI series).
  4. Histologic evaluation of endoscopic biopsy samples is considered by many the gold standard for accurate diagnosis of *H. pylori* infection. However, detection of *H. pylori* depends on the site and number of biopsy samples, the method of staining, and experience of the pathologist.
- Additional laboratory evaluation is indicated only in specific cases (e.g., amylase level in suspected pancreatitis, serum gastrin level in suspected Zollinger-Ellison [ZE] syndrome).

IMAGING STUDIES

- Conventional upper GI barium studies identify approximately 70% to 80% of PUD; accuracy can be increased to approximately 90% by using double contrast.
- Abdominal CT is helpful when suspecting perforating peptic ulcer disease (sensitivity >95%).

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Stop smoking; smoking increases the risk of PUD, decreases the healing rate, and increases the frequency of recurrence.
- Avoid NSAIDs and alcohol.
- Special diets have been proved unrelated to ulcer development and healing; however, avoid foods that cause symptoms.

ACUTE GENERAL Rx

Eradication of *H. pylori,* when present, can be accomplished with various regimens (see "*Helicobacter pylori* Infection")

PUD patients testing negative for *H. pylori* should be treated with antisecretory agents:

- H_2 receptor antagonists (H_2RAs): Ranitidine, famotidine, and nizatidine are all effective; they are usually given in split dose or at nighttime.
- PPIs: Can also induce rapid healing; they are usually given 30 min before meals.

Antacids and sucralfate are also effective agents for the treatment and prevention of PUD.

CHRONIC Rx

Maintenance therapy in peptic ulcer patients is indicated in the following situations:

- Persistent smokers
- Recurrent ulcerations
- Long-term treatment with NSAIDs, glucocorticoids
- Elderly or debilitated patients
- Aggressive or complicated ulcer disease (e.g., perforation, hemorrhage)
- Asymptomatic bleeders

DISPOSITION

- The recurrence rate for untreated PUD is ~60% (>70% in smokers). Treatment decreases the recurrence rate by nearly 30%.
- Patients with recurrent ulcers should be re-treated for an additional 8 wk and then placed on maintenance therapy with H_2RAs, PPIs, sucralfate, or antacids.
- An ulcer is considered refractory to treatment if healing is not evident after 8 wk for duodenal ulcers and 12 wk for gastric ulcers. In these patients, maximum acid inhibition (e.g., esomeprazole 40 mg bid) is preferred over continued therapy with standard antiulcer therapy.
- Eradication of *H. pylori* (when present) is indicated in all patients. A negative stool antigen test for *H. pylori* 6 wk after treatment accurately confirms cure of *H. pylori* infection with reasonable sensitivity in initially seropositive healthy subjects.
- Screening for ZE syndrome should also be considered in patients with multiple recurrent ulcers; in patients with ZE, the serum gastrin level is >1000 pg/ml and the basal acid output is usually >15 mEq/hr.
- Surgery for refractory ulcers is now only rarely performed; it consists of highly selective vagotomy for duodenal ulcers or ulcer removal with antrectomy or hemigastrectomy without vagotomy for gastric ulcers.

REFERRAL

- GI referral for patients requiring endoscopy
- Surgical referral for patients with nonhealing ulcers despite appropriate medical therapy

PEARLS & CONSIDERATIONS

COMMENTS

- Patients with gastric ulcers should generally have repeat endoscopy after 8 to 12 wk of antisecretory therapy to document healing and test exfoliative cytology for gastric carcinoma. Patients with duodenal ulcers and those with low risk gastric ulcers, such as young patients on NSAIDs, generally do not require endoscopic surveillance.
- After endoscopic treatment of bleeding peptic ulcers, bleeding recurs in up to 20% of patients. PPI administration intravenously by continuous infusion substantially reduces the risk of recurrent bleeding. High-dose IV esomeprazole (80 mg IV bolus followed by 8 mg/hr infusion over 72 hr) given after successful endoscopic therapy to patients with high-risk peptic ulcer bleeding has been reported to reduce recurrent bleeding at 72 hr and to maintain sustained clinical benefits for up to 30 days.
- Among low-dose aspirin recipients who had peptic ulcer bleeding, continuous aspirin therapy may increase the risk for recurrent bleeding.

BASIC INFORMATION

DEFINITION

Acute pericarditis is the inflammation (or infiltration) of the pericardium. It is characterized by at least two of the following four criteria: (1) chest pain, (2) specific electrocardiographic changes, (3) pericardial friction rub, or (4) pathognomonic pericardial friction rub.

ICD-10CM CODES

I30.0	Acute nonspecific idiopathic pericarditis
I30.1	Infectious pericarditis
I30.8	Other forms of acute pericarditis
I30.9	Acute pericarditis, unspecified
I301.0	Chronic adhesive pericarditis
I31.1	Chronic constrictive pericarditis
I31.3	Pericardial effusion (non-inflammatory)
I31.9	Diseases of pericardium, unspecified (tamponade)
I31.2	Hemopericardium

EPIDEMIOLOGY & DEMOGRAPHICS

- Most common form of pericardial disease worldwide
- It is diagnosed in 0.1% to 0.2% of hospitalized patients and is responsible for 5% of patients admitted for nonischemic chest pain.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Chest pain: Characteristically sharp, pleuritic, positional (improved by sitting up and leaning forward).
- Pericardial rub: A triphasic (ventricular systole, early diastole, atrial contraction), scratchy sound best heard at the lower left sternal border is pathognomonic. Unlike pleural friction rub, the rub of pericarditis is not affected by respiration.
- Pericardial effusion: Beck triad (hypotension, elevated jugular venous pressure, and muffled heart sounds) suggests pericardial tamponade.

ETIOLOGY

- Etiology is dichotomized into infectious and noninfectious causes.
- In developed countries, viral and idiopathic etiologies are the most common causes of pericarditis. Tuberculosis accounts for 80% to 90% of pericarditis in developing countries.
- Other infectious agents include HIV, fungus, parasites, and bacteria.
- Noninfectious causes include neoplasm (7% to 13%), autoimmune syndromes (3% to 4%), and perimyocardial infarction (Dressler syndrome, typically 2 wk after MI).
- Drug-induced: Procainamide, hydralazine, phenytoin, isoniazid, rifampin, doxorubicin, mesalamine, adalimumab.
- Metabolic: Uremia, myxedema, anorexia nervosa.
- Posttraumatic: Postpericardiotomy, postpacemaker lead placement, postcatheter ablation, post-CPR.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Angina pectoris and acute coronary syndrome
- Myopericarditis/perimyocarditis
- Dissecting aortic aneurysm
- Pulmonary causes: Embolism, infarction, pneumothorax, pneumonia with pleurisy
- Gastrointestinal causes: Hepatitis, cholecystitis, GERD, esophageal spasm or rupture
- Costochondritis
- Box 1 summarizes the differential diagnosis of pericardial effusion by etiology

WORKUP (TABLE 1)

Table 2 summarizes an initial approach to acute pericarditis. Diagnosis of pericarditis requires at least two of the four following clinical criteria:

- Typical pleuritic chest pain
- Pericardial friction rub
- Suggestive ECG changes (diffuse concave ST segment elevation, PR depression in all leads except for AVR where there is elevation)
- New or worsening pericardial effusion

LABORATORY TESTS

Laboratory tests may help elucidate the underlying cause and are adjunctive to the clinical criteria.

- Inflammatory markers: Erythrocyte sedimentation rate, (high-sensitivity) C-reactive protein (CRP), and complete blood count with differential are elevated in pericarditis.
- Basic metabolic profile.
- Cardiac biomarkers (troponin I and T) when elevated indicate involvement of the myocardium (i.e., myopericarditis).

The following tests may be useful when specific etiologies of pericarditis are suspected:

- HIV
- PPD
- Antinuclear antibody, rheumatoid factor
- Routine viral studies are not indicated since they are low yield

PERICARDIAL SAMPLING

Indications for echocardiogram or pericardiocentesis are:

- Tamponade physiology
- Moderate to large pericardial effusion with symptoms, or refractory to medical therapy
- Suspicion of a neoplastic, bacterial, or tuberculous process
- Evidence of constrictive or effusive-constrictive pericarditis
- Pericardiocentesis is for diagnostic and therapeutic purposes. The pericardial fluid should be analyzed for RBC, WBC, Gram stain, culture, cytology, glucose, pH, LDH, and protein. In select cases, consider checking triglyceride for chylopericardium, ADA or PCR for tuberculosis
- Pericardial biopsy may be helpful in recurrent pericardial effusion with an elusive diagnosis and when malignancy or tuberculosis is suspected

IMAGING STUDIES

- ECG (Fig. 1): Changes in the ECG reflect inflammation of the epicardium, since the parietal pericardium is electrically inert. The ECG changes are staged as follows:
  1. Stage I (Acute phase): Hours to few days. PR-segment depression in all leads except aVR (where PR elevation is seen) and diffuse concave ST-segment elevations
  2. Stage II (Intermediate phase): Seen in first wk with return of PR and ST segments to baseline
  3. Stage III (Intermediate): T-wave inversion in leads previously showing ST-segment elevation
  4. Stage IV (Late phase): Normalization of the ECG or indefinite persistence of T-wave inversions

BOX 1 Major Differential Diagnosis of Pericardial Effusion by Etiology

Noninfectious

- Malignancy (usually metastatic)
- Myocardial infarction associated (Dressler syndrome)
- Uremia
- Myxedema (rare cause of tamponade physiology)
- Trauma (penetrating or nonpenetrating)
- Chylopericardium
- Acute idiopathic
- Rheumatic fever
- Collagen vascular disease (systemic lupus erythematosus, rheumatoid arthritis, scleroderma, Wegener granulomatosis)
- Postsurgical (cardiac and intrathoracic)
- Drug induced (procainamide, hydralazine, phenytoin, doxorubicin, isoniazid)

Infectious

- Viral (coxsackievirus, echovirus, mumps, adenovirus, hepatitis, human immunodeficiency virus)
- Bacterial (pneumococcus, streptococcus, staphylococcus)
- Tuberculous
- Fungal (histoplasmosis, coccidiomycosis, *Candida*, particularly in immunosuppressed patients)

From Niederhuber JE: *Abeloff's clinical oncology*, ed 6, Philadelphia, 2020, Elsevier.

TABLE 1 Diagnostic Pathway and Sequence of Performance in Acute Pericarditis

Diagnostic Measure	Characteristic Findings
Obligatory	
Auscultation	Pericardial rub (monophasic, biphasic, or triphasic)
ECG*	*Stage I:* Anterior and inferior concave ST segment elevation. PR segment deviations opposite to P wave polarity
	Early stage II: All ST junctions return to the baseline. PR segments deviated
	Late stage II: T waves progressively flatten and invert
	Stage III: Generalized T-wave inversions in most or all leads
	Stage IV: ECG returns to prepericarditis state
Echocardiography	Effusion types B to D (Horowitz)
	Signs of tamponade
Blood analyses	Erythrocyte sedimentation rate, C-reactive protein, lactate dehydrogenase, leukocytes (inflammation markers)
	Troponin I,† CK-MB (markers of myocardial involvement)
Chest radiograph	Ranging from normal to "water bottle" shape of the heart shadow
	Performed primarily to reveal pulmonary or mediastinal pathology
Mandatory in Tamponade, Optional in Large/Recurrent Effusions or if Previous Tests Inconclusive in Small Effusions	
Pericardiocentesis/drainage	Polymerase chain reaction and histochemistry for etiopathogenetic classification of infection or neoplasia
Optional or if Previous Tests Inconclusive	
CT	Effusions, pericardium, and epicardium
MRI	Effusions, pericardium, and epicardium
Pericardioscopy, pericardial/epicardial biopsy	Establishing the specific etiology

CK-MB, Creatine kinase-MB; *CT,* computed tomography; *ECG,* electrocardiogram; *MRI,* magnetic resonance imaging.

*Typical lead involvement: I, II, aVL, aVF, and V3-V6. The ST segment is always depressed in aVR, frequently in V1, and occasionally in V2. Stage IV may not occur, and there are permanent T-wave inversions and flattenings. If an ECG is first recorded in stage III, pericarditis cannot be differentiated by ECG from diffuse myocardial injury, "biventricular strain," or myocarditis. ECG in early repolarization is very similar to stage I. Unlike stage I, this ECG does not acutely evolve, and J-point elevations are usually accompanied by a slur, oscillation, or notch at the end of the QRS just before and including the J point (best seen with tall R and T waves—large in an early repolarization pattern). Pericarditis is likely if, in lead V6, the J point is greater than 25% of the height of the T-wave apex (using the PR segment as a baseline).

†A rise in cardiac muscle troponin I (cTnI) is detected in 32.2% of patients, more frequently in younger, male patients, with ST segment elevation and pericardial effusion at presentation. An increase beyond 1.5 ng/ml is uncommon (7.6%) and associated with CK-MB elevation. cTnI increase and is not a negative prognostic marker for the incidence of recurrences, constrictive pericarditis, cardiac tamponade, or residual left ventricular dysfunction.

From Vincent JL et al: *Textbook of critical care*, ed 7, Philadelphia, 2017, Elsevier.

TABLE 2 Initial Approach to the Patient with Definite or Suspected Acute Pericarditis

1. If the diagnosis is suspected but not certain, listen often for pericardial rub and obtain ECGs frequently to check for diagnostic findings.
2. If the diagnosis is suspected or certain, obtain the following tests to help confirm the diagnosis (if necessary) and determine whether a specific causative diagnosis and/or significant associated conditions and/or complications are present:
   - Hemogram
   - hsCRP
   - Troponin I
   - Chest radiograph
   - Echocardiogram
   - Consider additional testing on the basis of clinical suspicion of a specific etiology
3. If the diagnosis is likely or certain, initiate therapy with an NSAID plus colchicine.

From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine*, ed 11, Philadelphia, 2019, Elsevier.

- Echocardiogram is used to evaluate for pericardial effusion (present in 50% to 60% of patients) (Fig. 2). Echocardiogram can help exclude STEMI (through absent wall motion abnormality) and make the diagnosis of constrictive pericarditis or tamponade.
- Chest x-ray: Done primarily to rule out abnormalities of the mediastinum or lung fields that may cause chest pain. Cardiac silhouette may appear enlarged in patients with pericardial effusion if ≥200 ml of fluid has accumulated (Fig. 3). Calcifications around the heart may be seen with chronic constrictive pericarditis.
- Computed tomography: Evaluation of associated pleuropulmonary and extra thoracic diseases and pericardial calcifications.
- MRI (Fig. 4) may be useful in patients with chronic constrictive pericarditis and when malignancy is suspected.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Physical activity restriction until pain abates and normalization of (high sensitivity) CRP, ECG, and echo
- Athletes should avoid competitive activity for 3 mo, whereas nonathletes can resume activities after remission (expert consensus)
- Patient education regarding potential complications: e.g., cardiac tamponade, recurrent pericarditis (which can occur in up to one third of patients), and chronic constrictive pericarditis

ACUTE GENERAL Rx

- High-dose aspirin (750 to 1000 mg tid) or NSAIDs (e.g., ibuprofen 600 to 800 mg tid, indomethacin 50 mg tid) for 1 to 2 wk. Proton pump inhibitor should be provided for gastric protection. NSAIDs should be avoided in patients with recent MI, CHF, acute renal failure, and upper GI bleed.
- Colchicine 0.5 to 0.6 mg once daily (<70 kg) or bid (>70 kg) for 3 mo. Current evidence (COPE, CORE, CORP, ICAP, CORP-2 trials) supports the effectiveness of colchicine in symptomatic relief and prevention of recurrent pericarditis.
- Corticosteroids should be used only as second-line treatment. They are associated with

severe adverse effects, more hospitalizations, and higher rates of recurrences.
- Low- to moderate-dose (0.25 to 0.5 mg/kg/day) systemic steroid therapy for 1 mo, followed by taper (6 to 12 wk), is restricted to patients with rheumatologic disease, renal failure, or contraindication to NSAID/colchicine.
- Azathioprine, intravenous immunoglobulins, anakinra can be considered for patients with refractory recurrent pericarditis.
- Pericardiectomy and pericardiotomy at specialized centers are reserved for recurrent cardiac tamponade or refractory pericarditis.
- Avoidance of anticoagulants (increased risk of hemopericardium).

TREATMENT OF UNDERLYING CAUSE:
- Bacterial pericarditis: Systemic antibiotics and drainage of pericardium
- Collagen vascular disease: Steroid (prednisone)
- Tuberculous pericarditis: Rifampicin, isoniazid, pyrazinamide, and ethambutol for 2 mo, then isoniazid and rifampicin for 6 mo
- Thyroid-related pericardial effusion: Thyroid replacement therapy
- Uremic: Dialysis
- Malignant pericardial effusion: Fig. 5

POTENTIAL COMPLICATIONS FROM PERICARDITIS:
- **Chronic constrictive pericarditis:** Occurs in <1% of patients with acute idiopathic pericarditis.
  1. Physical examination: Signs of right heart failure—hepatomegaly, splenomegaly, ascites, pedal edema, scrotal edema, possible anasarca, jugular venous pressure, Kussmaul sign (paradoxical increase in jugular venous pressure during inspiration), pericardial knock (early diastolic filling sound heard 0.06 to 0.1 sec after S2), and clear lungs.
  2. ECG: Low QRS voltage, nonspecific ST-segment changes, biatrial enlargement.
  3. Chest radiograph: Mild alveolar edema, pleural effusions, biatrial enlargement, pericardial calcification (seen in tuberculous pericarditis).
  4. Echocardiography: May show thickened pericardium (>4 mm), >25% mitral and >50% tricuspid valve inflow variation with respiration, interventricular septal bounce; and mitral annulus reversus (medial e' velocity > lateral e' velocity) suggests constrictive pericarditis.[1]
  5. Hemodynamics (Fig. 6): Elevation of right-sided filling pressures, equalization of diastolic pressures, as well as prominent "x" and rapid "y" descent in the atrial tracing are seen in constrictive pericarditis. Right ventricular pressure tracing typically shows a "dip and plateau" (square root sign) that is due to the unimpeded early filling of the RV with an abrupt halt to the late diastolic filling by the stiff pericardium. Discordance of right ventricular and left ventricular systolic pressures during respiration is also suggestive of constrictive pericarditis.
  6. Therapy: Complex surgical stripping or removal of both layers of the constricting pericardium improves the functional class in majority of late survivors, but has high operative mortality.[2]

[2]Vustarini N, Chen C, Mazine A et al: Pericardiectomy for constrictive pericarditis: 20 years of experience at the Montreal Heart Institute, *Ann Thorac Surg* 100(1):107–113, 2015.

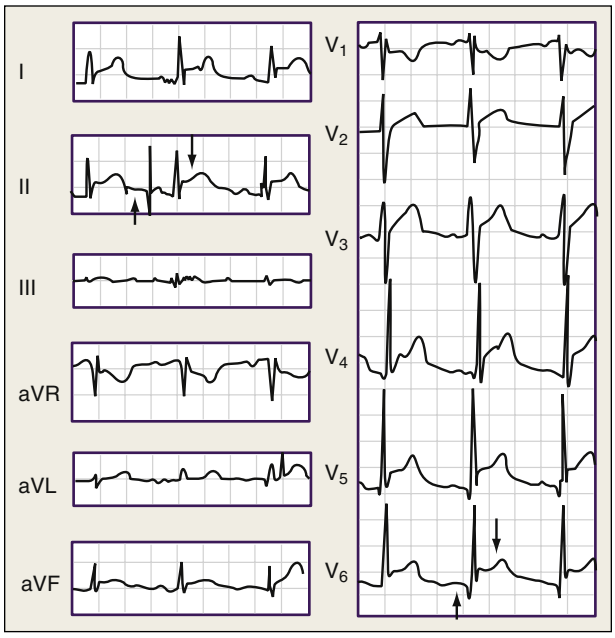

FIG. 1 Typical electrocardiographic changes in acute pericarditis: PR depression (*small arrow*) and concave ST-segment elevation (*large arrow*). *aVF,* Augmented vector foot; *aVL,* augmented vector left; *aVR,* augmented vector right. (From Vincent JL et al: *Textbook of critical care*, ed 7, Philadelphia, 2017, Elsevier.)

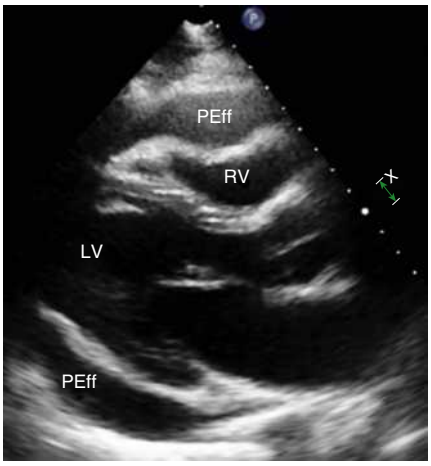

FIG. 2 Bedside echocardiogram showing pericardial effusion compressing the right ventricle during diastole, consistent with cardiac tamponade. *LV,* Left ventricle; *PEff,* pericardial effusion; *RV,* right ventricle.

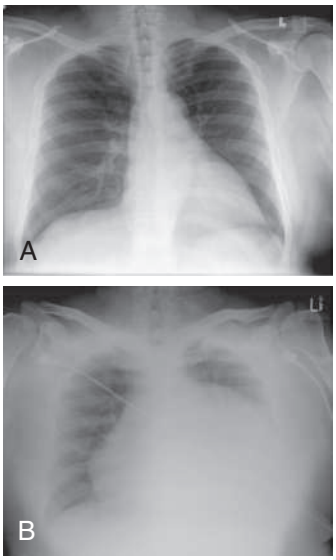

FIG. 3 Chest x-ray. A, Patient's chest radiograph 1 yr before presentation with cardiac tamponade. **B,** Same patient's chest radiograph on presentation to the emergency department with cardiac tamponade. (From Adams JG et al: *Emergency medicine, clinical essentials,* ed 2, Philadelphia, 2013, Elsevier.)

- **Cardiac tamponade:** Occurs in 5% to 15% of patients with idiopathic pericarditis, but in up to 60% of those with neoplastic, tuberculous, or purulent pericarditis.
  1. Signs and symptoms: Dyspnea, orthopnea, chest pain, fatigue
  2. Physical examination: Beck triad (distended neck veins, distant heart sounds, hypotension), reduced apical impulse, diaphoresis, tachypnea, tachycardia, narrowed pulse pressure, or pulsus para-

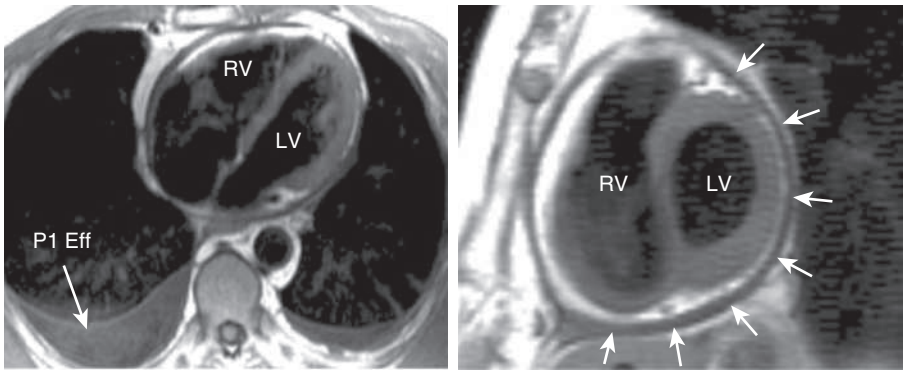

FIG. 4 Cardiovascular magnetic resonance in a patient with constrictive pericarditis. On the *right* is a basal short-axis view of the ventricles showing a thickened pericardium encasing the heart (*arrows*). On the *left* is a transaxial view, again showing the thickened pericardium, particularly over the right heart, but also a pleural effusion (*Pl Eff*). *LV,* Left ventricle; *RV,* right ventricle. (From Zipes DP et al [eds]: *Braunwald's heart disease,* ed 7, Philadelphia, 2005, Saunders.)

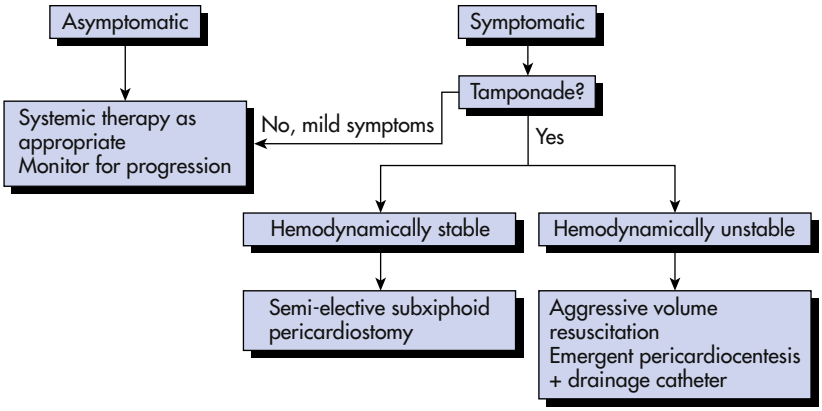

FIG. 5 Treatment approach algorithm to malignant pericardial effusions. (From Niederhuber JE*: Abeloff's clinical oncology*, ed 6, Philadelphia, 2020, Elsevier.)

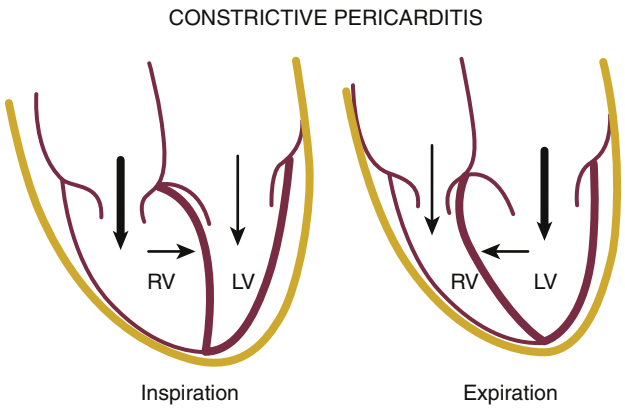

FIG. 6 Ventricular interdependence in constrictive pericarditis. *LV,* left ventricle; *RV,* right ventricle. (Courtesy Miguel Quinones, MD, Houston Methodist DeBakey Heart and Vascular Center. In Parrillo JE, Dellinger RP: *Critical care medicine, principles of diagnosis and management in the adult*, ed 5, Philadelphia, 2019, Elsevier.)

doxus (decrease in systolic blood pressure ≥10 mm Hg during inspiration; most specific sign)

3. ECG: Decreased amplitude of the QRS complex, electrical alternans (occurs more frequently with large neoplastic effusions)
4. Chest x-ray: Cardiomegaly ("water-bottle" configuration of the cardiac silhouette may be seen) with clear lungs
5. Echocardiography (Table 3): Pericardial effusion, >25% mitral and >50% tricuspid valve inflow variation with respiration, paradoxical motion of interventricular septum, diastolic right or left atrium collapse, diastolic right ventricular collapse (pathognomonic)
6. Hemodynamics: Equalization of diastolic pressures within chambers of the heart, elevation of right atrial pressure with a prominent "x" but blunted "y" descent. Table 4 summarizes hemodynamics in cardiac tamponade and constrictive pericarditis
7. Therapy: Cardiac tamponade is a life-threatening condition usually requiring emergent pericardiocentesis. Avoid drugs (diuretics, nitrates) or therapies (high PEEP) that reduce the preload, as volume repletion may be required. In patients with recurrent effusions (e.g., neoplasms), placement of a percutaneous drainage catheter or pericardial window may be necessary

- **Effusive-constrictive pericarditis:** Uncommon syndrome characterized by concomitant tamponade caused by tense pericardial effusion and constriction caused by the visceral pericardium.
  1. Signs and symptoms of both tamponade and or constriction. Pulsus paradoxus is present but Kussmaul sign and pericardial knock are typically absent.
  2. Echocardiography: Low sensitivity to distinguish effusive-constrictive pericarditis from other types.
  3. Cardiac catheterization: Before drainage, "y" descent is usually less prominent than expected, and right atrial "v" wave persists. After drainage, may continue to have elevated right atrial and pulmonary wedge pressures.
  4. Therapy: Extensive epicardiectomy (with disruption of the visceral layer of pericardium) is the procedure of choice in symptomatic patients.
- **Myopericarditis**: Myocarditis and pericarditis may coexist in 20% to 30% of patients presenting with pericarditis. The laboratory hallmark is the elevation of cardiac enzymes. Overall, myopericarditis has a good prognosis with very low rates of morbidity, mortality, and heart failure.

DISPOSITION

- Complete resolution of pain and other signs and symptoms during the initial 3 wk of therapy occurs in 70% to 90% of cases.
- Admission is highly recommended if any of the following poor prognostic features (high risk factors) is present: Fever >38° C (100.4° F), subacute onset, large pericardial effusion/tamponade, failure to respond to 1 wk of outpatient treatment.
- The following are considered moderate risk factors but should also prompt admission: myopericarditis, trauma, immunosuppression, oral anticoagulant therapy.
- Recurrent pericarditis occurs after 4 to 6 wk of a symptom-free interval after a first episode of pericarditis. Incidence is reported as 10% to 15% and increases to 50% in patients who are not on colchicine.

TABLE 3 Hemodynamic and Echocardiographic Features of Constrictive Pericarditis Compared with Restrictive Cardiomyopathy

	Constriction	Restriction
Prominent y descent in venous pressure	Present	Variable
Paradoxic pulse	~1/3 cases	Absent
Pericardial knock	Present	Absent
Equal right- and left-sided filling pressures	Present	Left at least 3-5 mm Hg higher than right
Filling pressures >25 mm Hg	Rare	Common
Pulmonary artery systolic pressure >60 mm Hg	No	Common
Square root sign	Present	Variable
Respiratory variation in left-sided and-right-sided pressures/flows	Exaggerated	Normal
Ventricular wall thickness	Normal	Usually increased
Pericardial thickness	Increased	Normal
Atrial size	Possible LA enlargement	Biatrial enlargement
Septal bounce	Present	Absent
Tissue Doppler E′ velocity	Increased	Reduced
Speckle tracking	Normal longitudinal, decreased circumferential restoration	Decreased longitudinal, normal circumferential restoration

From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

TABLE 4 Hemodynamics in Cardiac Tamponade and Constrictive Pericarditis

	Tamponade	Constriction
Paradoxical pulse	Usually present	Present in ~1/3
Equal left/right-sided filling pressure	Present	Present
Systemic venous wave morphology	Absent y descent	Prominent y descent (M or W shape)
Inspiratory change in systemic venous pressure	Decrease (normal)	Increase or no change (Kussmaul sign)
"Square root" sign in ventricular pressure	Absent	Present

From Mann DL, Zipes DP, Libby P, Bonow RO: *Braunwald's heart disease*, ed 10, Philadelphia, 2015, Elsevier.

- Incessant pericarditis is defined as pericarditis lasting for >4 to 6 wk but <3 mo without remission, while chronic pericarditis is pericarditis lasting for >3 mo.
- In patients with pericardial effusion after cardiac surgery, use of NSAIDs is not recommended because they have not been shown to reduce the size of the effusions or prevent late cardiac tamponade. The COPPS trial suggested that prophylactic colchicine may reduce the risk of developing a postpericardiotomy pericarditis.

BASIC INFORMATION

DEFINITION

A disorder characterized by periodic episodes of involuntary repetitive limb movements during sleep, causing sleep disturbances that are not due to a primary sleep disorder. They consist of triple flexion movements of the legs that repeat in 5- to 90-second cycles during sleep.

SYNONYMS

PLMD
Periodic leg movements of sleep (PLMS)
Nocturnal myoclonus

ICD-10CM CODE
G47.61 Periodic limb movement disorder

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Unknown
PEAK INCIDENCE: None
PREVALENCE: 5% to 8%
PREDOMINANT SEX AND AGE: Prevalence is higher in females and increases with age.
GENETICS: Unknown, but may share autosomal dominant inheritance pattern if concurrent with restless leg syndrome.
RISK FACTORS:

- Musculoskeletal disease, heart disease, obstructive sleep apnea, narcolepsy, psychiatric disorders, diabetes mellitus
- Shift work
- Snoring
- Stress
- Restless leg syndrome
- Parkinson disease, idiopathic REM sleep behavior disorder

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients may complain of excessive daytime sleepiness, fatigue, and unrestful sleep.
- During an episode of periodic limb movements, the patient may experience repetitive dorsiflexion of the ankle and extension of the big toe, but other movements may occur, such as kicking. These movements last up to 5 seconds and may recur every 5 to 90 seconds, with the total episode lasting minutes to an hour. The movements are typically involuntary, and the patient is unaware of their occurrence, in contrast to those of restless leg syndrome (RLS).
- Neurologic examination is usually normal but may reveal an associated neuropathy or myelopathy.
- Periodic leg movements of sleep are present in most patients with RLS but are not specific nor sensitive for RLS.

ETIOLOGY

The exact etiology is unknown. It is hypothesized that PLMD may share a common pathophysiology with restless leg syndrome, which involves iron metabolism and dopaminergic pathways in the brain.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Restless leg syndrome
- Neuroleptic-induced akathisia
- Positional discomfort
- Nocturnal leg cramps

WORKUP

In addition to a history of excessive daytime sleepiness or sleep disturbance, the diagnosis of PLMD requires a polysomnographic study to exclude other sleep disorders and to document the periodic limb movements resulting in sleep disturbances. During the study, the movements must occur in a series of at least four, recurring every 5 to 90 seconds, each with a duration of 0.5 to 5 seconds.

LABORATORY TESTS

- No laboratory tests are required to diagnose PLMD.
- A CBC, iron panel, and BMP may be ordered if RLS is suspected.

IMAGING STUDIES

Imaging studies are not required for diagnosis of PLMD.

TREATMENT

- Patients with periodic limb movements only, without sleep disturbances of insomnia or excessive daytime sleepiness, do not require treatment.
- The treatment of PLMD is the same as that for RLS.
- Calcium channel ligands such as gabapentin or pregabalin are effective and do not worsen symptoms with long-term use.
- Dopaminergic agonists such as pramipexole or ropinirole have been shown to decrease PLMS, but long-term use may be associated with worsening of symptoms (augmentation).
- Iron replacement should be started in case of iron deficiency, and the cause of iron-deficiency investigated.

NONPHARMACOLOGIC THERAPY

- Follow good sleep hygiene.
- Minimize shift work.
- Avoid caffeine, alcohol, nicotine.

ACUTE GENERAL Rx

- Treatment is indicated when PLMD is suspected and causing significant sleep fragmentation
- For calcium channel ligands: Gabapentin initial dose of 100 to 300 mg/day before bedtime, with therapeutic range of 300 to 2400 mg/day. Pregabalin initial dose of 50 to 75 mg/day, with therapeutic range of 75 to 450 mg/day
- For dopamine agonists: Pramipexole initial dose of 0.125 mg before bedtime, with a therapeutic range of 0.125 to 0.75 mg/day. Ropinirole initial dose of 0.25 mg/day, with a therapeutic range of 0.25 to 4 mg/day

CHRONIC Rx

For patients treated with dopamine agonists, close monitoring is recommended to screen for augmentation of symptoms.

COMPLEMENTARY & ALTERNATIVE MEDICINE

None

REFERRAL

Refer to neurologist if diagnosis is uncertain or an underlying disorder is suspected.

PEARLS & CONSIDERATIONS

COMMENTS

- Periodic limb movements disorder is a diagnosis of exclusion. PLMS occur during many sleep disorders and do not support a diagnosis of PLMD until all possible underlying causes are excluded.
- Certain medications such as antihistamines, dopamine receptor blockers, selective serotonin reuptake inhibitors, and stimulants may worsen PLMS and should be avoided if possible.

PREVENTION: As mentioned in "Nonpharmacologic Therapy."

PATIENT & FAMILY EDUCATION

BASIC INFORMATION

DEFINITION

Peripheral artery disease (PAD) refers to atherosclerotic, inflammatory, occlusive, and aneurysmal diseases involving the abdominal aorta and its branch arteries. (This topic focuses on lower-extremity PAD.)

SYNONYMS

PAD
Peripheral vascular disease (PVD)
Arteriosclerosis obliterans
Atherosclerotic occlusive disease
Atherosclerosis of the extremities
Peripheral arterial stenosis
Vasoocclusive disease of the legs
Chronic critical limb ischemia

ICD-10CM CODES

I70	Atherosclerosis
I70.2	Atherosclerosis of native arteries of the extremities
I70.21	Atherosclerosis of native arteries of extremities with intermittent claudication
I70.22	Atherosclerosis of native arteries of extremities with rest pain
I70.3	Atherosclerosis of unspecified type of bypass graft(s) of the extremities
I73	Other specified peripheral vascular diseases
I73.8	Other specified peripheral vascular diseases
I73.9	Peripheral vascular disease, unspecified
I79	Disorders of arteries, arterioles, and capillaries in diseases classified elsewhere

EPIDEMIOLOGY & DEMOGRAPHICS

- There are >202 million patients afflicted with PAD globally; it affects approximately 8.5 million Americans above the age of 40.
- The prevalence is nearly equal in men and women. It increases with age, from 5.28% in those aged 40 to 49 yr to 18.83% in those aged 70 to 79 yr. However, symptoms of claudication are more likely to be present in males with PAD (50%) vs. women with PAD (25%).
- As per the PARTNERS study, the prevalence of PAD in patients >70 yr or 50 to 69 yr with history of smoking or diabetes was 29%.
- Risk factors that increase risk of PAD according to a 2013 meta-analysis of 112,027 studied patients include:
  1. Smoking (odds ratio 2.72).
  2. Diabetes (odds ratio 1.88).
  3. Hypertension (odds ratio 1.55).
  4. Hypercholesterolemia (odds ratio 1.19).
- Smoking is three times more likely to lead to PAD than CAD. Conversely, the association of HTN and hyperlipidemia with PAD is lower than that with CAD and cerebrovascular disease.
- Patients at increased risk of PAD include those aged greater than 65 yr, those aged 50 to 64 yr with risk factors of atherosclerosis, those aged less than 50 yr with diabetes and an additional risk factor, as well as those individuals with known atherosclerotic disease in another vascular bed.
- Black race/ethnicity has greater prevalence according to NHANES data (odds ratio 2.83).
- Patients with newly diagnosed PAD are six times more likely to die within the next 10 yr when compared with patients without PAD.
- The total annual costs associated with the hospitalization of patients with PAD in the U.S. exceed $21 billion, and account for ~13% of all Medicare Part A and B expenditures.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Peripheral artery disease may present in a variety of ways:
  1. 20% to 50%: Asymptomatic
  2. 10% to 35%: Intermittent claudication (IC), defined as aching pain, cramping, weakness, numbness, or heaviness of the leg induced by exercise, relieved by rest
  3. 1% to 2%: Critical limb ischemia (CLI), defined as chronic (>2 wk) rest pain, or tissue loss with nonhealing ulceration, necrosis, or gangrene (Fig. E1)
  4. 40% to 50%: Atypical symptoms involving the calf, thigh, or buttock
  5. Acute limb ischemia (ALI) will be present in 14 per 100,000 individuals in the general population. It is defined as acute (<2 wk) onset of symptoms due to severe poor perfusion of the extremities, and further categorized into the following:
     a. Viable: No sensory or muscle weakness with audible Doppler pulses
     b. Threatened: Mild to moderate sensory or motor loss; inaudible arterial Doppler
     c. Irreversible: Severe sensory loss and muscle weakness; inaudible arterial Doppler
- Physical findings include:
  1. Diminished pulses and/or cool skin temperature of lower extremities
  2. Bruits heard over the distal aorta, iliac, or femoral arteries
  3. Change in skin color:
     a. Dependent rubor in critical limb ischemia
     b. Livedo reticularis, or a mottled reticulated vascular pattern that appears lacelike
  4. Trophic changes of hair loss, brittle nails, and muscle atrophy

ETIOLOGY

PAD is primarily the result of atherosclerotic narrowing of the arterial lumen that results in impaired blood flow to the lower-extremity tissues. Fig. 2 illustrates the pathophysiology of intermittent claudication.

Symptoms initially manifest with exercise as metabolic demands increase. Critical limb ischemia (CLI) may develop gradually from progressive atherosclerosis or in a subacute fashion from multisegmental atherothrombosis or atheroembolization. In contrast, acute limb ischemia (ALI) is marked by a sudden onset of symptoms (<2 wk) due to poor perfusion of the extremities.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Vasculitis
- Musculoskeletal disorder
- Spinal stenosis or nerve root compression (neurogenic or pseudoclaudication)
- Peripheral neuropathy
- Reflex sympathetic dystrophy
- Raynaud phenomenon
- Compartment syndrome
- Deep venous thrombosis
- Popliteal entrapment syndrome
- Direct vascular injury

WORKUP

- Thorough history, including symptoms regarding walking impairment, claudication, ischemic rest pain, or nonhealing wounds in patients ≥70 yr or those ≥50 yr with a history of smoking and/or diabetes
- Careful physical examinations include:
  1. Measurement of blood pressure in both arms; pressure difference of >15 to 20 mm Hg is abnormal and suggestive of subclavian artery stenosis
  2. Palpation and recording of carotid pulses, upstroke, amplitude, and presence of bruits
  3. Auscultation and palpation of abdomen for bruits, aortic pulsation, and diameter
  4. Palpation of brachial, radial, ulnar, femoral, popliteal, dorsalis pedis, and posterior tibial pulses. Pulse intensity should be recorded as follows: 0, absent; 1+, diminished; 2+, normal; 3+, bounding
  5. Auscultation of femoral arteries for the presence of bruits
  6. Extremities should be inspected for color, temperature, integrity of the skin, hair loss, and hypertrophic nails
- Classification/staging system for PAD
  1. Fontaine staging system (Table 1):
     a. I: Asymptomatic
     b. IIa: Mild claudication
     c. IIb: Moderate-severe claudication
     d. III: Ischemic rest pain
     e. IV: Ulceration or gangrene
- Resting ankle-brachial index (ABI) is the first-line noninvasive test to establish a diagnosis of PAD in individuals with symptoms or signs suggestive of disease (individuals with one or more of the following exertional leg symptoms: Nonhealing wounds, age >65 yr, or age >50 yr with smoking or diabetes history)
- ABI of each leg is calculated by dividing the highest dorsalis pedis or posterior tibial systolic blood pressure by the highest systolic brachial pressure obtained from either the right or left arm
  1. Noncompressible/calcified: >1.40
  2. Normal: 1.00 to 1.40 at rest

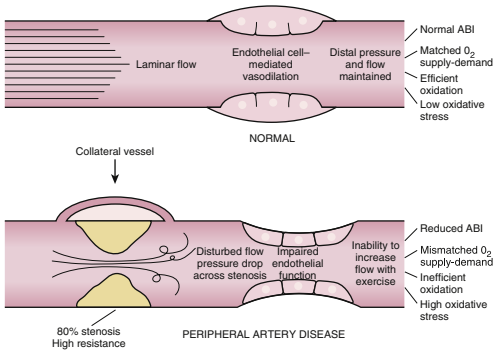

FIG. 2 Pathophysiology of intermittent claudication. In healthy arteries *(top),* flow is laminar and endothelial function is normal; therefore blood flow and oxygen delivery match muscle metabolic demand at rest and during exercise. Muscle metabolism is efficient and results in low oxidative stress. In contrast, in peripheral artery disease *(PAD) (bottom),* arterial stenosis results in disturbed flow, and the loss of kinetic energy results in a drop in pressure across the stenosis. Collateral vessels have high resistance and only partially compensate for the arterial stenosis. In addition, endothelial function is impaired, thereby resulting in further loss of vascular function. These changes limit the blood flow response to exercise and result in a mismatch of oxygen delivery to muscle metabolic demand. Changes in skeletal muscle metabolism further compromise the efficient generation of high-energy phosphates. Oxidant stress, the result of inefficient oxidation, further impairs endothelial function and muscle metabolism. *ABI,* Ankle-brachial index. (From the text *Anatomie, physiologie, pathologie des vaisseaux lymphatiques* by PC Sappey [1874], courtesy Harvard Medical Library, Francis A. Countway Library of Medicine, in Hiatt WR, Brass EP: Pathophysiology of intermittent claudication. In Creager MA et al [eds]: *Vascular medicine. A companion to Braunwald's heart disease*, ed 2, Philadelphia, 2013, Elsevier.)

TABLE 1 Fontaine Classification of Peripheral Artery Disease

Stage	Symptoms
I	Asymptomatic
II	Intermittent claudication
IIa	Pain free, claudication walking >200 m
IIb	Pain free, claudication walking <200 m
III	Rest and nocturnal pain
IV	Necrosis, gangrene

From Bonow RO et al: *Braunwald's heart disease: a textbook of cardiovascular medicine,* ed 9, Philadelphia, 2012, WB Saunders.

3. Borderline: 0.91 to 0.99 at rest
4. Abnormal: ≤0.90

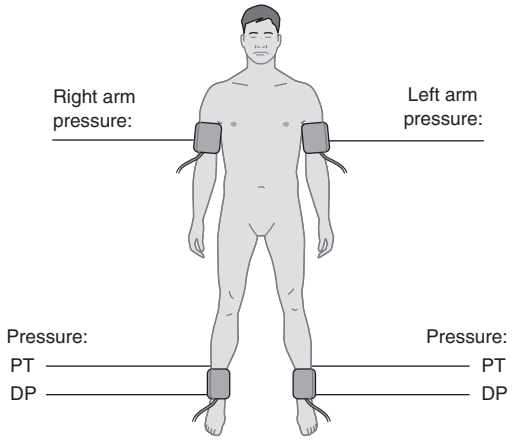
- ABI should be measured in both legs in all new patients (Fig. 3)
- Exercise ABI is recommended if resting ABI is borderline or normal (>0.9) and symptoms of claudication are suggestive
- Toe-brachial index should be used in patients suspected of PAD with ABI of >1.4. A TBI of <0.70 is abnormal and diagnostic of PAD. TBI may be used to assess perfusion in patients with suspected CLI
- Routine screening for lower-extremity PAD in the absence of risk factors, history, signs, or symptoms is not recommended
- PAD is recognized as a risk factor for abdominal aortic aneurysm (AAA), and in observational studies the prevalence of AAA was higher in patients with symptomatic PAD

LABORATORY TESTS

Laboratory tests can help identify risk factors or other potential causative etiologies. These include lipid profile, hemoglobin A_{1C}, d-dimer, and CRP/ESR.

How to Perform and Calculate the ABI

Partners Program ABI Interpretation
Above 0.90—Normal
0.71-0.90—Mild Obstruction
0.41-0.70—Moderate Obstruction
0.00-0.40—Severe Obstruction



RIGHT ABI **LEFT ABI**

$$\frac{\text{Higher right ankle pressure}}{\text{Higher arm pressure}} = \frac{\text{mm Hg}}{\text{mm Hg}} ____ = \frac{\text{Higher left ankle pressure}}{\text{Higher arm pressure}} = \frac{\text{mm Hg}}{\text{mm Hg}} = ____$$

EXAMPLE

$$\frac{\text{Higher ankle pressure}}{\text{Higher arm pressure}} = \frac{92 \text{ mm Hg}}{164 \text{ mm Hg}} = 0.56$$ See ABI Chart

FIG. 3 Performing pressure measurements and calculating the ankle-brachial index *(ABI).* To calculate the ABI, systolic pressures are determined in both arms and both ankles with the use of a handheld Doppler instrument. The highest readings for the dorsalis pedis (DP) and posterior tibial (PT) arteries are used to calculate the index. (From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.)

PHYSIOLOGIC TESTING AND IMAGING STUDIES

- Rest or exercise pulse volume recordings (PVRs) and segmental limb pressures are also useful. PVRs measure volume of limb flow per pulse in different segments of the limb (e.g., thigh, calf, ankle, metatarsal, and toes). They help to assess the location and severity of the lesion with alterations in the pulse volume contour and amplitude indicating proximal arterial obstruction.
- Duplex ultrasound (DUS) incorporates anatomic and physiologic evaluation by combining 2D ultrasound to visualize arterial segments and pulse wave Doppler to sample blood flow velocities at specific locations in the arterial lumen.
- Conventional contrast angiography remains the gold standard, but duplex ultrasonography, computed tomography angiography (CTA), and magnetic resonance angiography (MRA) have largely replaced catheter-based

angiography in anatomic assessment for revascularization. Contrast angiography (Fig. 4) is now reserved for patients with PAD who are being considered for endovascular revascularization. It allows assessment of translesional pressure gradients prior to percutaneous intervention.

- Carotid intima-media thickness and brachial artery flow-mediated dilation have shown promise but have not been widely applied.

Rx TREATMENT

The treatment goal in patients with PAD is to focus on cardiovascular risk factor reduction to decrease morbidity and mortality as well as to improve limb-related symptoms. There are also medical and surgical approaches to management of limb-related symptoms. Fig. 5 illustrates an approach to a patient with PAD. ACCF/AHA guidelines for medical management of patients with peripheral artery disease are summarized in Table 2.

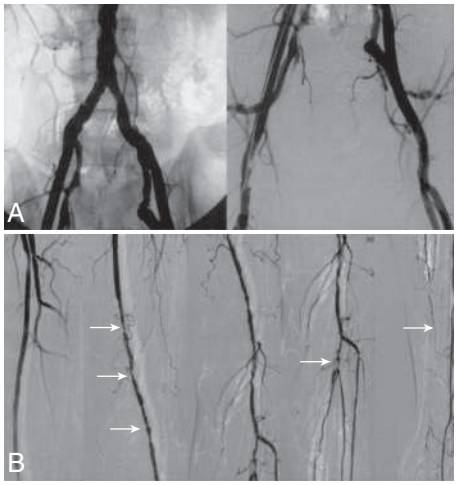


FIG. 4 Angiogram of a patient with disabling left calf claudication. A, The aorta and bilateral common iliac arteries are patent. **B,** The left superficial femoral artery has multiple stenotic lesions *(arrows).* There is a significant stenosis of the left tibioperoneal trunk and left posterior tibial artery *(arrows).* (From Zipes DP et al [eds]: *Braunwald's heart disease,* ed 7, Philadelphia, 2005, WB Saunders.)

MEDICAL THERAPY (TABLE 3)

LOWERING CARDIOVASCULAR RISK FACTORS, MORBIDITY, AND MORTALITY:

- Smoking cessation or avoidance of secondhand smoke should be emphasized in patients with PAD at each visit with assistance of behavioral and pharmacologic treatment (Class I).
- Proper foot care, including use of appropriate footwear, chiropody/podiatric medicine, daily foot inspection, skin cleansing, and use of topical moisturizing creams, should be encouraged, and skin lesions and ulcerations should be addressed urgently in all patients with diabetes and lower-extremity PAD (Class I).
- A foot infection should be suspected in patients presenting with local pain, peri-wound erythema, edema, or discharge; these patients should undergo prompt diagnosis and treatment with an interdisciplinary care team to avoid amputation.
- Antiplatelet therapy is indicated to reduce risk of myocardial infarction, stroke, and

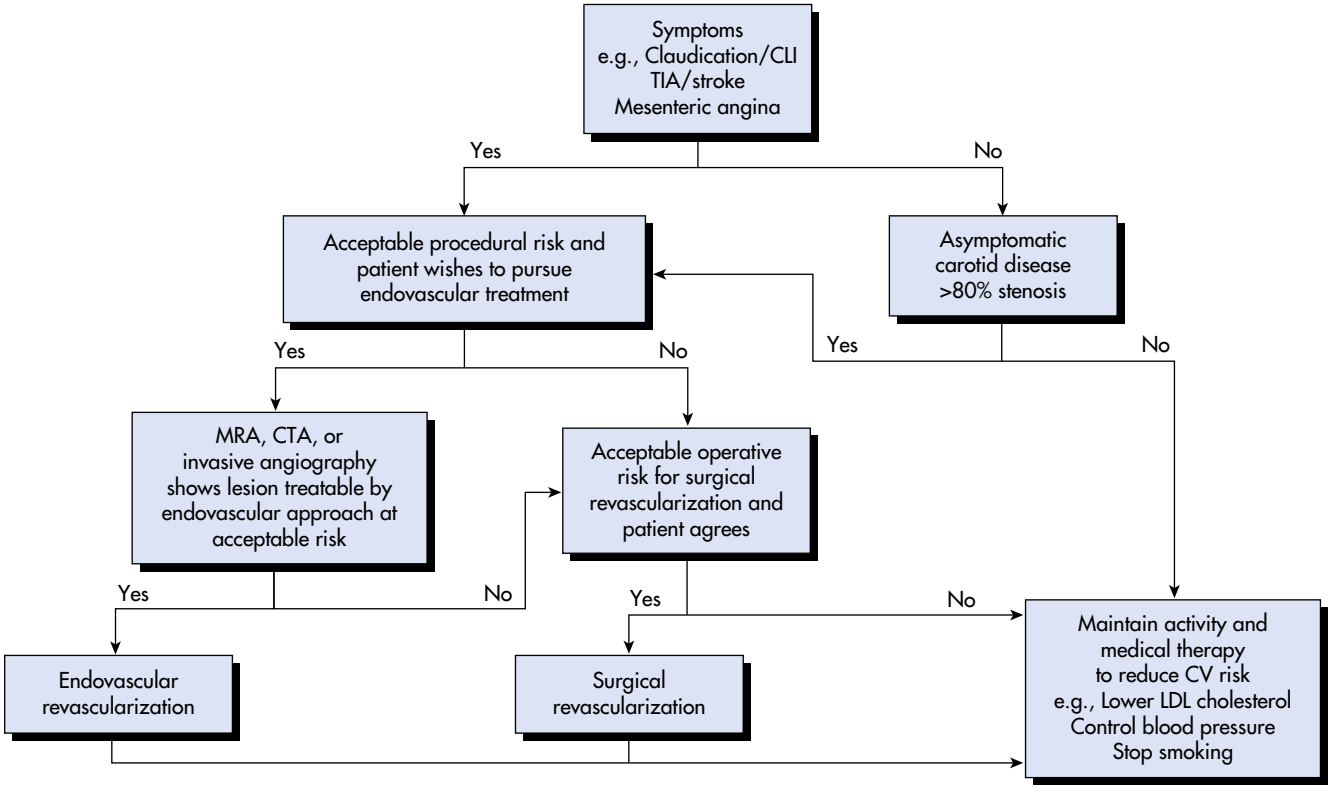

FIG. 5 Approach to a patient with peripheral artery disease. This strategy is based on assessment of the risk for adverse events with and without treatment by taking into consideration procedural or operative risks and the patient's informed decision to proceed with revascularization. *CLI,* Critical limb ischemia; *CTA,* computed tomographic angiography; *CV,* cardiovascular; *LDL,* low-density lipoprotein; *MRA,* magnetic resonance angiography; *TIA,* transient ischemic attack. (From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.)

TABLE 2 ACCF/AHA Guidelines for Medical Therapy for Patients with Peripheral Artery Disease

COR	Indication	LOE
I	1. Antiplatelet therapy with aspirin alone (range, 75 to 325 mg/day) or clopidogrel alone (75 mg/day) is recommended to reduce MI, stroke, and vascular death in patients with symptomatic PAD.	A
	2. Treatment with a statin medication is indicated for all patients with PAD.	A
	3. Antihypertensive therapy should be administered to patients with hypertension and PAD to reduce the risk of MI, stroke, heart failure, and cardiovascular death.	A
	4. Patients with PAD who smoke cigarettes or use other forms of tobacco should be advised at every visit to quit.	A
	5. Patients with PAD who smoke cigarettes should be assisted in developing a plan for quitting that includes pharmacotherapy (varenicline, bupropion, and/or nicotine replacement therapy) and/or referral to a smoking cessation program.	A
	6. Patients with PAD should avoid exposure to environmental tobacco smoke at work, at home, and in public places.	B-NR
	7. Management of diabetes mellitus in the patient with PAD should be coordinated between members of the health care team.	C-EO
	8. Cilostazol is an effective therapy to improve symptoms and increase walking distance in patients with claudication.	A
	9. Patients with PAD should have an annual influenza vaccination.	C-EO
IIa	1. In asymptomatic patients with PAD (ABI ≤0.90), antiplatelet therapy is reasonable to reduce the risk of MI, stroke, or vascular death.	C-EO
	2. The use of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers can be effective to reduce the risk of cardiovascular ischemic events in patients with PAD.	A
	3. Glycemic control can be beneficial for patients with CLI to reduce limb-related outcomes.	B-NR
IIb	1. In asymptomatic patients with borderline ABI (0.91-0.99), the usefulness of antiplatelet therapy to reduce the risk of MI, stroke, or vascular death is uncertain.	B-R
	2. The effectiveness of dual-antiplatelet therapy (aspirin and clopidogrel) to reduce the risk of cardiovascular ischemic events in patients with symptomatic PAD is not well established.	B-R
	3. Dual-antiplatelet therapy (aspirin and clopidogrel) may be reasonable to reduce the risk of limb-related events in patients with symptomatic PAD after lower extremity revascularization.	C-LD
	4. The overall clinical benefit of vorapaxar added to existing antiplatelet therapy in patients with symptomatic PAD is uncertain.	B-R
	5. The usefulness of anticoagulation to improve patency after lower extremity autogenous vein or prosthetic bypass is uncertain.	B-R
III	1. Anticoagulation should not be used to reduce the risk of cardiovascular ischemic events in patients with PAD.	A
	2. Pentoxifylline is not effective for treatment of claudication.	B-R
	3. Chelation therapy (e.g., ethylenediaminetetraacetic acid) is not beneficial for treatment of claudication.	B-R
	4. B-complex vitamin supplementation to lower homocysteine levels for prevention of cardiovascular events in patients with PAD is not recommended.	B-R

ABI, Ankle-brachial index; *ACCF,* American College of Cardiology Foundation; *AHA,* American Heart Association; *CLI,* critical limb ischemia; *COR,* class of recommendation; *LOE,* level of evidence; *MI,* myocardial infarction.

From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

vascular death in individuals with symptomatic PAD with either aspirin (75 to 325 mg) or clopidogrel (75 mg) (Class I) and in asymptomatic patients (Class IIa). Uncertain benefit has been observed with combination aspirin and clopidogrel therapy (Class IIb). Limited data on use of newer P2Y12 receptor antagonists in PAD. In the EUCLID trial, ticagrelor was not shown to be superior to clopidogrel for the reduction of cardiovascular events, with major bleeding being similar in the two groups. Uncertain benefit with vorapaxar (Class IIb).

- Anticoagulation with low-dose (2.5 mg twice daily) rivaroxaban (Xarelto) plus aspirin daily showed significant reductions in both major cardiovascular and limb events, including amputations, in patients with peripheral arterial disease in the COMPASS trial.
- Warfarin is not indicated except in select postsurgical bypass conditions.
- Lipid-lowering therapy in patients with lower limb PAD has been shown to help slow disease progression, alleviate symptoms, and improve walking distance. The 2018 ACC/AHA Guideline on the Treatment of Blood Cholesterol recommends that patients with atherosclerotic PAD receive high-intensity statin therapy in order to lower risk of cardiovascular events regardless of baseline cholesterol values (Class I). In patients who are judged to be very high risk and considered for PCSK9 inhibitor therapy, maximally tolerated LDL-C lowering therapy should include maximally tolerated statin therapy and ezetimibe (Class I). Prior guidelines have recommended goal LDL cholesterol of <100 mg/dl and possibly <70 mg/dl in high-risk patients.
- Management of hypertension should be in accordance with current HTN guidelines.
- Control of blood sugar in diabetic patients with PAD is recommended (hemoglobin A_{1C} goal <6.5), although studies have failed to demonstrate a beneficial effect on intensive insulin therapy in lowering risk of PAD. Annual influenza vaccination reduces CV event rates in patients with PAD (Class I).

TREATMENT OF CLAUDICATION:

- Exercise therapy: Supervised exercise-training may be as beneficial as stent revascularization in symptomatic improvement. Patients should be prescribed exercise for a minimum of 30 to 45 min, in sessions performed at least three times per wk for a minimum of 12 wk (Class I).
  1. Pharmacologic therapy:
     a. Cilostazol (100 mg bid) is indicated as effective therapy for enabling pain-free and maximal walking distance (Class 1). It is a phosphodiesterase (PDE-3) inhibitor that reduces platelet aggregation and causes vasodilatation. It may have an added benefit of reducing restenosis and repeat revascularization following endovascular therapy. Cilostazol is contraindicated in patients with systolic heart failure.
     b. Pentoxifylline is no longer considered effective in treatment of claudication (Class III).

REVASCULARIZATION

In general, there is no difference in clinical outcomes in percutaneous vs. surgical revascularization in iliac and femoropopliteal disease except for the higher morbidity with surgery and greater re-interventions in the percutaneous approach.

- The 2016 ACC/AHA guidelines on PAD have recommended revascularization as a reasonable treatment option for the patient with lifestyle-limiting claudication with inadequate response to guideline-directed medical therapy. The following approach is discussed:
  1. Considerations in percutaneous/endovascular treatment:
     a. In patients with a vocational- or lifestyle-limiting disability due to claudication or limb ischemia from either significant aortoiliac or femoropopliteal disease despite optimal medical therapy when clinical features

TABLE 3 Approved Medical Therapies for Patients with Peripheral Artery Disease (PAD)

			Indications			
Therapy	**Mechanism of Action**	**Key Clinical Trials**	**European Medicines Agency**	**European Society of Cardiology**	**FDA**	**ACC/AHA**
Statin (Class effect)	Cholesterol lowering HMG-CoA reductase inhibitor	Heart Protection Study 13% RRR with simvastatin 40 mg daily vs. placebo in all-cause mortality, 18% RRR in coronary heart death Approval for PAD based on subgroup of 6748 patients, 2700 had PAD and no CHD	Reduction in MACE and mortality	Class I for lipid lowering with LDL <2.5 mmol/L, optimally <1.8 mmol/L	Reduction in MACE and mortality	Class I, LOE A
ACEI or ARB (Class effect)	Blood pressure lowering and other vascular effects Renin-angiotensin system inhibition	HOPE 22% RRR with ramipril 10 mg daily vs. placebo for composite of MI, stroke, or CV death Approval for PAD based on subgroup of 4051 patients, 1725 with "clinical PAD"	Reduction in MACE	Class I for blood pressure lowering to ≤140/90 mm Hg	Reduction in MACE	Class I, LOE A for antihypertensive therapy Class IIa, LOE A for ACEI/ARB specifically
Clopidogrel	Antiplatelet $P2Y_{12}$ inhibitor	CAPRIE 8.7% RRR vs. aspirin for composite of ischemic stroke, MI, or vascular death Approval for PAD based on subgroup of 6452 patients	As monotherapy Reduction in MACE	Class I monotherapy for risk reduction Class I added to ASA after lower extremity stenting	As monotherapy Reduction in MACE	Class I, LOE A for monotherapy Class IIb, LOE B-R, C-LD, when added to aspirin as DAPT
Vorapaxar	Antiplatelet PAR-1 antagonist	TRA2P-TIMI 50 20% RRR vs. placebo for composite of MI, stroke, or CV death Approval for PAD based on subgroup of 3787 patients	Added to aspirin or clopidogrel Reduction in MACE, limb benefits mentioned	Approved after most recent guidelines	Added to aspirin and/or clopidogrel Reduction in MACE	Class IIb, LOE B-R added to aspirin and/or clopidogrel
Pentoxifylline	Decreases blood viscosity Mechanism not fully understood	Meta-analysis of six studies including 788 patients who showed minimal increase in maximal walking distance with (+59 m)	Improve function and symptoms in patients with intermittent claudication	Described but no clear recommendation	Improve function and symptoms in patients with intermittent claudication	Class III, LOE B-R
Cilostazol	Antiplatelet and vasodilator Mechanism not fully understood	50 mg bid (n = 303), 100 mg bid (n = 998), and placebo (n = 973) Improvement in maximal walking distance with 100 mg bid, expressed as the percent mean change from baseline, 28%-100% vs. placebo, which were −10%-41%	Reduction of symptoms of intermittent claudication, as indicated by an increased walking distance	Class I for symptoms	Reduction of symptoms of intermittent claudication, as indicated by an increased walking distance	Class I, LOE A

ACC/AHA, American College of Cardiology/American Heart Association; *ACEI,* angiotensin-converting enzyme inhibitor; *ARB,* angiotensin receptor blocker; *bid,* twice daily; *ASA,* acetylsalicylic acid; *CAPRIE,* Clopidogrel versus Aspirin in Patients at Risk of Ischaemic Events; *CHD,* coronary heart disease; *CV,* cardiovascular; *DAPT,* dual-antiplatelet therapy; *FDA,* U.S. Food and Drug Administration; *HOPE,* Heart Outcomes Prevention Evaluation; *LDL,* low-density lipoprotein; *LOE,* level of evidence *(B-R,* moderate-quality evidence from one or more randomized clinical trials; *C-LD,* randomized or nonrandomized observational/registry studies or a meta-analysis); *MACE,* major adverse cardiovascular events; *MI,* myocardial infarction; *PAR-1,* protease-activated receptor 1; *RRR,* relative risk reduction; *TRA2P-TIMI 50,* Thrombin Receptor Antagonist in Secondary Prevention of Atherothrombotic Ischemic Events–Thrombolysis in Myocardial Infarction.
From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine,* ed 11, Philadelphia, 2019, Elsevier.

suggest a reasonable likelihood of symptomatic improvement with endovascular intervention.
   b. Endovascular intervention is not indicated as prophylactic therapy in an asymptomatic patient with lower-extremity PAD.
   c. Durability of endovascular intervention is greater in iliac artery than in the femoropopliteal segment.
2. Considerations in surgical revascularization:
   a. Individuals with claudication symptoms who have a significant functional disability that is vocational or lifestyle limiting. These patients need to also be unresponsive to exercise or pharmacotherapy and should have a reasonable likelihood of symptomatic improvement with an acceptable surgical risk and technical factors favoring surgical vs. endovascular approach.
   b. Autogenous vein graft is superior to prosthetic graft if surgical revascularization is performed (Class I).
   c. Iliac or femoropopliteal disease with long segments; multifocal segments; long segment occlusions; and eccentric, calcified stenosis, which are less amenable to percutaneous interventions.
   d. Surgical intervention is not indicated to prevent progression to limb-threatening ischemia in patients with intermittent claudication as generally claudication does not progress to severe ischemia.
3. Revascularization for acute limb ischemia (Table 4):
   a. Management approach is dependent on whether affected limb is viable, threatened, or irreversible. Initial management will depend on the absence of sensation and movement. If absent, then urgent surgery should be considered.
   b. Heparin should be given to all patients with ALI; direct thrombin inhibitor is used if patient has history of HIT.
   c. Catheter-based thrombolysis is effective in ALI with salvageable limb.
   d. Amputation should be performed in patients with irreversible damage.

DISPOSITION

Risk factors for atherosclerosis should be assessed, and appropriate modification instituted. Focus should be placed on smoking cessation, dietary adjustment, and pharmacotherapy for dyslipidemia, hyperglycemia, and hypertension. All patients with PAD should receive aspirin therapy unless contraindicated. Revascularization should be considered for refractory lifestyle-limiting symptoms.

TABLE 4 ACCF/AHA Guidelines for Management of Patients with Acute Limb Ischemia (ALI)

COR	Indication	LOE
I	1. Patients with ALI should be emergently evaluated by a clinician with sufficient experience to assess limb viability and implement appropriate therapy.	C-EO
	2. In patients with suspected ALI, initial clinical evaluation should rapidly assess limb viability and potential for salvage and does not require imaging.	C-LD
	3. In patients with ALI, systemic anticoagulation with heparin should be administered unless contraindicated.	C-EO
	4. In patients with ALI, the revascularization strategy should be determined by local resources and patient factors (e.g., etiology, degree of ischemia).	C-LD
	5. Catheter-based thrombolysis is effective for patients with ALI and a salvageable limb.	A
	6. Amputation should be performed as the first procedure in patients with a nonsalvageable limb.	C-LD
	7. Patients with ALI should be monitored and treated (e.g., fasciotomy) for compartment syndrome after revascularization.	C-LD
	8. In the patient with ALI, a comprehensive history should be obtained to determine the cause of thrombosis and/or embolization.	C-EO
IIa	1. In patients with ALI with a salvageable limb, percutaneous mechanical thrombectomy can be useful as adjunctive therapy to thrombolysis.	B-NR
	2. In patients with ALI due to embolism and with a salvageable limb, surgical thromboembolectomy can be effective.	C-LD
	3. In the patient with a history of ALI, testing for a cardiovascular cause of thromboembolism can be useful.	C-EO
IIb	The usefulness of ultrasound-accelerated catheter-based thrombolysis for patients with ALI with a salvageable limb is unknown.	C-LD

ACCF, American College of Cardiology Foundation; *AHA,* American Heart Association; *COR,* class of recommendation; *LOE,* level of evidence.
From Zipes DP: *Braunwald's heart disease, a textbook of cardiovascular medicine*, ed 11, Philadelphia, 2019, Elsevier.

- More than 1 in 6 patients with peripheral arterial disease who undergo peripheral arterial revascularization have unplanned readmission within 30 days with high associated mortality risks and costs. Procedure- and patient-related factors were the primary reasons for readmission.[1]

REFERRAL

Consultation with vascular medicine, vascular surgery, interventional cardiology, or other physicians with expertise in PAD is recommended in patients with rest pain, functional disability from pain, ABI <0.90 at rest, or any physical signs of limb ischemia or gangrene.

PEARLS & CONSIDERATIONS

COMMENTS

- PAD is a highly prevalent disease process that remains underdiagnosed and undertreated.
- Patients with PAD are at markedly higher risk of future coronary, cerebrovascular, and other vascular events.
- Medical treatment is aimed mainly at cardiovascular risk factor modification, except for cilostazol.
- Studies of the natural history of claudication show the relative safety of initial conservative treatment of PAD in the absence of critical limb ischemia.
- When PAD limits a patient's ability to walk and exercise, revascularization should be considered.
- Exercise training is an important and often neglected treatment strategy that has proven beneficial in improving functional status, reducing symptoms, and improving quality of life. Exercise capacity alone is the strongest predictor of mortality in patients with PAD.
- Surgical intervention should be considered in patients who meet the criteria for intervention but have lesions that are not amenable to PTA/stenting or in older patients with a low surgical risk. Advances in endovascular therapy have broadened the range of revascularization options for refractory claudication and critical and acute limb ischemia in patients with multiple comorbidities.

PREVENTION

Cardiovascular disease is the major cause of death in patients with intermittent claudication. Therefore, the treatment of claudication is directed not only at improving walking distance but also at reducing cardiovascular risk.

PATIENT & FAMILY EDUCATION

Perirectal Abscess PTG

BASIC INFORMATION

DEFINITION

A perirectal abscess is a localized inflammatory process that can be associated with infections of soft tissue and anal glands based on anatomic location. Perianal and perirectal abscesses may be simple or complex, causing suppuration. Infections in these spaces may be classified as superficial perianal or perirectal with involvement in the following anatomic spaces: Ischiorectal, intersphincteric, perianal, and supralevator. The Parks classification of anorectal abscess is subdivided into intersphincteric, transsphincteric, suprasphincteric, and extrasphincteric abscess (Fig. 1).

SYNONYMS

Rectal abscess
Perianal abscess
Anorectal abscess

ICD-10CM CODES
K61.0 Anal abscess
K61.1 Rectal abscess

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Commonly encountered
PREDOMINANT SEX: Male > female
PREDOMINANT AGE: All ages
PEAK INCIDENCE: Not seasonal; common
GENETICS: None known

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Localized perirectal or anal pain—often worsened with movement or straining
- Perirectal erythema or cellulitis
- Perirectal mass by inspection or palpation
- Fever and signs of sepsis with deep abscess
- Urinary retention

ETIOLOGY

- Polymicrobial aerobic and anaerobic bacteria involving one of the anatomic spaces (see "Definition"), often associated with localized trauma
- Microbiology: Most infections are polymicrobial, mixed enteric, and skin flora
- Predominant anaerobic bacteria:
  1. *Bacteroides fragilis*
  2. *Peptostreptococcus* spp.
  3. *Prevotella* spp.
  4. *Porphyromonas* spp.
  5. *Clostridium* spp.
  6. *Fusobacterium* spp.
- Predominant aerobic bacteria:
  1. *Staphylococcus aureus*
  2. *Streptococcus* spp.
  3. *Escherichia coli*
  4. *Enterococcus* spp.

Dx DIAGNOSIS

Many patients will have predisposing underlying conditions including:
- Malignancy or leukemia
- Immune deficiency
- Diabetes mellitus
- Recent surgery
- Steroid therapy

DIFFERENTIAL DIAGNOSIS

- Neutropenic enterocolitis
- Crohn disease (inflammatory bowel disease)
- Pilonidal disease
- Hidradenitis suppurativa
- Tuberculosis or actinomycosis; Chagas disease
- Cancerous lesions
- Chronic anal fistula
- Rectovaginal fistula
- Proctitis—often STD-associated, including syphilis, gonococcal, chlamydia, chancroid, condylomata acuminata
- AIDS-associated: Kaposi sarcoma, lymphoma, CMV

WORKUP

- Examination of rectal, perirectal/perineal areas
- Rule out necrotic process and crepitance suggesting deep tissue involvement
- Local aerobic and anaerobic culture
- Blood cultures if toxic, febrile, or compromised
- Possible sigmoidoscopy

IMAGING STUDIES

Usually not indicated unless extensive disease is suspected. CT has a sensitivity of 77% and is relatively poor in detecting a perirectal abscess in immunocompromised patients.

Rx TREATMENT

ACUTE GENERAL Rx

- Incision and drainage of abscess
- Debridement of necrotic tissue
- Rule out need for fistulectomy
- Local wound care—packing
- Sitz baths
- Antibiotic treatment: Directed toward coverage for mixed skin and enteric flora

OUTPATIENT—ORAL:
- Trimethoprim/sulfamethoxazole DS bid or ciprofloxacin 500 mg bid or levofloxacin 500 mg q24h plus metronidazole 500 mg q8h x 7 to 10 days
- Amoxicillin/clavulanic acid 875 to 1000 mg 1 tabs bid
- Clindamycin 150 to 300 mg PO q6 to 8h ± ciprofloxacin

INPATIENT—INTRAVENOUS:
- Piperacillin/tazobactam 3.375 g IV q6 to 8h
- Ampicillin/sulbactam 1.5 to 3 g IV q6h
- Cefotetan 1 to 2 g IV q8h
- Imipenem or meropenem 500 to 1000 mg IV q8h

DISPOSITION

Follow-up with a general surgeon or infectious disease physician is often warranted.

REFERRAL

- General surgeon or colorectal surgeon for drainage.
- AIDS specialist may be needed for perirectal complications of HIV infection.
- Gastroenterologist follow-up may be warranted in Crohn disease with perirectal fistula and other complications.
- Endoscopic ultrasound–guided perirectal abscess drainage is a recently described promising alternative treatment.

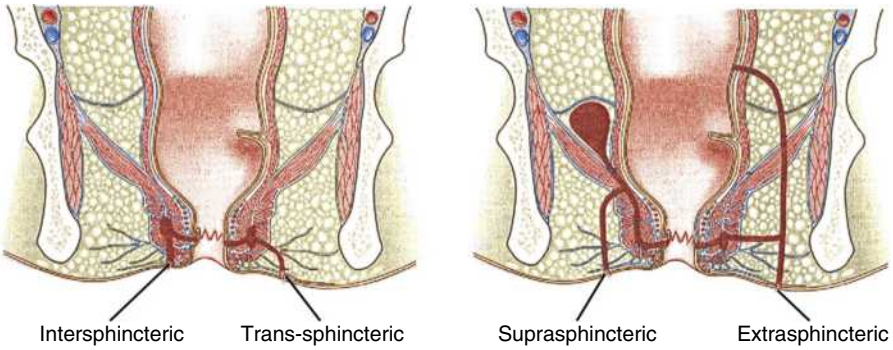

FIG. 1 Parks classification of anorectal abscess. (From Cameron JL, Cameron AM: *Current surgical therapy*, ed 10, Philadelphia, 2011, WB Saunders.)

PEARLS & CONSIDERATIONS

Perirectal abscess may be a presenting manifestation of type 2 diabetes mellitus in older adults. Check the blood sugar in patients to exclude the possibility of undiagnosed diabetes mellitus.

BASIC INFORMATION

DEFINITION

Peritonitis refers to the acute onset of severe abdominal pain caused by peritoneal inflammation.

Secondary peritonitis is peritonitis stemming from another condition; commonly a defect in an abdominal viscus.

SYNONYMS

Acute abdomen
Surgical abdomen

ICD-10CM CODES

K65.0	Generalized (acute) peritonitis
K65.8	Other peritonitis
K65.9	Peritonitis, unspecified
A18.31	Tuberculous peritonitis
A54.85	Gonococcal peritonitis
A74.81	Chlamydial peritonitis
K35.2	Acute appendicitis with generalized peritonitis
K35.3	Acute appendicitis with localized peritonitis
K65.2	Spontaneous bacterial peritonitis
N73.3	Female acute pelvic peritonitis
N73.4	Female chronic pelvic peritonitis
N73.5	Female pelvic peritonitis, unspecified
P78.1	Other neonatal peritonitis

EPIDEMIOLOGY & DEMOGRAPHICS

Common presentation as a result of diverse etiologies; for example, 5% to 10% of the population has acute appendicitis at some point in their lives.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Acute abdominal pain
- Abdominal distention and ascites
- Abdominal rigidity, rebound, and guarding
- Altered mental status
- Fever, chills
- Exacerbation with movement
- Anorexia, nausea, and vomiting
- Constipation or diarrhea
- Decreased bowel sounds
- Hypotension and tachycardia
- Tachypnea, dyspnea

ETIOLOGY

- One of the early steps is disturbance in gut flora with overgrowth and extraintestinal organismal overtake. Most common are gram-negative bacteria (*Escherichia coli, Enterobacter, Klebsiella, Proteus*), gram-positive bacteria (enterococci, streptococci, staphylococci), anaerobic bacteria (*Bacteroides, Clostridium*), and fungi
- It can be acute perforation peritonitis: Gastrointestinal perforation, intestinal ischemia, pelvic peritonitis, and other forms
- Postoperative peritonitis: Anastomotic leak, accidental perforation, and devascularization
- Posttraumatic peritonitis: After blunt or penetrating abdominal trauma

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Postoperative: Abscess, sepsis, bowel obstruction, injury to internal organs
- Gastrointestinal: Perforated viscus, appendicitis, inflammatory bowel disease, infectious colitis, diverticulitis, acute cholecystitis, peptic ulcer perforation, pancreatitis, bowel obstruction
- Gynecologic: Ruptured ectopic pregnancy, pelvic inflammatory disease, ruptured hemorrhagic ovarian cyst, ovarian torsion, degenerating leiomyoma
- Urologic: Nephrolithiasis, interstitial cystitis
- Miscellaneous: Abdominal trauma, penetrating wounds, infections caused by intraperitoneal dialysis

WORKUP

- Acute peritonitis is mainly a clinical diagnosis based on patient history and physical examination.
- Laboratory and imaging studies assist in determining the need for and type of intervention.
- If patient is hemodynamically unstable, immediate diagnostic laparotomy should be performed in lieu of adjuvant diagnostic studies.

LABORATORY TESTS

- Ascitic fluid testing
  1. Anaerobic and aerobic cultures
  2. Cell count and differential
  3. Albumin, protein, amylase, bilirubin
  4. Glucose
  5. LDH
- Complete blood count: Leukocytosis, left shift, anemia
- SMA7: Electrolyte imbalances, kidney dysfunction
- Liver function tests: Indicative of cirrhosis as ascites from liver disease, cholelithiasis
- Amylase: Pancreatitis
- Blood cultures: Bacteremia, sepsis
- Blood gas: Respiratory versus metabolic acidosis
- Urinalysis and culture: Urinary tract infection
- Cervical cultures for gonorrhea and *Chlamydia*
- Urine/serum human chorionic gonadotropin

IMAGING STUDIES

- Abdominal series: Free air from perforation, small or large bowel dilation from obstruction, identification of fecalith
- Chest x-ray examination: Elevated diaphragm, pneumonia
- Pelvic/abdominal ultrasound: Abscess formation, abdominal mass, intrauterine versus ectopic pregnancy, identify free fluid suggestive of hemorrhage or ascites
- CT: Mass, ascites

TREATMENT

NONPHARMACOLOGIC THERAPY

- IV hydration to correct dehydration, hypovolemia
- Blood transfusion to correct anemia from hemorrhage
- Nasogastric decompression, especially if obstruction is present
- Oxygen: Intubation if necessary
- Bed rest

ACUTE GENERAL Rx

- Surgery to correct underlying pathology, such as controlling hemorrhage, correcting perforation, draining abscess
- Broad-spectrum antibiotics to cover both gram-negative aerobic and gram-negative anaerobic bacteria:
  1. Mild-moderate disease: Piperacillin-tazobactam 3.375 g IV q6h or 4.5 g IV q8h *or* ticarcillin-clavulanate 3.1 g IV q6h. Alternative agents are ciprofloxacin 400 mg IV q12h or levofloxacin 750 mg IV q24h *plus* metronidazole 1 g IV q12h.
  2. Severe life-threatening disease: Imipenem 500 mg IV q6h or meropenem 1 g IV q8h. Alternative agents are ampicillin *plus* metronidazole *plus* ciprofloxacin.
  3. Antibiotic therapy should be tailored to culture results and sensitivities.
- Pain control: Morphine or meperidine as needed (hold until diagnosis confirmed)

DISPOSITION

Depends on etiology of peritonitis, age of patient, coexisting medical disease, and duration of process before presentation.

REFERRAL

Surgical consultation is required in all cases of acute peritonitis.

PEARLS & CONSIDERATIONS

Computed tomographic scan guides therapeutic approach and should be considered as the primary imaging study if available. As with forms of sepsis, early administration of broad spectrum antibiotics, fluid resuscitation, and rapidly obtaining anatomic source control (when appropriate) will lead to improved outcomes.

AUTHOR: **Ghamar Bitar, MD**

BASIC INFORMATION

DEFINITION

Peritonsillar abscess is an acute infection located between the capsule of the palatine tonsil and the superior constrictor muscle of the pharynx.

SYNONYMS

Quinsy
PTA

ICD-10CM CODE
J36 Peritonsillar abscess

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): 30:100,000/yr for ages 5 to 59. For adolescents, the incidence is 40:100,000/yr. It is the most common deep infection of the head and neck in children and adolescents, accounting for at least 50% of cases.
PREVALENCE: 45,000 cases/yr in the U.S.
PREDOMINANT SEX: Male > female
PREDOMINANT AGE: Highest incidence is adults aged 20 to 40 yr
PEAK INCIDENCE: Bimodal frequency during the yr, with highest occurrence from November to December and April to May
RISK FACTORS: Smoking, periodontal disease, oropharyngeal or dental infection, male gender

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- There is often a delay of 2 to 5 days between abscess formation and local and systemic symptoms
- Sore throat, which may be severe and unilateral (Table 1)
- Dysphagia and odynophagia
- Otalgia on the side of abscess
- Foul-smelling breath
- Facial swelling
- Drooling
- Headache
- Fever
- Trismus: The examination of the pharynx can be limited by trismus
- Hoarseness, muffled voice (also called "hot potato voice")
- Tender submandibular and anterior cervical lymph nodes
- Tonsillar hypertrophy with likely peritonsillar edema
- Contralateral deflection of the uvula: The distinguishing feature of peritonsillar abscess is inferior medial displacement of the infected tonsil with contralateral deviation of the uvula (Fig. E1)
- Stridor

ETIOLOGY

- Peritonsillar abscess is usually a complication of tonsillitis or acute bacterial pharyngitis caused by blockage of salivary ducts. Tonsillitis → peritonsillar cellulitis → peritonsillar abscess.
- Group A β-hemolytic *Streptococcus* is the most common bacterial cause, accounting for 15% to 30% of cases in children and 5% to 10% of cases in adults.
- Less common aerobic causes are *Staphylococcus aureus, Haemophilus influenzae, Neisseria* species.
- The most common anaerobic organism is *Fusobacterium.*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Hypertrophic tonsillitis
- Infectious mononucleosis
- Peritonsillar cellulitis
- Retropharyngeal abscess
- Epiglottitis
- Dental abscess (retromolar)
- Lymphoma
- Ludwig angina
- Tubercular granuloma
- Cervical adenitis
- Diphtheria
- Foreign body
- Neoplasm

WORKUP

- Based on history and physical exam. Aspiration of pus established diagnosis of peritonsillar abscess.
- Consider additional testing if presentation is less clear.

LABORATORY TESTS

- Consider rapid strep antigen testing and/or pharyngeal culture and sensitivity.
- Aspiration of the abscess for culture and sensitivity (see "Treatment" for role of aspiration in Tx).
- Consider lab testing for mononucleosis (patients with peritonsillar abscess have a 20% incidence of mononucleosis).

IMAGING STUDIES

- Consider ultrasound, CT scan (Fig. 2), or MRI (Fig. 3) to help differentiate abscess from cellulitis or mass when diagnosis is unclear.
- Intraoral ultrasound may improve diagnosis and aspiration of PTA compared with visual inspection in adult patients.
- MRI provides better soft-tissue differentiation than CT.

TREATMENT

NONPHARMACOLOGIC THERAPY

Drainage of the abscess by needle aspiration or by surgical incision and drainage. Intraoral ultrasound-guided needle aspira-

TABLE 1 Clinical Differentiation of Common Conditions Arising as Sore Throat

Feature	Viral Pharyngitis	Bacterial Tonsillitis	Peritonsillar Abscess	Epiglottitis
Tonsillar Enlargement	Usual	Rare	None	None
Tonsillar Exudates	Occasional (mononucleosis)	Usual	Often	None
Tonsillar Asymmetry	None	None	Usual	None
Trismus (Inability to Open Jaw)	None	None	Usual	None
Cervical Adenopathy	Occasional	Usual (tender)	Usual (tender)	None
Tender Larynx	Rare	None	None	Usual

From Goldman L, Schafer AI: *Goldman's Cecil Medicine*, ed 24, Philadelphia, 2012, Saunders.

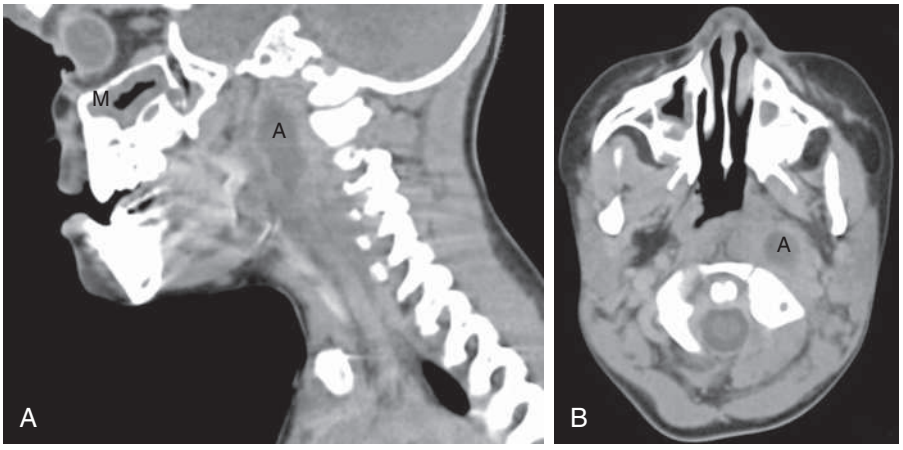

FIG. 2 Computed tomography of parapharyngeal abscess in a 3-yr-old child. A, Sagittal section demonstrating parapharyngeal abscess *(A)* and mucosal swelling *(M)* in the maxillary sinus. **B,** Coronal section of parapharyngeal abscess *(A).* (From Kliegman RM et al: *Nelson textbook of pediatrics*, ed 19, Philadelphia, 2011, Saunders.)

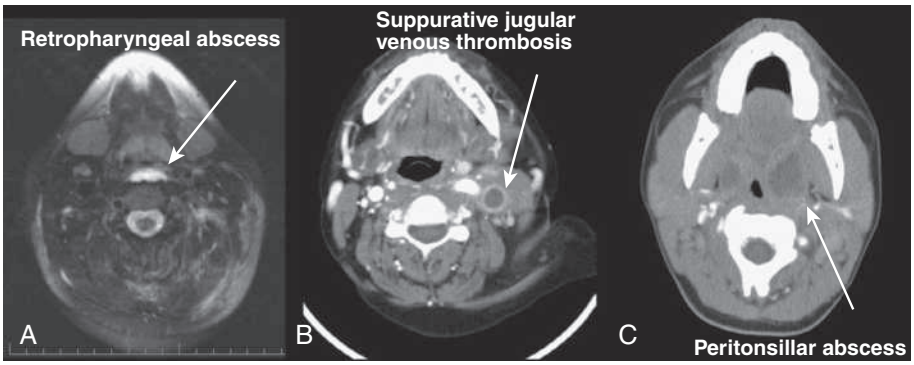

FIG. 3 Magnetic resonance imaging and computed tomography images showing a variety of life-threatening head and neck infections including retropharyngeal abscess **(A),** suppurative jugular venous thrombosis **(B),** and peritonsillar abscess **(C).** (Images provided by Dr. Joshua Brody, Department of Radiology, the Cooper Health System, Camden, NJ. In Parrillo JE, Dellinger RP: *Critical Care Medicine, Principles of Diagnosis and Management in the Adult*, ed 5, Philadelphia, 2019, Elsevier.)

tion is a useful adjunct in the presence of trismus.

ACUTE GENERAL Rx

- Aspiration or surgical drainage AND antibiotics for 10 to 14 days
- Initial antibiotics should cover group A *Streptococcus* and anaerobes
- Intravenous
  1. Piperacillin/tazobactam or ticarcillin/clavulanate. If penicillin allergic, use IV clindamycin (600 to 900 mg IV q8h)
  2. Ampicillin-sulbactam 3 g q6h
  3. Penicillin G 10 million units q6h AND metronidazole 500 mg q6h (may use clindamycin 900 mg q8h if penicillin allergic)
- OR oral
  1. Amoxicillin-clavulanic acid 875 mg twice daily
  2. Penicillin VK 500 mg 4 times daily AND metronidazole 500 mg 4 times daily
  3. Clindamycin 600 mg twice daily or 300 mg 4 times daily
- Selection of antibiotics should be guided by culture and sensitivity of the organism. Consulting local antimicrobial guidelines for resistance profiles is also advisable for empiric coverage before culture results are available

CHRONIC Rx

- Tonsillectomy can be considered 3 to 6 mo after diagnosis of peritonsillar abscess with or without the diagnosis of recurrent tonsillitis.
- Though rare, in adults and children with an acute case of peritonsillar abscess and a history of recurrent pharyngitis or previous peritonsillar abscess, a specialist may recommend a *quinsy or hot tonsillectomy,* an immediate removal of the tonsils after starting IV antibiotics.

DISPOSITION

- Successful treatment is defined by symptomatic improvement in sore throat, fever, and/or tonsillar swelling within 24 hr of intervention.
- Treatment failure is defined by lack of symptomatic improvement or worsening despite 24 hr of antimicrobial therapy (with or without surgical drainage).

REFERRAL

- Consider ENT or diagnostic radiology for drainage of abscess.
- Consider ENT for tonsillectomy if criteria are met.

PEARLS & CONSIDERATIONS

COMMENTS

- Risk for a recurrence is immediate (within 4 days) and long term (2 to 3 yr).
- Most recurrences occur shortly after the initial presentation, suggesting continued infection rather than recurrence.
- Overall recurrence rate is 10% to 15%.
- Supportive treatment for pain control and hydration. Newer reports suggest a single dose of dexamethasone (10 mg) administered following needle aspiration will reduce pain at 24 hours as compared with placebo (see "Suggested Readings").

PREVENTION

- Adequate treatment of peritonsillar abscess.
- Up to 30% of patients with peritonsillar abscess meet criteria for tonsillectomy.

PATIENT & FAMILY EDUCATION

Advise family members to call with any trouble breathing, swallowing, or talking.

BASIC INFORMATION

DEFINITION

Pertussis is a prolonged bacterial infection of the upper respiratory tract characterized by paroxysms of an intense cough.

SYNONYM

Whooping cough

ICD-10CM CODES

A37.00	Whooping cough due to Bordetella pertussis without pneumonia
A37.01	Whooping cough due to Bordetella pertussis with pneumonia
A37.10	Whooping cough due to Bordetella parapertussis without pneumonia
A37.11	Whooping cough due to Bordetella parapertussis with pneumonia
A37.80	Whooping cough due to other Bordetella species without pneumonia
A37.81	Whooping cough due to other Bordetella species with pneumonia
A37.90	Whooping cough, unspecified species without pneumonia
A37.91	Whooping cough, unspecified species with pneumonia

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.): Case reports from 2016 were 15,737, including seven deaths. This represents a decrease in the number of case reports compared with each of the 3 previous yr. The reported rates were 20,762 and 32,971 in 2015 and 2014, respectively. In 2012, there were 48,277 cases reported, which is the highest rate reported since 1955. The highest incidence, in 2016, was among infants <6 mo (85.5/100,000), with a second peak in adolescents 11 to 19 yr of age (13.9/100,000).

PEAK INCIDENCE:

- Childhood
- Usually affects children aged <1 yr
- Increasing infections seen in adolescence

PREDOMINANT AGE:

- 50% in children aged <1 yr
- 20% in children aged >15 yr
- Classically an infection of infants and young children, pertussis is often overlooked as a cause of chronic cough in adults. However, a resurgence of pertussis has been observed in recent yr, with nearly 50% of all cases identified in adolescents and adults, likely due to waning immunity and decreased effectiveness of acellular vaccines in early childhood compared to older, whole-cell-derived vaccines

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Infection is characterized by three phases: Catarrhal, paroxysmal, and convalescent.
- Catarrhal phase: Usually begins with a 1- to 2-wk prodrome that resembles a common cold. This phase may be mild or absent in adolescents and adults given partial immunity from prior immunization.
- After this initial phase, increased production of mucus occurs. Excessive lacrimation and conjunctival infection should heighten the suspicion for pertussis.
- Paroxysmal phase: Increased mucus production is followed by an intense, paroxysmal cough, ending with gasps and an inspiratory whoop.
- In some children, apnea, cyanosis, and anoxia are noted; posttussive gagging and vomiting are characteristic of pertussis.
- Cases can be severe and life-threatening in young infants, particularly children <6 mo old.
- When prolonged, frank exhaustion and even apnea occur. The paroxysmal phase lasts from 2 wk to 2 mo.
- Convalescent phase: Lasts over 2 mo and is characterized by cough of decreasing severity.
- See Box 1 for complications of pertussis.

ETIOLOGY

Bordetella pertussis, a gram-negative rod that adheres to human cilia and respiratory epithelia

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Croup
- Epiglottitis
- Foreign body aspiration
- Bacterial pneumonia
- Viral pneumonia

WORKUP

Pertussis is often overlooked as a cause of chronic cough, especially in adolescents and adults. The presence of posttussive emesis and/or inspiratory whoop increases the likelihood of pertussis but only modestly. Therefore, clinicians must use their overall impression in pursuing the diagnosis.

- Enzyme-linked immunosorbent assay for detection of antibody to pertussis. Polymerase chain reaction (PCR) is the most sensitive method for rapid detection of pertussis. PCR testing should be used only to confirm a diagnosis in persons with signs and symptoms consistent with pertussis. PCR testing sensitivity declines and is unlikely to be positive after 1 mo of infection. PCR testing after 5 days of treatment with antibiotics can cause false-negative results and is generally not recommended
- Blood cultures in hospitalized patients
- Chest x-ray
- Culture of bacteria, usually from nasopharynx by aspiration or by swabbing the posterior nasopharynx with a polyester-tipped, rayon-tipped, or nylon-flocked swab
- Immunofluorescent staining of nasopharyngeal secretions
- Serologic tests for immunoglobulin G (IgG) or A (IgA) are available. A twofold increase between acute and convalescent sera is considered proof of seroconversion. A single elevated IgG or IgA titer is considered diagnostic when no acute serum is available. Can be useful for diagnosis later in illness

BOX 1 Pertussis Complications

- Periorbital edema
- Subconjunctival hemorrhage
- Petechiae
- Epistaxis
- Hemoptysis
- Subcutaneous emphysema
- Pneumothorax
- Pneumomediastinum
- Diaphragmatic rupture
- Umbilical and inguinal hernias
- Rectal prolapse

From Marx J et al: *Rosen's emergency medicine: Concepts and clinical practice*, ed 7, Philadelphia, 2010, Mosby.

LABORATORY TESTS

Complete blood count, which usually demonstrates marked lymphocytosis:

- Up to 18,000 white blood cells
- 70% to 80% lymphocytes

IMAGING STUDIES

Chest x-ray examination is of value if secondary bacterial pneumonia is suspected.

TREATMENT

ACUTE GENERAL Rx

- Intensive supportive care:
  1. Adequate hydration
  2. Control of secretions
  3. Maintenance of airway
- Antibiotics (Table 1) are indicated, even though their ability to alter the course of the disease is controversial
  1. Azithromycin 500 mg on day 1, followed by 250 mg for days 2 to 5. Erythromycin 50 mg/kg/day for 14 days. Recent literature reports indicate that a 7-day treatment regimen may be as effective as a 14-day course of erythromycin. TMP/SMX 320/1600 mg per day in divided doses can be used in patients with allergy or intolerance to macrolides
  2. Although unproved, dexamethasone 1 mg/kg/day in four doses for severe, life-threatening paroxysms
  3. Ceftriaxone 75 mg/kg/day in two doses for broad coverage of secondary bacterial pneumonias
  4. Close observation of infants <6 mo old as risk for apnea is high in this age group
- Vaccination is successful in preventing the disease: Universal vaccination is advised for all children and adults. Children are recommended to receive the five-dose DTaP series at months 2, 4, 6, and 15 to 18, and at 4 to 6 yr of age
- The Advisory Committee on Immunization Practices (ACIP) updated Tdap recommendations to include a single dose of Tdap vaccine in place of routine Td for adults age 19 to 64 yr and a single-dose Tdap for adults 65

TABLE 1 Recommended Antimicrobial Treatment and Postexposure Prophylaxis for Pertussis, by Age Group

	Primary Agents		Alternate Agent*	
Age Group	**Azithromycin**	**Erythromycin**	**Clarithromycin**	**TMP-SMZ**
<1 mo	Recommended agent. 10 mg/kg/day in a single dose for 5 days (only limited safety data available)	Not preferred. Erythromycin is substantially associated with infantile hypertrophic pyloric stenosis. Use if azithromycin is unavailable; 40-50 mg/kg/day in 4 divided doses for 14 days	Not recommended (safety data unavailable)	Contraindicated for infants aged <2 mo (risk for kernicterus)
1-5 mo	10 mg/kg/day in a single dose for 5 days	40-50 mg/kg/day in four divided doses for 14 days	15 mg/kg/day in two divided doses for 7 days	Contraindicated at age <2 mo. For infants aged ≥2 mo: TMP 8 mg/kg/day plus SMZ 40 mg/kg/day in two divided doses for 14 days
Infants aged ≥6 mo and children	10 mg/kg in a single dose on day 1 (maximum 500 mg), then 5 mg/kg/day (maximum 250 mg) on days 2-5	40 mg/kg/day (maximum 1-2 g/day) in four divided doses for 14 days	15 mg/kg/day in 2 divided doses (maximum 1 g/day) for 7 days	TMP 8 mg/kg/day plus SMZ 40 mg/kg/day in two divided doses for 14 days
Adolescents and adults	500 mg in a single dose on day 1 then 250 mg/day on days 2-5	2 g/day in four divided doses for 14 days	1 g/day in two divided doses for 7 days	TMP 320 mg/day, SMZ 1600 mg/day in two divided doses for 14 days

SMZ, Sulfamethoxazole; *TMP,* trimethoprim; *TMZ,* trimethoprim.

*Trimethoprim-sulfamethoxazole (TMP-SMZ) can be used as an alternative agent to macrolides in patients aged ≥2 mo who are allergic to macrolides, who cannot tolerate macrolides, or who are infected with a rare, macrolide-resistant strain of *Bordetella pertussis*.

From Centers for Disease Control and Prevention: Recommended antimicrobial agents for treatment and postexposure prophylaxis of pertussis: 2005 CDC guidelines, *MMWR Morbid Mortal Wkly Rep* 54:1-16, 2005.

yr and older who have or will have close contact with an infant (<12 mo). The ACIP also recommends that all pregnant women receive a dose of Tdap with every pregnancy, preferably during wk 27 to 36 of gestation

- Azithromycin, clarithromycin, or erythromycin is recommended for all household contacts and should be given to all persons at high risk of severe disease from pertussis and who were in contact with a pertussis case within 21 days of cough onset: TMP/SMX in two oral doses per day for those intolerant to macrolides

DISPOSITION

Close attention to accepted vaccination schedules is the best prevention.

REFERRAL

To intensive care setting for life-threatening infections:

- Pulmonologist
- Infectious disease specialist

PEARLS & CONSIDERATIONS

- The diagnosis of pertussis in a young child is easily recognized, but in adults pertussis can be a subtle diagnosis and is often missed. The tip-off is often a persistent, hacking, and productive cough with minor or no fever in a previously healthy person that lasts <2 wk.
- Approximately 11% of pertussis cases in the pediatric population are attributable to vaccine refusal, dispelling the myth that herd immunity protects children whose parents refuse pertussis vaccine.

BASIC INFORMATION

DEFINITION

- A hamartomatous polyp is a benign intestinal growth that may contain all components of the intestinal mucosa. In Peutz-Jeghers syndrome (PJS), hamartomas are found primarily in the small bowel but can also be present in the colon and stomach. In gastrointestinal polyposis, multiple such polyps coexist within the intestinal tract, and associated manifestations are usually also present.
- Juvenile polyps are benign polyps composed of cystic dilations of glandular structures within the fibroblastic stroma of the lamina propria. They may cause bleeding or intussusception.
- Commonly recognized syndromes are Peutz-Jeghers syndrome, juvenile polyposis syndrome, Cowden disease, Bannayan-Ruvalcaba-Riley syndrome, and Cronkhite-Canada syndrome. Other, lesser-known inherited hamartomatous polyposis syndromes are hereditary mixed polyposis syndrome, intestinal ganglioneuromatosis and neurofibromatosis (variant of von Recklinghausen syndrome), Devon family syndrome, basal cell nevus syndrome, and tuberous sclerosis (may involve gastrointestinal tract). Table 1 describes general features of some inherited colorectal cancer syndromes.

ICD-10CM CODE

D12.6 Colon, unspecified (adenomatosis of colon, hereditary polyposis)

EPIDEMIOLOGY

- The incidence of PJS is 1 in 200,000.
- Colonic adenomas, the precursors of nearly all colorectal cancers, are found in nearly 40% of patients by age 60 yr.
- 25% of men and 15% of women who undergo colonoscopy are found to have one or more adenomas.
- Detection of any adenoma in patients <60 yr confers an increased risk of colorectal cancer (by a factor of 2.6) in their first-degree relatives.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

PEUTZ-JEGHERS SYNDROME:

- Transmission: Autosomal dominant with incomplete penetrance. The syndrome is caused in the majority of patients by a germline mutation of the *STK11/LKB1* tumor suppression gene on chromosome 19P13.
- Disease expression:
  1. Stomach, small and large intestinal hamartomas with bands of smooth muscle in the lamina propria
  2. Pigmented lesions around mouth (lips and buccal mucosa [Fig. E2]), nose, hands, feet, genitals, and perineal areas
  3. Ovarian tumors
  4. Sertoli cell testicular tumors
  5. Airway polyps
  6. Pancreatic cancer
  7. Breast cancer
  8. Urinary tract polyps
- Cumulative lifetime cancer risk:
  1. Colon cancer: 39%
  2. Stomach cancer: 29%
  3. Small intestine cancer: 13%
  4. Pancreatic cancer: 36%
  5. Breast cancer: 54%
  6. Ovarian cancer: 10%
  7. Sertoli cell tumor: 9%
  8. Overall cancer risk: 93%
- Clinical manifestation:
  1. Gastrointestinal, small-bowel obstruction, intussusception, gastrointestinal bleeding
  2. See chapters on relevant malignancies for their signs and symptoms

DIAGNOSIS: The diagnosis of PJS is made with any of four major criteria:

1. Two or more histologically confirmed PJS polyps
2. Any number of PJS polyps and a family history of PJS
3. Characteristic mucocutaneous pigmentation and a family history of PJS, or
4. Any number of PJS polyps and characteristic mucocutaneous pigmentation

JUVENILE POLYPOSIS SYNDROME:

- Transmission: Autosomal dominant
- Disease expression:
  1. Solitary juvenile polyps numbering 10 or more in the rectum or throughout the gastrointestinal tract; the polyps are smooth and covered with normal epithelium
  2. Various congenital abnormalities coexist in 20%
- Cumulative cancer risk is increased (may be as high as 50%)
- Clinical manifestation:
  1. Intestinal obstruction
  2. Intussusception
  3. Gastrointestinal bleeding

COWDEN DISEASE:

- Transmission: Autosomal dominant, rare
- Disease expression:
  1. Juvenile intestinal polyposis
  2. Orocutaneous hamartomas
  3. Fibrocystic breast disease and breast cancer
  4. Goiter and thyroid cancer
  5. Facial tricholemmomas (papules) in 83%
- Cumulative cancer risk:
  1. Gastrointestinal: Same as general population
  2. Thyroid: 3% to 10%
  3. Breast: 25% to 50%

BANNAYAN-RUVALCABA-RILEY SYNDROME:

- Transmission: Autosomal dominant, rare
- Disease expression:
  1. Juvenile intestinal polyposis
  2. Macrocephaly
  3. Developmental delay
  4. Penile pigmented spots
  5. Cumulative cancer risk unknown

TABLE 1 General Features of Some Inherited Colorectal Cancer Syndromes

Syndrome	Polyp Histology	Polyp Distribution	Age of Onset	Risk of Colon Cancer	Genetic Lesion	Clinical Manifestations	Associated Lesions
Familial adenomatous polyposis (Fig. E1)	Adenoma	Large intestine, duodenum	16 yr (range, 8-34 yr)	100%	5q (*APC* gene)	Rectal bleeding, abdominal pain, bowel obstruction	Desmoids, CHRPE
Peutz-Jeghers syndrome	Hamartoma	Large and small intestine	First decade	Slightly above average	19p (*STK11* gene)	Possible rectal bleeding, abdominal pain, intussusception	Orocutaneous melanin pigment spots, other tumors
MUTYH-associated polyposis	Adenoma	Large intestine, duodenum	45-50 yr (range, 13-60 yr)	75% (range, 50%-100%)	1p (*MYH* gene)	Rectal bleeding, abdominal pain, bowel obstruction	CHRPE, osteomas
Juvenile polyposis	Hamartoma (rarely adenoma)	Large and small intestine	First decade	~9%	*PTEN, SMAD4, BMPR1*	Possible rectal bleeding, abdominal pain, intussusception	Pulmonary AVMs
Hereditary nonpolyposis colon cancer	Adenoma	Large intestine	40 yr (range, 18-65 yr)	30%	Mismatch repair genes+*	Rectal bleeding, abdominal pain, bowel obstruction	Other tumors (e.g., ovary, uterus, pancreas, stomach)

AVM, Arteriovenous malformation; *CHRPE,* congenital hypertrophy of the retinal pigment epithelium; *MUTYH,* mutY homolog (*Escherichia coli*).
*Including *hMSH2, hMSH3, hMSH6, hMLH1, hPMS1*, and *hPMS2*.
From Goldman L, Schafer AI: *Goldman's Cecil medicine,* ed 24, Philadelphia, 2012, WB Saunders.

CRONKHITE-CANADA SYNDROME:
- Transmission: Acquired
- Age of onset: Midlife
- Disease expression:
  1. Diffuse gastrointestinal juvenile polyposis (50% to 95% of cases)
  2. Chronic diarrhea and protein-losing enteropathy (the entire intestinal mucosa may be inflamed), which leads to abdominal pain, weight loss, and various complications of malnutrition
  3. Dystrophic nails
  4. Alopecia
  5. Hyperpigmentation
- Cumulative cancer risk: Same as the average population

Dx DIAGNOSIS

Diagnosis is suggested in many cases by family history and confirmed by colonoscopy and physical findings described previously.

Rx TREATMENT

GENERAL Rx/SURVEILLANCE

Peutz-Jeghers syndrome:
- Colonoscopies with polypectomies and upper endoscopy every 2 to 3 yr beginning in teen yr
- MRI or endoscopic ultrasound of the pancreas every 1 to 2 yr beginning at age 30
- Screening for breast cancer, testicular cancer, possibly ovarian cancer
- Surveillance of small bowel with capsule endoscopy or CT or magnetic resonance enterography every 2 to 3 yr starting at age 8 to 10 yr

Juvenile polyposis syndrome:
- Colonoscopies with polypectomies and upper endoscopy every 2 to 3 yr beginning at age 15
- Total colectomy if numerous polyps
- Esophagogastroscopies and polypectomies

Cowden disease:
- Rigorous breast cancer screening or prophylactic simple bilateral mastectomy with reconstruction

Cronkhite-Canada syndrome:
- Progressive malabsorption syndrome is the hallmark of this syndrome, and no specific treatment exists. Enteral or parenteral feeding is the cornerstone of management and can result in remission.

Other syndromes:
- Serrated polyposis syndrome: Colonoscopy yearly
- PTEN hamartoma tumor syndrome: Colonoscopy every 5 yr beginning at age 35

DISPOSITION

- The screening of first-degree relatives of patients with colonic adenomas detected before 60 yr of age is controversial. Some recommend beginning colonoscopic screening at age 40 yr, or 10 yr younger than the age at diagnosis of the youngest person in the family with an adenoma.
- Recommended intervals between colonoscopies from the U.S. Consensus Guidelines for Colonoscopic Surveillance after Polypectomy are as follows:
  1. 10 yr for small, rectal hyperplastic polyps
  2. 5 to 10 yr for one to two low-risk adenomas (tubular adenomas <1 cm)
  3. 3 yr for low-risk adenomas or any high-risk adenoma (large [≥1 cm] or histologically advanced adenomas [tubulovillous or villous adenomas or villous adenomas and those with high-grade dysplasia])
  4. <3 yr for presence of >10 adenomas
  5. 2 to 6 mo for inadequately removed adenomas

Peyronie Disease PTG ALG

BASIC INFORMATION

DEFINITION

Peyronie disease is an abnormal curvature and shortening of the penis during an erection. This is caused by scarring of the tunica albuginea of the corpora cavernosa.

SYNONYMS

Plastic induration of the penis
Penile fibromatosis

ICD-10CM CODE
N48.6 Induratio penis plastica

EPIDEMIOLOGY & DEMOGRAPHICS

- Peyronie disease occurs in approximately 1% of men.
- It is commonly seen between the ages of 45 and 60 yr.
- A genetic predisposition has been suggested.
- There are no incidence and prevalence data available in the literature.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Painful erections
- Tenderness over the scar tissue area
- Erectile dysfunction
- Curvature of the erected penis interfering with penetration
- Dupuytren contracture is a commonly associated finding in patients with Peyronie disease

ETIOLOGY

- Specific cause is unknown. It is believed that scar tissue forms on either the dorsal or ventral midline surface of the penile shaft. The scar restricts expansion at the involved site, causing the penis to bend or curve in one direction.
- The precipitating factor appears to be trauma from repetitive microvascular injury caused by vigorous sexual intercourse, accidents, or prior surgeries (e.g., transurethral or radical prostatectomy, cystoscopy).

DIAGNOSIS

Diagnosis is based on the clinical findings.

DIFFERENTIAL DIAGNOSIS

- The history differentiates congenital from acquired curvatures of the penis.
- Other causes of erectile dysfunction must be excluded, including metabolic, diabetic, thyroid, and renal causes, in addition to hypogonadism and hyperprolactinemia.

WORKUP

History and physical examination alone will usually establish the diagnosis of Peyronie disease. The curvature can be measured with goniometer (Fig. E1).

LABORATORY TESTS

There are no specific blood tests to diagnose Peyronie disease. Electrolytes, blood urea nitrogen, creatinine, glucose, thyroid function tests (thyroid-stimulating hormone, T_3U, T_4), testosterone, and prolactin levels are blood tests to exclude other medical causes of erectile dysfunction.

IMAGING STUDIES

Penile duplex ultrasonography (Fig. E2, Box E1)

TREATMENT

NONPHARMACOLOGIC THERAPY

A conservative approach of reassurance and observation is taken at first because the disease process may be self-limiting.

FIG. E1 Measurement of curvature with goniometer. (From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.)

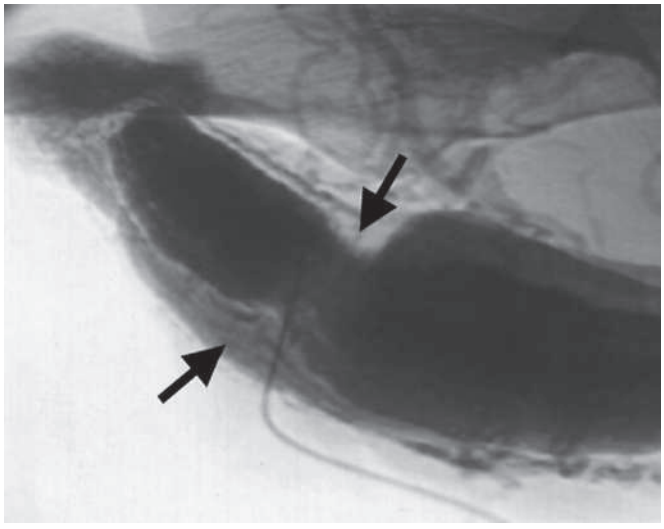

FIG. E2 Peyronie disease. Cavernosogram in a patient with erectile failure confined to the distal penis. There is a circumferential stricture *(arrows)* of the mid-shaft of both corpora cavernosa. (From Adam A et al: *Grainger & Allison's diagnostic radiology*, ed 5, 2007, Churchill Livingstone. In Grant LA: *Grainger & Allison's diagnostic radiology essentials*, ed 2, 2019, Elsevier.)

BOX E1 Value of Penile Duplex Ultrasonography for Peyronie Disease

- Identification and measurement of plaque calcification
- Identification of corporeal fibrosis
- Observation of erectile response to vasoactive intracavernosal injection
- Measurement of penile vascular parameters (peak systolic velocity, end-diastolic velocity, and resistive index)
- Optimum objective measurement of erect penile deformity (curvature, girth irregularities, hinge effect)

From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

ACUTE GENERAL Rx

Other medications that can be helpful include verapamil, tamoxifen, and interferon. Oral agents for Peyronie disease are summarized in Table E1. Although not substantiated by direct randomized, controlled clinical trials, the following treatment modalities have been tried:

- Vitamin E 400 mg bid
- Paraaminobenzoic acid 12 g/day
- Colchicine 0.6 mg bid for 2 to 3 wk
- Fexofenadine 60 mg bid for 3 mo
- Steroid injection into the scar tissue
- Collagenase injection into the scar tissue
- Table E2 summarizes intralesional agents for Peyronie disease
- Radiation to the scar tissue area
- Extracorporeal shockwave therapy (ESWT): Current evidence on the safety, but not the efficacy, of ESWT appears adequate. From comparative studies, the main benefits of ESWT were the alleviation of pain and reduction of angulation of the penis. In one comparative study, 10 of 20 patients receiving ESWT had a decrease in the curvature of at least 30%. Case series evidence also suggested some improvement of sexual performance
- Table E3 summarizes external force applications for treatment of Peyronie disease

CHRONIC Rx

In patients who have progressed to intractable pain with erection or erectile dysfunction, surgical treatment with excision of the plaque and skin grafting may be indicated. Boxes E2 and E3 summarize indications for surgery and preoperative consent. An algorithm for the surgical management of Peyronie disease is described in Fig. E3.

DISPOSITION

Peyronie disease evolves slowly and, in some cases, can resolve on its own. Waiting for 1 yr before proceeding with surgical attempts is recommended.

TABLE E1 Oral Agents for Peyronie Disease (PD)

Treatment	Mechanism of Action	Study Outcomes	Adverse Effects
Potaba	Decreases serotonin levels by increasing monoamine oxidase activity, resulting in enhancement of the antifibrotic properties of tissues	Decreased plaque size, no decrease in curvature	Anorexia, nausea, fever, skin rash, hypoglycemia, acute hepatitis
Vitamin E	Antioxidant, limits oxidative stress of reactive oxygen species shown to be increased in PD	No benefit	Possible cerebrovascular events, nausea, vomiting, diarrhea, headache, dizziness
Tamoxifen	Induces the production of TGF-β in an estrogen receptor–independent fashion, theoretically causing macrophage deactivation and T-lymphocyte suppression, thus preventing further fibrogenesis	No benefit	Alopecia, retinopathy, thromboembolism, pancytopenia
Colchicine	Microtubule depolymerization; inhibits cell mitosis, mobility, adhesion of leukocytes, and transcellular movement of collagen and stimulates the production of collagenase	No benefit	Myelosuppression, diarrhea, nausea, vomiting
Carnitine	Increases mitochondrial respiration; decreases free radical formation	No benefit	Seizures, diarrhea, nausea, stomach cramps, vomiting
Pentoxifylline	Blocks the TGF-β1–mediated pathway of inflammation; prevents deposition of collagen type I; is a nonspecific phosphodiesterase inhibitor; decreases platelet-activating factor	Decreased curvature in 33% of patients, mean 23 degrees	Nausea, vomiting, dyspepsia, malaise, flushing, dizziness, and headache

TGF, Transforming growth factor.
From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

TABLE E2 Intralesional Agents for Peyronie Disease (PD)

Treatment	Mechanism of Action	Study Outcomes	Adverse Effects
Verapamil	Calcium channel blocker inhibits fibroblast proliferation, extracellular matrix protein synthesis and secretion; increases collagenase activity	Reduction of curvature and plaque-associated penile narrowing, improvement in quality of erection	Nausea, light-headedness, penile pain, ecchymoses
Nicardipine	DHP type of calcium channel blocker. In vitro study demonstrated that it is more effective than a non-DHP type, verapamil, in reducing glycosaminoglycan biosynthesis and production of extracellular matrix, such as collagen	Reduction of pain, improvement in IIEF-5 score, and reduction of plaque size; no benefit in curvature	No severe side effects, such as hypotension or other cardiovascular events
Interferon alfa-2b	Decreases plaque fibroblast proliferation in dose-dependent fashion, decreases the production of extracellular collagen, and increases the production of collagenase	Decrease in curvature of 27% (13.5 degrees) vs. 9% (4.5 degrees) in the placebo group	Sinusitis, flulike symptoms (fever, chills, and arthralgia), and minor penile swelling with ecchymosis
Clostridial collagenase	Selectively degrades collagen types I and III in connective tissues despite the presence of TIMPs, which have been shown to be elevated in PD and to increase apoptosis of fibroblasts	Decrease in penile curvature by 34%, mean decrease of 17 degrees vs. 18%, mean decrease 9.3 degrees in placebo; PD symptom bothersomeness score significantly improved vs. placebo	Contusions, ecchymoses, corporeal rupture

DHP, Dihydropyridine; *IIEF,* International Index of Erectile Function; *TIMPs,* tissue inhibitors of metalloproteinases.
From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

TABLE E3 External Force Application for Peyronie Disease

Treatment	Mechanism of Action	Study Outcomes	Adverse Effects
Electromotive drug administration	Bypasses hepatic metabolism, increases concentration of drug to target tissues compared with topical application alone	Verapamil alone: No benefit Verapamil + dexamethasone: Decreases in plaque volume as well as penile curvature from 43 to 21 degrees	Temporary erythema at the electrode site
Extracorporeal shockwave therapy	Direct damage to the penile plaque; increases vascularity of the targeted area inducing an inflammatory reaction, resulting in lysis of the plaque and removal by macrophages	Improvements in pain, IIEF-5 score, and mean QoL score; no curvature reduction	Local petechiae and ecchymoses
Penile traction	Decreases α-smooth muscle actin, increases matrix metalloproteinases involved in collagen degradation	Length increased 0.5-2.0 cm; girth increased 0.5-1.0 cm; curvature mean decrease of 20 degrees; pain decreased; softening or shrinking of plaque; overall satisfaction 85%	Erythema in the balanopreputial sulcus, discomfort
Vacuum therapy	Unknown; mechanical effects similar to traction have been suggested	Reduction in the angle of curvature by 5-25 degrees in 21 of 31 patients	Development of PD, urethral bleeding, skin necrosis, and penile ecchymosis
Radiation therapy	Antiinflammatory effects via functional modulation of the adhesion of white blood cells to activated endothelial cells and modulation of the induction of nitric oxide synthase in activated macrophages	No clinical benefit	Possible malignant change, increased risk of ED in elderly

ED, Erectile dysfunction; *IIEF,* International Index of Erectile Function; *PD*, Peyronie disease; *QoL*, quality of life.
From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

BOX E2 Indications for Surgery

- Stable deformity for at least 6 mo from onset of symptoms
- Inability to engage in satisfactory penetrative sexual intercourse because of deformity and/or inadequate rigidity
- Failed conservative treatment
- Desire for most rapid and reliable result

From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

BOX E3 Preoperative Consent

Set expectations regarding outcome:
- Persistent or recurrent curvature: The goal is "functionally straight" (curvature <20 degrees)
- Change in length: The result is more likely shorter with plication than with grafting
- Diminished rigidity
  - ≥5% in all studies—grafting more than plication
  - ≥30% if suboptimal preoperative rigidity—dependent on preoperative erectile quality
- Decreased sexual sensation
  - Typically resolves in 1 to 6 mo
  - Rarely compromises orgasm or ejaculation

From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.

REFERRAL

A urologic consultation is recommended in patients with progressive symptoms and erectile dysfunction.

PEARLS & CONSIDERATIONS

COMMENTS

- Peyronie disease is not commonly seen in younger patients because they are able to sustain intracorporeal pressures high enough to stretch the scar tissue, preventing it from deforming the penis during erection.
- Trauma from buckling of the erected penis is thought to be the precipitant cause of scar formation and Peyronie disease. It is found more often in men who are sexually very active and vigorous, having sexual intercourse daily or almost daily.
- Sexual positions with the woman being on top or thrusting the penis into the anterior vaginal wall are thought to increase the chances of developing Peyronie disease.

(From Wein AJ et al: *Campbell-Walsh urology*, ed 11, Philadelphia, 2016, Elsevier.)

BASIC INFORMATION

DEFINITION

Inflammation of the pharynx or tonsils

SYNONYMS

Sore throat
Group A streptococci (GAS)
Pharyngitis
Tonsillitis
GABHS

ICD-10CM CODES

J02.9	Acute pharyngitis, unspecified
J03.0	Acute tonsillitis
J03.9	Acute tonsillitis, unspecified
J04.0	Acute laryngitis

EPIDEMIOLOGY & DEMOGRAPHICS

Acute pharyngitis accounts for 1.3% of outpatient visits to health care providers in the U.S. and is diagnosed in 2 million persons in the outpatient setting each yr in the U.S.

PEAK INCIDENCE: Late winter/early spring (GAS infections)

PREDOMINANT SEX: Females = males

PREDOMINANT AGE:

- All ages affected
- Streptococcal pharyngitis most common among school-age children (5 to 15 yr of age). GAS are responsible for 5% to 15% of cases of pharyngitis in adults and 20% to 30% of cases in children (5 to 15 yr of age).

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Pharynx:
  1. May appear normal to severely erythematous (Fig. E1)
  2. Tonsillar hypertrophy and exudates commonly seen but do not indicate etiology
- Viral infection:
  1. Rhinorrhea
  2. Conjunctivitis
  3. Cough
- Bacterial infection, especially GAS:
  1. High fever
  2. Systemic signs of infection
- Herpes simplex or enterovirus infection: Vesicles
- Streptococcal infection:
  1. Rare complications:
     a. Scarlet fever
     b. Rheumatic fever
     c. Acute glomerulonephritis
  2. Extension of infection (Fig. E2): Tonsillar, parapharyngeal, or retropharyngeal abscess presenting with severe pain, high fever, trismus
- Streptococcal tonsillitis is manifested as acute onset of fever, headache, neck pain, odynophagia, sore throat, otalgia, red tongue with enlargement of papillae, sore throat, red swollen uvula, and tender anterior cervical adenitis.
- Peritonsillar abscess (accumulation of pus between the tonsil and its capsule) is the most common complication of acute tonsillitis. Clinical signs include deformed posterior pharynx, medial displacement of the uvula, trismus, and muffled voice (hot-potato voice).
- Lingual tonsillitis is a rarely diagnosed cause of pharyngitis that predominantly occurs in patients who have had palatine tonsils removed. The lingual tonsils are located below the inferior pole of the palatine tonsils and anterior to the vallecula at the base of the tongue. The lymphoid tissue may enlarge after tonsillectomy and repeated infections. Patients have a sore throat that worsens with movement of the tongue. Physical findings often include a normal-appearing pharynx and hyperemia. Lateral soft tissue neck films reveal a normal-appearing epiglottis and a scalloped appearance of the lingual tonsil (Fig. E3).
- Table 1 describes seven danger signs in patients with sore throat.

ETIOLOGY

- Viruses:
  1. Respiratory syncytial virus
  2. Influenza A and B
  3. Epstein-Barr virus
  4. Adenovirus
  5. Herpes simplex
- Bacteria:
  1. GAS: *Streptococcus pyogenes*. β-Hemolytic GAS are the most common cause of acute tonsillitis.
  2. *Neisseria gonorrhoeae*
  3. *Fusobacterium necrophorum* (10% of pharyngitis): Highest incidence in patients aged 15 to 30 yr
- Other organisms:
  1. *Mycoplasma pneumoniae*
  2. *Chlamydophila pneumoniae*
  3. *Arcanobacterium haemolyticum*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Sore throat associated with granulocytopenia, thyroiditis
- Tonsillar hypertrophy associated with lymphoma

TABLE 1 Seven Danger Signs in Patients with Sore Throat

1. Persistence of symptoms longer than 1 wk without improvement
2. Respiratory difficulty, particularly stridor
3. Difficulty in handling secretions
4. Difficulty in swallowing
5. Severe pain in the absence of erythema
6. A palpable mass
7. Blood, even in small amounts, in the pharynx or ear

From Andreoli TE et al: *Andreoli and Carpenter's Cecil essentials of medicine,* ed 8, Philadelphia, 2010, WB Saunders.

- Section II describes the differential diagnosis of sore throat

WORKUP

The Centor criteria (Boxes 1 and 2) to identify patients at risk for GAS consists of (1) fever subjective or measured >38.1° C (100.5° F), (2) absence of cough, (3) tonsillar exudates, (4) tender anterior cervical lymphadenopathy. Patients with ≤1 criteria are at low risk and do not need additional testing. The McIsaac criteria adds one point for ages 3 to 14 and subtracts one point for ages ≥45 yr.

- Rapid streptococcal antigen test (culture should be performed if rapid test negative)
- Throat swab for culture to exclude *S. pyogenes, N. gonorrhoeae* (requires specific transport medium) in selected cases

LABORATORY TESTS

- Bloodwork is only rarely necessary
- Complete blood count with differential
  1. May help support diagnosis of bacterial infection when diagnosis is unclear
  2. Streptococcal infection suggested by leukocytosis >15,000/mm^3
- Viral cultures, serologic studies rarely needed
- Monospot if diagnosis is unclear

IMAGING STUDIES

Seldom indicated. If necessary to distinguish between tonsillitis and peritonsillar abscess, CT or MRI of the neck can be done.

BOX 1 Centor Criteria for Determining Group A Beta-Hemolytic Streptococcal Pharyngitis

- Tonsillar exudates
- Tender anterior lymphadenopathy or lymphadenitis
- Absence of cough
- History of fever

From Marx JA et al: *Rosen's emergency medicine*, ed 8, Philadelphia, 2014, Elsevier.

BOX 2 Centor Criteria Scoring for Determining Testing and Treatment for Group A Beta-Hemolytic Streptococcal Pharyngitis

Centor Score	Testing and Treatment
0-1	None
2-3	Treatment based on results of rapid streptococcal test results
4	Treat without testing

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Fluids
- Saltwater gargles

ACUTE GENERAL Rx

- Analgesics: Aspirin (adults) or acetaminophen or ibuprofen (adults and children). Clinical trials have shown that corticosteroids can hasten pain relief in patients with sore throat. Single dose oral dexamethasone (10 mg in adults, 0.6 ms/kg for children) was the most common intervention and resulted in pain resolution approximately 11 hours sooner than placebo.[1] Prescribing corticosteroids in all cases of sore throat is not indicated and should be considered only in cases of severe sore throat.
- If streptococcal infection proven or suspected:
  1. Amoxicillin 500 mg bid or penicillin V 500 mg PO bid for 10 days or benzathine penicillin 1.2 million U IM once (adults). Children: Penicillin V 250 mg bid or tid
  2. Azithromycin 500 mg on day 1, then 250 mg on days 2 through 5 or erythromycin 500 mg PO bid or 250 mg qid for 10 days if penicillin allergic
- If gonococcal infection proven or suspected: ceftriaxone 250 mg IM once.
- Treatment of peritonsillar abscess is drainage through needle or incision.
- Avoid quinolones, sulfonamides, and tetracyclines due to treatment failures.

CHRONIC Rx

- Recurrent streptococcal infections are common and may represent reinfection from other household members, including pets.
- There is no conclusive evidence from randomized clinical trials that tonsillectomy is superior to antibiotic therapy for recurrent tonsillitis in adults.
- Tonsillopharyngitis is generally managed in an outpatient setting with follow-up arranged in 1 to 2 wk. Admission to the hospital is indicated for local suppurative complications (peritonsillar abscess; lateral pharyngeal or posterior pharyngeal abscess; impending airway closure; or inability to swallow food, medications, or water).

REFERRAL

- To otolaryngologist:
  1. If peritonsillar or other abscess is suspected
  2. If tonsillar hypertrophy persists

BASIC INFORMATION

DEFINITION

Pheochromocytomas are catecholamine-producing tumors that originate from the chromaffin cells of the adrenergic system. While they generally secrete both norepinephrine and epinephrine, norepinephrine is usually the predominant amine.

SYNONYM

Paraganglioma

ICD-10CM CODES

C74.9 Malignant neoplasm of adrenal gland, unspecified
C75.9 Malignant neoplasm of endocrine gland, unspecified
E27.5 Adrenomedullary hyperfunction

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence: 0.05% of population; peak incidence in 30s and 40s.
- Approximately 25% of patients with apparently sporadic pheochromocytoma may be carriers of mutations.
- Approximately 25% of pheochromocytomas are familial and associated with genetic disorders (Table 1). Pheochromocytoma is a feature of two disorders with an autosomal-dominant pattern of inheritance:
  1. Multiple endocrine neoplasia (MEN) type 2
  2. von Hippel-Lindau disease: Angioma of the retina, hemangioblastoma of the central nervous system, renal cell carcinoma, pancreatic cysts, and epididymal cystoadenoma
- Pheochromocytomas occur in 5% of patients with neurofibromatosis type 1.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Hypertension: Can be sustained (55%) or paroxysmal (45%).
- Headache (80%): Usually paroxysmal in nature and described as "pounding" and severe.
- Palpitations (70%): Can be present with or without tachycardia.
- Hyperhidrosis (60%): Most evident during paroxysmal attacks of hypertension.
- Physical examination may be entirely normal if done in a symptom-free interval; during a paroxysm the patient may demonstrate marked increase in both systolic and diastolic pressure, profuse sweating, visual disturbances (caused by hypertensive retinopathy), dilated pupils (from catecholamine excess), paresthesias in the lower extremities (caused by severe vasoconstriction), tremor, and tachycardia.
- Orthostatic hypotension is common among patients with pheochromocytoma due to reduction of blood volume and desensitization of adrenergic receptors by the chronic excess of catecholamines.
- Table E2 summarizes features suggestive of pheochromocytoma.

ETIOLOGY

- Catecholamine-producing tumors that are usually located in the adrenal medulla.
- Specific mutations of the RET protooncogene cause familial predisposition to pheochromocytoma in MEN 2.
- Mutations in the von Hippel-Lindau tumor suppressor gene (VHL gene) cause familial disposition to pheochromocytoma in von Hippel-Lindau disease.
- Recently identified genes for succinate dehydrogenase subunit D *(SDHD)* and succinate dehydrogenase subunit B *(SDHB)* predispose carriers to pheochromocytoma and globus tumors.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Anxiety disorder
- Thyrotoxicosis
- Amphetamine or cocaine abuse
- Carcinoid
- Essential hypertension

WORKUP

Laboratory evaluation and imaging studies to locate the neoplasm (Fig. 1). Anatomic and functional imaging studies that can be used to localize pheochromocytomas are summarized in Table E3. Misdiagnosis of pheochromocytoma is common. Correct interpretation of biochemical tests and imaging is crucial to a correct diagnosis.

LABORATORY TESTS

- Although there is no consensus on the best test, plasma-free metanephrines have been suggested as the test of first choice for excluding the tumor. Elevated plasma concentrations of normetanephrine or metanephrine have a sensitivity of up to 100%, but the specificity is markedly lower (85%).
- 24-hr urine collection will also show increased metanephrines (90% sensitivity, 95% specificity); the accuracy of the 24-hr urinary levels for metanephrines can be improved by indexing urinary metanephrine levels by urine creatinine levels.

IMAGING STUDIES

- Abdominal CT scan (Fig. E2) with and without contrast (88% sensitivity) is useful in locating pheochromocytomas >0.5 inch in diameter (90% to 95% accurate).

TABLE 1 Autosomal Dominant Syndromes Associated with Pheochromocytoma and Paraganglioma

Syndrome	Gene	Gene Locus	Protein Product	Protein Function	Gene Mechanism	Typical Tumor Location
SDHD (familial paraganglioma type 1)*	*SDHD*	11q23	SDH D subunit	ATP production	Tumor suppressor	Skull base and neck; occasionally adrenal medulla, mediastinum, abdomen, pelvis
Familial paraganglioma type 2*	*SDHAF2*	11q13.1	Flavination cofactor	ATP production	Tumor suppressor	Skull base and neck; occasionally abdomen and pelvis
SDHC (familial paraganglioma type 3)	*SDHC*	1q21	SDH C subunit	ATP production	Tumor suppressor	Skull base and neck
SDHB (familial paraganglioma type 4)	*SDHB*	1p36.1-35	SDH B subunit	ATP production	Tumor suppressor	Abdomen, pelvis and mediastinum; rarely adrenal medulla, skull base, and neck
MEN1	*MEN1*	11q13	Menin	Transcription regulation	Tumor suppressor	Adrenal medulla
MEN2A and MEN2B	*RET*	10q11.2	RET	Tyrosine kinase receptor	Protooncogene	Adrenal medulla, bilaterally
Neurofibromatosis type 1	*NF1*	17q11.2	Neurofibromin	GTP hydrolysis	Tumor suppressor	Adrenal-periadrenal
von Hippel-Lindau disease	*VHL*	3p25-26	VHL	Transcription elongation suppression	Tumor suppressor	Adrenal medulla, bilaterally; occasionally paraganglioma
Familial pheochromocytoma	*FP/TMEM127*	2q11	Transmembrane protein	Regulation of the mTORC1 signaling complex	Tumor suppressor	Adrenal medulla

*Associated with maternal imprinting.
ATP, Adenosine triphosphate; *GTP,* guanosine triphosphate; *MEN,* multiple endocrine neoplasia; *mTORC1,* mammalian target of rapamycin complex 1; *RET,* "rearranged during transfection" protooncogene; *SDH,* succinate dehydrogenase; *VHL*, von Hippel–Lindau disease.
From Melmed S: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders, Elsevier.

- MRI with contrast: Pheochromocytomas demonstrate a distinctive MRI appearance (up to 100% sensitivity); MRI may become the diagnostic imaging modality of choice.
- Scintigraphy with 131 or 1-123 I-MIBG (up to 100% sensitivity) (Fig. E2): This norepinephrine analog localizes in adrenergic tissue; it is particularly useful in locating extraadrenal pheochromocytomas.
- 6-[18F]Fluorodopamine positron emission tomography is reserved for cases in which clinical symptoms and signs suggest pheochromocytoma, and results of biochemical tests are positive but conventional imaging studies cannot locate the tumor. It is also used for identification of metastatic disease.

Rx TREATMENT

GENERAL Rx

Laparoscopic adrenalectomy (surgical resection for both benign and malignant disease):

- Preoperative stabilization with combination of alpha-adrenergic blocking agents (phenoxybenzamine, prazosin, doxazosin, or terazosin), beta-blocker, and liberal fluid and salt intake starting 10 to 14 days before surgery. Beta-blockers should be avoided until patients receive adequate alpha-adrenergic blockade for several days to avoid hypertensive crisis due to unopposed alpha stimulation. Amlodipine or verapamil can be added to beta-blockers if blood pressure control is still inadequate. Table E4 describes orally administered drugs to treat pheochromocytoma.
- Hypertensive crisis preoperatively and intraoperatively can be controlled with nitroprusside. Table E5 summarizes intravenously administered drugs used to treat pheochromocytoma.

PEARLS & CONSIDERATIONS

COMMENTS

- Obtaining a detailed family history is important because 25% of pheochromocytomas are familial.
- Screening for pheochromocytoma should be considered in patients with any of the following:
  1. Malignant hypertension
  2. Poor response to antihypertensive therapy
  3. Paradoxical hypertensive response
  4. Hypertension during induction of anesthesia, parturition, surgery, or thyrotropin-releasing hormone testing
  5. Hypertension associated with imipramine or desipramine
  6. Neurofibromatosis (increased incidence of pheochromocytoma)
- All patients with pheochromocytoma should be screened for MEN-2 and von Hippel-Lindau disease with the pentagastrin test, serum parathyroid hormone, ophthalmoscopy, MRI of the brain, CT scan of the kidneys and pancreas, and ultrasonography of the testes.
- In patients with pheochromocytoma, routine analysis for mutations of *RET, VHL, SDHD,* and *SDHB* is indicated to identify pheochromocytoma-associated syndromes.

TABLE E2 Features Suggestive of Pheochromocytoma

Hypertension, Persistent or Paroxysmal

Markedly variable blood pressures (± orthostatic hypotension)
Sudden paroxysms (± subsequent hypertension) in relation to:
- Stress: Anesthesia, angiography, parturition
- Pharmacologic provocation: Histamine, nicotine, caffeine, beta blockers, glucocorticoids, tricyclic antidepressants
- Manipulation of tumors: Abdominal palpation, urination

Rare patients persistently normotensive
Unusual settings
Childhood, pregnancy, familial
Multiple endocrine adenomas: Medullary carcinoma of the thyroid (MEN-2), mucosal neuromas (MEN-2B)
von Hippel-Lindau disease
Neurocutaneous lesions: Neurofibromatosis

Associated Symptoms

Sudden spells with headache, sweating, palpitations, nervousness, nausea, vomiting
Pain in chest or abdomen

Associated Signs

Sweating, tachycardia, arrhythmia, pallor, weight loss

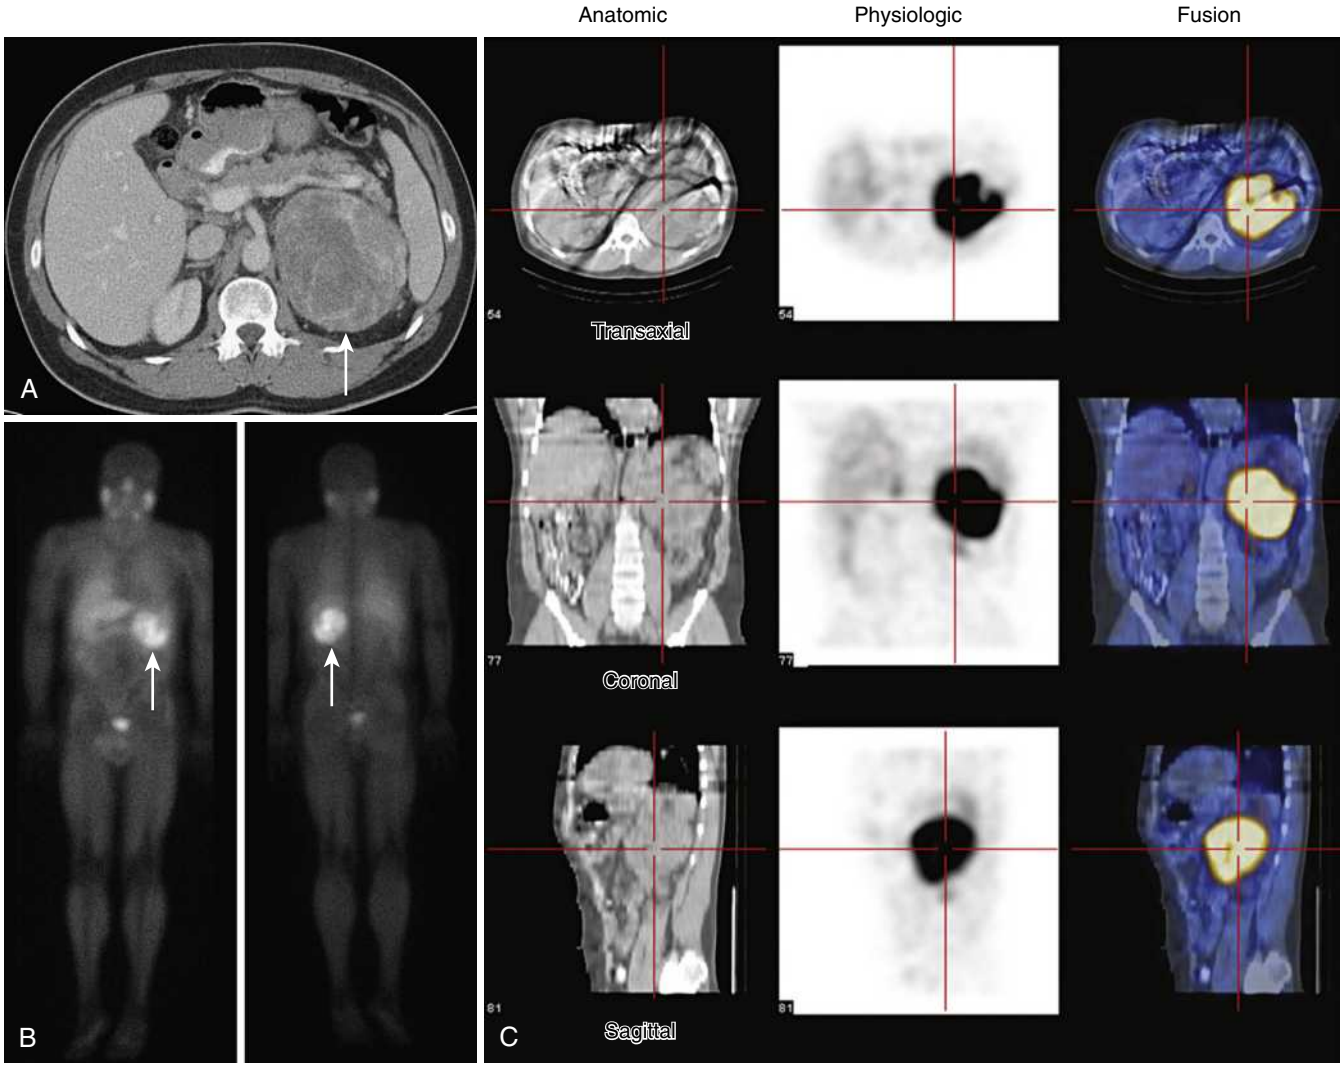

FIG. E2 Computed tomography (CT) and ^{123}I-metaiodobenzylguanidine (^{123}I-MIBG) imaging of a 44-yr-old man. He presented with a 9-yr history of hypertension and recent onset of head throbbing, chest pressure, and abdominal pain. The 24-hour urine studies were abnormal: Norepinephrine, 900 μg (normal, <170); epinephrine, 28 μg (normal, <35); dopamine, 468 μg (normal, <700); and total metanephrines, 17,958 μg (normal, <1000). **A,** Axial CT image with contrast shows a large, partially vascular, and partially necrotic left adrenal tumor *(arrow).* **B,** ^{123}I-MIBG whole-body scan shows a large focus of increased radiotracer uptake in the left upper abdomen *(arrow)* that corresponds to the mass seen on the CT image; no other abnormal uptake is seen. **C,** ^{123}I-MIBG and single-photon emission computed tomography (SPECT) fusion CT images correlate the images seen on CT (anatomic) with those seen on ^{123}I-MIBG (physiologic) in the axial, coronal, and sagittal planes. After α- and β-adrenergic blockade, a 13.5-cm × 12-cm × 9-cm, 680-g pheochromocytoma was removed. (From Melmed S: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders, Elsevier.)

TABLE E4 Orally Administered Drugs Used to Treat Pheochromocytoma

Drug	Initial Dosage, mg/day* (Maximum)	Side Effects
α-Adrenergic Blocking Agents		
Phenoxybenzamine	10† (100)†	Postural hypotension, tachycardia, meiosis, nasal congestion, diarrhea, inhibition of ejaculation, fatigue
Prazosin	1 (20)‡	First-dose effect, dizziness, drowsiness, headache, fatigue, palpitations, nausea
Terazosin	1 (20)†	First-dose effect, asthenia, blurred vision, dizziness, nasal congestion, nausea, peripheral edema, palpitations, somnolence
Doxazosin	1 (20)	First-dose effect, orthostasis, peripheral edema, fatigue, somnolence
Combined α- and β-Adrenergic Blocking Agent		
Labetalol	200† (1200)†	Dizziness, fatigue, nausea, nasal congestion, impotence
Calcium Channel Blocker		
Nicardipine sustained-release	30† (120)†	Edema, dizziness, headache, flushing, nausea, dyspepsia
Catecholamine Synthesis Inhibitor		
α-Methyl-ϱ-l tyrosine (metyrosine)	1000‡ (4000)‡	Sedation, diarrhea, anxiety, nightmares, crystalluria, galactorrhea, extrapyramidal symptoms

*Given once daily unless otherwise indicated.
†Given in two doses daily.
‡Given in three or four doses daily.
From Melmed S: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders, Elsevier.

TABLE E5 Intravenously Administered Drugs Used to Treat Pheochromocytoma

Agent	Dosage Range
For Hypertension	
Phentolamine	Administer a 1-mg IV test dose, then 2- to 5-mg IV boluses as needed or continuous infusion.
Nitroprusside	IV infusion rates of 2 μg/kg of body weight per min are suggested as safe. Rates >4 μg/kg per min may lead to cyanide toxicity within 3 hr. Doses >10 μg/kg per min are rarely required, and the maximal dose should not exceed 800 μg/min.
Nicardipine	Initiate therapy at 5.0 mg/hr; the IV infusion rate may be increased by 2.5 mg/hr q15 min up to a maximum of 15.0 mg/hr.
For Cardiac Arrhythmia	
Lidocaine	Initiate therapy with an IV bolus of 1-1.5 mg/kg (75-100 mg); additional boluses of 0.5-0.75 mg/kg (25-50 mg) can be given q5-10 min if needed up to a maximum of 3 mg/kg. Loading is followed by maintenance IV infusion of 2-4 mg/min (30-50 μg/kg per min) adjusted for effect and settings of altered metabolism (e.g., heart failure, liver congestion) and as guided by blood level monitoring.
Esmolol	An initial IV loading dose of 0.5 mg/kg is infused over 1 min, followed by a maintenance infusion of 0.05 mg/kg per min for the next 4 min. Depending on the desired ventricular response, the maintenance infusion may then be continued at 0.05 mg/kg per min or increased stepwise (e.g., by 0.1 mg/kg per min increments to a maximum of 0.2 mg/kg per min), with each step being maintained for ≥4 min.

IV, Intravenous.
From Melmed S: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders, Elsevier.

Phobias PTG ALG

BASIC INFORMATION

DEFINITION

Specific phobias are anxiety disorders characterized by an excessive, persistent fear elicited by a specific object or situation that is then avoided or tolerated with intense distress. The provoking stimulus may be a specific object, such as an animal or insect; natural environments, such as heights or water; or a specific situation, such as the sight of blood, the receipt of an injection, or being in a tunnel or on a bridge. Social anxiety disorder (formerly named social phobia) is a specific, separately diagnosed disorder characterized by a fear of being embarrassed, humiliated, or rejected in social or performance situations. Agoraphobia also is a separately diagnosed disorder, characterized by an intense anxiety about being in a place or situation from which they would not be able to escape in the event of a panic attack or panic-like symptoms. Such situations include being in enclosed/crowded spaces or being more than a certain distance from home while alone. If agoraphobia is present in individuals with panic disorder, both diagnoses are given.

SYNONYMS

Simple phobia (obsolete name for specific phobia)

Phobias named for the provoking stimulus, such as arachnophobia (fear of spiders) and acrophobia (fear of heights)

Specific phobias:
ICD-10CM CODES
F40.1 Social phobias
F40.2 Specific phobias
F40.8 Other phobic anxiety disorders
F40.9 Phobic anxiety disorder, unspecified
DSM-5 CODE
300.23 Social phobias
300.29 Other isolated specific phobias
Agoraphobia:
ICD-10CM CODES
F40.00 Agoraphobia, unspecified
DSM-5 CODE
300.22 Agoraphobia

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: The majority of cases of specific phobia tend to onset prior to age 10; median onset is from ages 7 to 10.

PREVALENCE (IN U.S.):

- Specific phobias are prevalent in 7% to 9% of the general population (12-mo prevalence rate); cross-national prevalence rates are 7.4% (lifetime) and 5.5% (12-mo).
- Agoraphobia is prevalent in approximately 1.7% of the general population per yr.

PREDOMINANT SEX AND AGE:

- Females with specific phobias outnumber males 2:1, though rates vary by phobia.
- Agoraphobia is more prevalent in women than men (2:1).
- Most specific phobias have childhood onset (median onset = 8 yr), although it is possible for them to develop at any age.
- Specific phobia often precedes the onset of other mental disorders.
- Situational phobias tend to have a later age of onset compared to natural environment, animal, or blood-injection phobias.
- Onset of agoraphobia typically occurs in late adolescence or early adulthood; two thirds of cases onset prior to age 35.

GENETICS: Specific phobia is more common in first-degree relatives.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- When approaching the phobic stimulus, the experience of extreme anxiety is often accompanied by autonomic symptoms such as tachycardia, tremor, and diaphoresis; depersonalization may occur. In blood or injection phobias, symptoms are often followed by a parasympathetic response that can cause vasovagal syncope.
- Specific phobias frequently occur with other anxiety disorders.

ETIOLOGY

There is no clear etiology and likely is a combination of factors including temperamental (e.g., behavioral inhibition, neuroticism), environmental (e.g., negative encounters with the feared stimulus, parental overprotection), and genetic.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Social anxiety disorder is distinguished from specific phobias in that what is feared is humiliation or embarrassment in social interaction or performance situations rather than fear of a specific object or environment.
- Panic attacks (with or without agoraphobia): Anxiety symptoms seen in specific phobia may resemble symptoms of panic attacks, but the stimulus in the specific or social situation is clear, whereas panic attacks do not have a clearly associated provoking stimulus (i.e., they occur unexpectedly in the absence of a trigger).
- Posttraumatic stress disorder (PTSD): Anxiety and physiologic arousal associated with specific cues from the traumatic event defining the PTSD may resemble the symptoms induced by a phobia.
- Psychotic disorders can present with a fear of being in public that arises from delusions.

WORKUP

- History: Usually diagnostic. This should include information about other medical disorders, medications, any history of past trauma, and substance abuse. Fig. E1 describes a diagnostic decision tree for specific phobias.
- Physical examination: To confirm absence of cardiovascular abnormalities such as arrhythmias or evidence of endocrinologic reasons for hyperarousal such as an enlarged or tender thyroid gland.

LABORATORY TESTS

No specific laboratory tests are indicated.

IMAGING STUDIES

No specific imaging studies are recommended.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Cognitive-behavioral therapy (CBT) and exposure-based treatments have been effective for treating specific phobia in controlled trials and are considered an appropriate first-line treatment.
- Behavioral treatments sometimes involve relaxation training, often paired with visualization and progressive desensitization.
- Success rates in treating specific phobias are higher when the phobia is not complicated by other anxiety disorders.

ACUTE GENERAL Rx

Although benzodiazepines provide rapid relief of anxiety associated with exposure to provoking stimuli, they are associated with adverse effects including somnolence, accidents, abuse, and dependence, and thus are not recommended as a first-line treatment.

CHRONIC Rx

If the phobic stimulus is rarely encountered, benzodiazepines used on an as-needed basis can be an appropriate long-term treatment; however, there is a risk of abuse and dependence that makes them a less desirable choice for long-term treatment.

COMPLEMENTARY & ALTERNATIVE MEDICINE

No definitive evidence supports complementary or alternative medicines in the treatment of phobic disorders.

DISPOSITION

Phobic disorders are generally present for life, although outpatient-based treatment may effectively reduce symptoms.

REFERRAL

Recommended for confirmation of diagnosis and for evaluation for psychotherapy and other treatment modalities.

Pilonidal Disease PTG

BASIC INFORMATION

DEFINITION

From the Latin words *pilus,* meaning "hair," and *nidus,* meaning "nest."

A *pilonidal sinus* is a short tract extending from the skin surface that contains hair and skin debris. It is most commonly found in the intergluteal fold sacrococcygeal region, but it can also occur in the interdigital area, umbilicus, chest wall, and scalp. An *acute pilonidal abscess* consists of pus and a wall of edematous fat. A chronic *pilonidal cyst* develops from a chronic abscess of long duration as a thin and flat lining of epithelium grows into the cavity from the skin surface.

SYNONYMS

Jeep disease: During World War II, many soldiers developed pilonidal cysts thought to be caused by hours of riding on Jeeps
Pilonidal sinus
Pilonidal cyst

ICD-10CM CODES

L05	Pilonidal cyst
L05.0	Pilonidal cyst with abscess
L05.9	Pilonidal cysts without abscess

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 26 cases per 100,000 persons
PREDOMINANT SEX: Males are more commonly affected than females (2.2:1).
AVERAGE AGE OF PRESENTATION: 21 yr
RISK FACTORS:

- Male sex
- Local trauma or irritation
- Family predisposition
- Obesity
- Sedentary lifestyle
- Occupation requiring prolonged sitting or excessive exposure to hair (barbers)
- Local hirsutism
- Poor hygiene
- Increased sweat activity

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Asymptomatic pits or pores in the natal cleft (Fig. E1)
- Tenderness after physical activity or prolonged sitting
- Acute pilonidal abscess presents as a hot, tender, fluctuant swelling just lateral to the midline over the sacrum that may exude pus through the midline pit
- Acute pilonidal abscess in 20% of patients with pilonidal disease
- Chronic pilonidal may have recurrent pain and drainage
- Chronic pilonidal abscess in 80% of patients with pilonidal disease
- Infrequently, systemic reaction: Occasionally fever, leukocytosis, and malaise

ETIOLOGY

- Currently believed to be acquired rather than congenital.
- Drilling of hair shed from the perineum or the head into sebaceous or hair follicles in the natal cleft.
- Drilling is facilitated by the friction of the natal cleft.
- Subsequent infection by skin organisms leads to pilonidal abscess.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Perianal abscess arising from the posterior midline crypt
- Hidradenitis suppurativa
- Skin abscess: Furuncle or carbuncle
- Folliculitis
- Anorectal fistula
- Anal complication of Crohn disease
- Case report of squamous cell carcinoma arising from neglected chronic pilonidal sinuses

WORKUP

- Diagnosis is based on history and physical examination.
- Midline pits present behind the anus overlying the sacrum and coccyx.
- Broken hairs are often seen extruding from the midline pits.
- Insert probe in pilonidal sinus in path away from the anus.
- Complicated anal fistula may be angulating posteriorly before passing into a retrorectal abscess, but thorough examination of the anal cavity usually discloses point of origin.

TREATMENT

NONPHARMACOLOGIC THERAPY

Prevention of exacerbations:

- Local hygiene
- Avoidance of prolonged sitting position
- Weight reduction
- Early in the infection, sitz baths may decrease pain and decrease the chance that a cyst may develop into an abscess
- Treatment of an asymptomatic sinus is not indicated

Treatment of acute abscess:

- Procedure of choice for first-episode acute abscess: Simple incision and drainage in an outpatient setting. Box E1 describes surgical options for the treatment of pilonidal sinus.
- Cure rate of about 50% within 5 wk; recurrence rate 20% to 55%.
- Antibiotics: Generally not indicated, except for the treatment of cellulitis or in patients with immunosuppression, high risk of endocarditis, methicillin-resistant Staphylococcus aureus (MRSA), or underlying systemic disease.
- First-generation cephalosporin plus metronidazole is the antibiotic regimen of choice.

TREATMENT OF CHRONIC OR RECURRENT DISEASE

Elective treatment of pilonidal disease:

- Minimal surgery:
  1. Remove hair from midline pits and shave buttocks.
  2. May use a fine wire brush with local anesthesia to clear the pits and any lateral openings of granulation tissue and hair (Fig. E2).
  3. Keep area clean.
- Fistulotomy and curettage:
  1. Used when minimal surgery does not control episodes of suppuration.
  2. Pass probe to outline the pilonidal sinus and open tract surgically.
  3. Curette granulation tissue at the base of the sinus and excise edges of the skin.
  4. Keep open granulating wound meticulously clean and allow to heal.
  5. If complete healing does not take place, use a skin graft or advancement flap to close the defect.
- Marsupialization:
  1. This is the treatment of choice for chronic pilonidal disease.
  2. Wide excision of the pilonidal area is performed, including all affected skin and subcutaneous tissues down to the presacral fascia.
  3. Wound is left open, allowed to marsupialize, or closed as a primary procedure.
  4. Give antibiotics for 24 hr (particularly those directed against *Staphylococcus* and *Bacteroides* species).
- Other procedures:
  1. Excision and primary closure or closure with skin grafts or flaps: Z-plasty, V-Y advancement flap, rhomboid flap, gluteus maximus myocutaneous flap
  2. Bascom procedure (follicle removal and lateral drainage)
  3. Recurrence rate for excision (most definitive procedure): 1% to 6%
  4. Incidence of squamous cell carcinoma in a chronic, recurrent pilonidal sinus is rare (<1%)

REFERRAL

- Emergency department for incision and drainage for an acute abscess
- General surgeon for elective treatment or management of chronic or recurrent disease

PEARLS & CONSIDERATIONS

COMMENTS

Because of significant associated morbidity, the elective surgical procedures outlined are performed only after the potential risks versus benefits are carefully weighed by a general or colorectal surgeon.

Pilonidal Cyst (Patient Information)

AUTHOR: **Maria E. Soler, MD, MPH, MBA**

FIG. E1 Midline pits in the gluteal cleft represent a classic finding of pilonidal disease. (From Cameron JL, Cameron AM: *Current surgical therapy*, ed 19, Philadelphia, 2011, Saunders.)

BOX E1 Surgical Options for the Treatment of Pilonidal Sinus

Midline Approach
Sinus excision: open vs. marsupialization vs. closure

Unroofing and Curettage
- Asymmetric or oblique excision
- Karydakis procedure
- Bascom: open vs. closure
- Cleft
- Flaps
  1. Rhomboid
  2. V-Y advancement
  3. Z-plasty
  4. Gluteal myocutaneous

Others
- Phenolization
- Vacuum-assisted closure

From Cameron JL, Cameron AM: *Current surgical therapy,* ed 10, Philadelphia, 2011, Saunders.

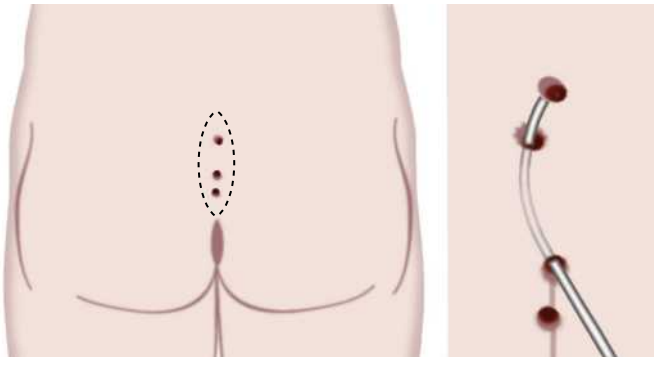

FIG. E2 Pilonidal disease. On examination, there may be multiple pits or external openings in the intergluteal cleft proximal to the anus **(A).** The openings often communicate with each other **(B).** A probe can be passed between the communicating network of tracts. Trapped loose hair is usually found in these tracts. One successful treatment option is to unroof all the tracts. (From Feldman M et al [eds]: *Sleisenger and Fordtran's gastrointestinal and liver disease*, ed 10, Philadelphia, 2016, Saunders.)

BASIC INFORMATION

DEFINITION

Pinworms are a noninvasive infestation of the intestinal tract by *Enterobius vermicularis,* a helminth of the nematode family. It is a small (1 cm in length), white, thread-like roundworm that typically inhabits the cecum, appendix, and adjacent areas of the ileum and ascending colon.

SYNONYMS

Enterobiasis
Oxyuriasis

ICD-10CM CODE
B80 Enterobiasis

EPIDEMIOLOGY & DEMOGRAPHICS

- Most common intestinal nematode; approximately 30,000 cases annually in the U.S.
- Worldwide distribution, but most common in temperate climates.
- The prevalence of pinworm infection is lowest in infants and reaches highest infection rate in school-age children (ages 5 to 14 yr).
- Eggs are infective within 6 hr of oviposition and may remain so for 20 days.
- Clusters are found in families, institutionalized persons, and homosexual men.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Most infested persons are asymptomatic.
- Perianal itching is the most common reported symptom, with scratching leading to excoriation and sometimes secondary infection.
- The vagina may become infested with pinworms.
- Rarely insomnia, irritability, anorexia, and weight loss are described.
- Granulomas have been described in various organs resulting from worms wandering outside the intestines and dying there.

ETIOLOGY & PATHOGENESIS

- *E. vermicularis* is highly prevalent throughout the world, particularly in countries of the temperate zone. Human beings are the only host for this worm. Infestation is by fecal-oral route; ingested eggs hatch in the stomach and the larvae migrate to the colon, where they mature. Gravid female worms containing an average of 10,000 ova migrate to the perianal skin at night, lay their eggs there, and die. The eggs embryonate within 6 hr and cause itching; scratching causes egg deposition under fingernails, from which they can contaminate food or lead to autoreinfection. Ova may also be airborne and collect in dust that may be on the floor or on furniture.
- *E. vermicularis* may be transmitted between sexual partners, especially those engaging in oral-anal sex.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Perianal itching related to poor hygiene. Section II describes the causes of pruritus ani.
- Hemorrhoidal disease and anal fissures
- Perineal yeast/fungal infections

WORKUP

Identification of adult worms or eggs. *E. vermicularis* ova are ovoid but flattened on one side and measure approximately 56 × 27 micrometers (Fig. 1). The eggs can be identified on transparent tape (Fig. 2) placed on the perianal skin on awakening. (NOTE: Five consecutive negative tests rule out the diagnosis.) A single examination detects 50% of infections, three examinations detect 90%, and five examinations detect 99%.

TREATMENT

- Single dose of mebendazole (100 mg) with a repeat dose given after 2 wk results in cure rates of 90% to 100%.
- Single dose of albendazole (400 mg) with a second dose given 2 wk later is also highly effective.
- Pyrantel pamoate (11 mg/kg up to 1 g) can prevent against *E. vermicularis.* It is available as a suspension and has minimal toxicity (mild transient gastrointestinal symptoms, headache, drowsiness). A repeat dose after 2 wk is recommended because of the frequency of reinfection and autoinfection.
- Other infected family members, classmates, or residents of long-term care facilities should be treated at the same time as the index case.

FIG. 1 Adult male pinworm, *Enterobius vermicularis,* with curved posterior end; note prominent esophageal bulb (4x). (From McPherson RA, Pincus MR: *Henry's clinical diagnosis and management by laboratory methods,* ed 23, Philadelphia, 2017, Elsevier.)

FIG. 2 Numerous eggs of *Enterobius vermicularis* as seen on a cellophane tape preparation (400x). (From McPherson RA, Pincus MR: *Henry's clinical diagnosis and management by laboratory methods,* ed 23, Philadelphia, 2017, Elsevier.)

PEARLS & CONSIDERATIONS

- Eosinophilia is not observed in most cases because tissue invasion does not occur.
- Good hand hygiene is the most effective method of prevention.
- Frequent changing of underclothes, bed clothes, and bed sheets is helpful to decrease risk of autoinfection.
- Personal hygiene and cleanliness are crucial. Fingernails should be cut short and scrubbed frequently.

RELATED CONTENT

Pinworms (Patient Information)

AUTHOR: **Fred F. Ferri, MD**

BASIC INFORMATION

DEFINITION

Piriformis syndrome is a form of low back pain caused by impingement of the sciatic nerve by prolonged or excessive contraction of the piriformis muscle and causing buttock pain, sciatica, or both. The pain is also present in the hip, groin, buttock, coccyx, and distal part of the lower extremity. Four main symptoms that constitute piriformis syndrome are:

1. Buttock pain
2. Pain aggravated on sitting
3. External tenderness near the greater sciatic notch
4. Pain with increased piriformis muscle tenderness

SYNONYMS

Deep gluteal syndrome
Pelvic outlet syndrome
Infrapiriform foramen syndrome
Wallet sciatica
Pocket sciatica

ICD-10CM CODE

S74.00 Injury of sciatic nerve at hip and thigh level

EPIDEMIOLOGY & DEMOGRAPHICS

- Women are affected more than men.
- Female-to-male incidence ratio is 6:1.
- It occurs in middle-aged patients (mean age of about 38).
- Incidence of piriformis syndrome has been estimated at 2.4 million/yr.
- About 0.3% to 6% of patients with sciatica have piriformis syndrome.

PHYSICAL FINDING & CLINICAL PRESENTATION

CLINICAL PRESENTATION: Patients with piriformis syndrome may present the following symptoms:

- Gluteal pain (97.9% of cases), which may:
  1. Be chronic
  2. Radiate to the distal part of the lower extremities
  3. Worsen with squatting or walking
- Rectal pain (worse during defecation)
- Hip movements (especially adduction and internal rotation) cause pain
- Labia majora or scrotal pain
- Dyspareunia in women
- Disturbances of potency in men
- Pain and discomfort on sitting (leading to the "wallet sign" in males who are unable to sit on their wallets without causing symptoms

PHYSICAL FINDINGS:

- Piriformis syndrome is a diagnosis of exclusion (after ruling out signs of lumbar radiculopathy via provocative tests).
- There are no neurologic deficits in patients with piriformis syndrome.
- There is tenderness over the gluteal area (the only sign that is predictive of the disease).
- Gluteal atrophy may be present.
- Sacroiliac tenderness.
- Shortening of the limb on the affected side.
- Other signs used in diagnosing piriformis syndrome include:
  1. *Lasègue sign*—Extension of the knee with the hip flexed to 90 degrees produces pain in the vicinity of the greater sciatic notch.
  2. *Pace sign*—Resisted abduction-external rotation of the thigh causes pain and weakness on the affected side.
  3. *Freiberg sign*—With the patient in the supine position, passive internal rotation of the extended thigh causes pain.
  4. Pain in the back when the patients lie down with the painful side up and involved leg flexed.

ETIOLOGY

- Trauma to the buttocks/gluteal region
- Spinal stenosis
- Anatomic variations of the division of the sciatic nerve
- As the sciatic nerve passes through the greater sciatic foramen, it is in close proximity to the piriformis muscle (Fig. E1). Pain results from compression of the sciatic nerve by the piriformis muscle
- Laminectomy
- Intragluteal injection
- Hypertrophy and spasm of the piriformis muscle
- Excessive exercise
- Leg length discrepancy (leading to altered biomechanics causing stretching and shortening of piriformis muscle)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Lumbosacral disk or spine injury (lumbar radiculopathy)
- Sacroiliac joint injury/inflammation (sacroiliitis)
- Hamstring injury
- Sciatic nerve entrapment
- Paraspinal muscle spasm
- Herniated intervertebral disk
- Unrecognized pelvic fracture
- Iliac vein thrombosis
- Postlaminectomy syndrome
- Undiagnosed nephrolithiasis
- Trochanteric bursitis

WORKUP

Usually involves imaging studies

- Computed tomography scan:
  1. Used to identify spinal stenosis
  2. May show a large mass anterior to the piriformis muscle
- Magnetic resonance imaging:
  1. May show an enlarged piriformis muscle on T1- or T2-weighted images
  2. Asymmetry in piriformis muscle size between symptomatic and asymptomatic sides (Fig. E2)
- Electromyogram (EMG):
  1. Normal EMG findings in the gluteus minimus, gluteus medius, and tensor fasciae latae muscles
  2. Abnormal EMG findings in the gluteus maximus and piriformis muscles

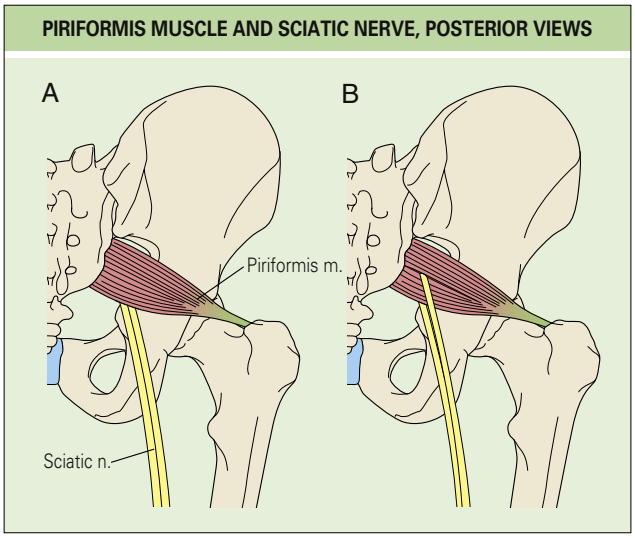

FIG. E1 Piriformis muscle and sciatic nerve, posterior views. The piriformis muscle arises from the anterior surface of the sacrum and the gluteal surface of the ilium and crosses the greater sciatic foramen to insert onto the superior border of the greater trochanter. **A,** In most instances, the sciatic nerve passes along the anterior surface of the piriformis muscle and exits the pelvis below the piriformis muscle, passing posteriorly along its inferior border. **B,** In some individuals, a portion of the sciatic nerve passes through the piriformis muscle. Other anatomic variants have been described. *m*, Muscle; *n*, nerve. (From Hochberg MC et al: *Rheumatology,* ed 5, St Louis, 2011, Mosby.)

TREATMENT

Sciatica due to piriformis syndrome is usually treated conservatively. Treatment modalities include physical therapy, lifestyle modalities, medications, and psychotherapy.

TREATMENT DURING ACUTE PHASE

- Stop offending activities
- Start physical therapy (PT) and occupational therapy treatment
- PT:
  1. The basic PT treatment is **stretching** and **manual therapy.**
  2. PT modalities are most beneficial when used in conjunction with stretching exercise.
  3. Ultrasound and/or moist heat is recommended before stretching.
  4. Massage of the lumbosacral and gluteal areas reduces muscle tightness and sciatic nerve irritation.
  5. Cold pack and/or electrical stimulation may be applied after exercise.
- Occupational therapy: Advise patients to:

1. Avoid sitting for prolonged periods.
   2. Make frequent stops when driving to get up and stretch.
- Surgical intervention: This is considered only when medical treatment fails and symptoms become intractable and/or disabling. Indications for surgical intervention include hematoma, abscess, neoplasm, compression of the nerve by gluteal vein varicosities. Response to surgical treatment is often disappointing. Promising results include:
  1. Piriformis tendon release (piriformis tenotomy)
  2. Sciatic neurolysis
- Other treatment modalities:
  1. Local injection of glucocorticoids or anesthetics into trigger points
  2. Botulinum toxin injection
  3. Nonsteroidal antiinflammatory drugs (NSAIDs)
  4. Consider brief course of opioids only in severe pain refractory to NSAIDs
  5. Transrectal massage

TREATMENT DURING RECOVERY PHASE

- Start gradual strengthening activities for the piriformis and gluteal muscles.
- Continue therapeutic modalities.
- Start light sport-specific activities and functional training if patient is asymptomatic.
- Some athletes may consider changing their footwear to avoid additional stress on the piriformis muscle.

TREATMENT DURING MAINTENANCE PHASE

- Continue performing a home exercise program for increasing flexibility and strength.
- Athletes may increase their training volume as tolerated.
- Compliance to a daily stretching program is crucial to avoid recurrence of this syndrome.

REFERRAL

- Physical therapist: To instruct patients about stretching and pain-relieving maneuvers
- Orthopedic: When diagnosis is in doubt, the patient failed conservative treatment, and surgical evaluation is needed
- Neurologist: For EMG studies

PEARLS & CONSIDERATIONS

COMMENTS

Athletes may return to play when:

- They are pain free with full range of motion
- They have full strength in the affected side

PREVENTION

To prevent the recurrence of pain:

- Avoid risk factors.
- Continue stretching exercises.
- Correction of biomechanical deficiencies.

BASIC INFORMATION

DEFINITION

Pituitary adenoma is a benign neoplasm of the anterior lobe of the pituitary that causes symptoms, either by excess secretion of hormones or by a local mass effect as the tumor impinges on other, nearby structures (e.g., optic chiasm, hypothalamus, pituitary stalk). Pituitary adenomas are classified by their size, function, and features that characterize their appearance. Microadenomas are <10 mm in size, macroadenomas are ≥10 mm in size, and giant adenomas are ≥40 mm in size.

- *Nonsecretory pituitary adenomas* are those in which the neoplasm is a space-occupying lesion whose secretory products do not cause a specific disease state.
- *Secretory pituitary adenomas* can cause endocrine manifestations related to what they are secreting.

Endocrine manifestations of secretory adenomas include:

Acromegaly, a disease state characterized by a pituitary adenoma that secretes growth hormone (GH)

Galactorrhea, which is the result of a *prolactinoma* that secretes prolactin (PRL)

Cushing disease, a disease state of hypersecretion of adrenocorticotropic hormone (ACTH)

Hyperthyroidism due to a thyrotropin-secreting pituitary adenomas, which secrete primarily thyroid-stimulating hormone (TSH)

ICD-10CM CODE

D35.2 Benign neoplasm of pituitary gland

EPIDEMIOLOGY & DEMOGRAPHICS

CLASSIFICATION (BY HORMONE SECRETED):

- PRL only: 35%
- No hormone: 30%
- GH only: 20%
- PRL and GH: 7%
- ACTH: 7%
- Luteinizing hormone (LH), follicle-stimulating hormone (FSH), TSH: 1%

PREVALENCE/INCIDENCE:

- Pituitary adenomas: Up to 10% to 15% of all intracranial neoplasms; 3% to 27% at autopsy series. True prevalence is likely underestimated due to nonfunctioning pituitary adenomas going undiagnosed until they are large
- Prolactinomas: Up to 20% in women with unexplained primary or secondary amenorrhea
- GH-secreting pituitary adenoma: 50 to 60 cases per 1 million persons. They account for 8% to 16% of pituitary tumors and are most common in men over age 50
- Thyrotropin-secreting pituitary adenoma: 1% of pituitary adenomas with a slight female/male predominance of 1.7:1
- Corticotropin-secreting pituitary adenomas: Female/male predominance of 8:1 but overall uncommon diagnosis, accounting for 2% to 6% of adenomas

PHYSICAL FINDINGS & CLINICAL PRESENTATION

All sellar masses can cause visual defects by compression of the optic chiasm (bitemporal hemianopsia) or headaches.

PROLACTINOMAS:

- Females:
  1. Galactorrhea
  2. Amenorrhea
  3. Oligomenorrhea with anovulation
  4. Infertility
  5. Estrogen deficiency and associated osteopenia
  6. Decreased vaginal lubrication
- Males:
  1. Large tumors more common as a result of delayed diagnosis
  2. Possible impotence, decreased libido, or hypogonadism
  3. Galactorrhea rare because males lack the estrogen-dependent breast growth and differentiation

GH-SECRETING PITUITARY ADENOMA: ACROMEGALY:

- Coarse facial features
- Oily skin
- Prognathism
- Carpal tunnel syndrome
- Osteoarthritis
- History of increased hat, glove, or shoe size
- Decreased exercise capacity
- Visual field deficits
- Diabetes mellitus

CORTICOTROPIN-SECRETING PITUITARY ADENOMA: CUSHING DISEASE:

- Usually present when the tumor is small (1 to 2 mm)
- 50% of the tumors are <5 mm
- Other symptoms:
  1. Truncal obesity
  2. Round facies (moon face)
  3. Dorsocervical fat accumulation (buffalo hump)
  4. Hirsutism
  5. Acne
  6. Menstrual disorders
  7. Hypertension
  8. Striae
  9. Bruising
  10. Thin skin
  11. Hyperglycemia

THYROTROPIN-SECRETING PITUITARY ADENOMA:

- In males, larger, more invasive, and more rapidly growing tumors that present later in life
- Other symptoms: Thyrotoxicosis, goiter, visual impairment

NONSECRETORY PITUITARY ADENOMAS (ENDOCRINE INACTIVE PITUITARY ADENOMA):

- Usually large at the time of diagnosis
- Symptoms:
  1. Bitemporal hemianopsia as a result of compression of the optic chiasm
  2. Hypopituitarism from compression of the pituitary gland
  3. Hypogonadism in men and in premenopausal women
  4. Cranial nerve deficits caused by extension into the cavernous sinus
  5. Hydrocephalus from extension into the third ventricle, compressing the foramen of Monro
  6. Diabetes insipidus resulting from compression of the hypothalamus or pituitary stalk (a rare complication)

ETIOLOGY

Benign neoplasms of epithelial origin linked to genetic mutations of *MEN1, Gs-Alpha,* and *AIP*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

PROLACTINOMA:

- Pregnancy
- Postpartum puerperium
- Primary hypothyroidism
- Breast disease
- Breast stimulation
- Drug ingestion (especially phenothiazines, antidepressants, haloperidol, methyldopa, reserpine, opiates, amphetamines, and cimetidine)
- Chronic renal failure
- Liver disease
- Polycystic ovarian disease
- Chest wall disorders
- Spinal cord lesions
- Previous cranial irradiation

ACROMEGALY: Ectopic production of GH-releasing hormone from a carcinoid or other neuroendocrine tumor

CUSHING DISEASE:

- Diseases that cause ectopic sources of ACTH overproduction (including small-cell carcinoma of the lung, bronchial carcinoid, intestinal carcinoid, pancreatic islet cell tumor, medullary thyroid carcinoma, or pheochromocytoma)
- Adrenal adenomas, adrenal carcinoma
- Nelson syndrome

THYROTROPIN-SECRETING PITUITARY ADENOMAS: Primary hypothyroidism

NONSECRETORY PITUITARY ADENOMA: Nonneoplastic mass lesions of various etiologies (e.g., infectious, granulomatous)

WORKUP

Pituitary adenomas should be identified at an early stage so that effective treatment can be implemented.

Screening tests for functional pituitary adenomas are described in Table 1.

PROLACTINOMA: First step: Measurement of basal PRL levels (practitioners should be aware of discriminatory values in their own institutions).

- Elevated PRL levels are correlated with tumor size.
- Level >200 ng/ml indicates likely prolactinoma, with levels of 100 to 200 ng/ml being equivocal and possibly associated with medications or other sources.
- Basal PRL levels between 20 and 100 suggest a microadenoma but can be due to common medications (estrogen, antidepressants,

TABLE 1 Screening Tests for Functional Pituitary Adenomas

Disorder	Test	Comments
Acromegaly	IGF-1 OGTT with GH obtained at 0, 30, and 60 min	Interpret IGF-1 relative to age- and gender-matched controls. Normal subjects should suppress GH to <1 μg/L.
Prolactinoma	Serum PRL level	A level >500 μg/L is pathognomonic for macroprolactinoma. If >200 μg/L, prolactinoma is likely.*
Cushing disease	24-hr UFC Nighttime salivary cortisol dexamethasone (1 mg) at 11 P.M. and fasting plasma cortisol measured at 8 A.M. ACTH assay	Ensure that urine collection is total and accurate by measuring urinary creatinine. Free salivary cortisol reflects circadian rhythm, and elevated levels may indicate Cushing disease. Normal subjects suppress to <1.8 μg/dl. Distinguishes adrenal adenoma from ectopic ACTH or Cushing disease.
TSH-secreting tumor	TSH measurement free T_4 by dialysis total T_3	If T_4 or T_3 is elevated and TSH is measurable or elevated, a TSH-secreting tumor may be present.

*Risperidone may result in prolactin levels >200 μg/L.
ACTH, Adrenocorticotropic hormone; *GH*, growth hormone; *IGF-1*, insulin-like growth factor type 1; *OGTT*, oral glucose tolerance test; *PRL*, prolactin; T_3, triiodothyronine; T_4, thyroxine; *TSH*, thyroid-stimulating hormone; *UFC*, urinary free cortisol.
From Melmed S et al: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders.

metoclopramide, Aldomet, and others) or recent breast stimulation.
- Basal level <20 ng/ml is usually considered normal. Each laboratory should develop its own normative values, however, and practitioners should refer to these values.
- Threshold level for obtaining imaging such as MRI should be developed by individual providers depending on the level of specificity and sensitivity desired.

ACROMEGALY:
- First screening tests are the measurement of the serum insulin-like growth factor I level, postprandial serum GH, and thyrotropin-releasing hormone (TRH) stimulation test.
- Follow with an oral glucose tolerance test.
- Failure to suppress serum GH to <2 ng/ml with an oral load of 100 g glucose is considered conclusive.
- A GH-releasing hormone level >300 ng/ml is indicative of an ectopic source of GH.

CUSHING DISEASE:
- Measurement of late-night salivary cortisol level is the best screening test.
- Normal or slightly elevated corticotropin levels ranging from 20 to 200 pg/ml; normal is 10 to 50 pg/ml (normative data should be developed by each institution for its population).
- Level <10 pg/ml usually indicates an autonomously secreting adrenal tumor.
- Level >200 pg/ml suggests an ectopic corticotropin-secreting neoplasm.
- Cushing disease can be assessed by absence of cortisol suppression with the low-dose dexamethasone test but with the presence of cortisol suppression after the high-dose test. As a method to distinguish Cushing disease from an ectopic source of ACTH, this test is robust.
- 24-hr urine collection should demonstrate an increased level of cortisol excretion.

THYROTROPIN-SECRETING PITUITARY ADENOMA:
- Highly sensitive thyrotropin assays, which evaluate the presence of thyrotoxicosis, are one way to detect a thyrotropin-secreting tumor.
- Free alpha subunit is secreted by >80% of tumors, with the ratio of the alpha subunit to thyrotropin <1.
- With central resistance to thyroid hormone, ratio is <1, and the sella is normal.
- Laboratory tests show elevated serum levels of both T_3 and T_4.

NONSECRETORY PITUITARY ADENOMA:
- Visual field testing
- Assessment of the pituitary and organ function to determine if there is hypopituitarism or hypersecretion of hormones (even if the effects of hypersecretion are subclinical)
- TRH to provoke secretion of FSH, LH, and LH-beta-subunit; will not elicit response in normal persons
- Exclusion of Klinefelter syndrome in patient with longstanding primary hypogonadism, elevated gonadotropin levels, and enlargement of the sella

IMAGING STUDIES

Study of choice: MRI of the pituitary (Fig. E1) and hypothalamus. If an MRI shows the tumor impinging on the optic chiasm, then formal visual field testing is indicated.
- When evaluating Cushing disease, small size at the onset of symptoms noted.
- MRI, in this case, only 60% sensitive at best and may yield false-positive results.
- CT scan only when MRI is unavailable or is otherwise contraindicated.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

SURGERY:
- Selective transsphenoidal resection of the adenoma (Table 2) is the treatment of choice for acromegaly, Cushing disease, and thyrotropin-secreting pituitary adenomas, all of which tend to be microadenomas at the time of onset of symptoms.

TABLE 2 Transsphenoidal Pituitary Surgery

Primary Indications

General
Visual tract or central nervous system compression arising from within sella
Relief of compressive hypopituitarism by presenting, residual, or recurrent tumor tissue
Tumor recurrence after surgery or irradiation
Pituitary hemorrhage
Cerebrospinal fluid leak
Resistance to medical therapy
Intolerance of medical therapy
Personal choice
Desire for immediate pregnancy with macroadenoma
Requirement for diagnostic tissue histology

Specific
Acromegaly
Cushing disease
Clinically nonfunctioning macroadenoma
Prolactinoma
Nelson syndrome
TSH-secreting adenoma

Side Effects

Transient
Diabetes insipidus
Cerebrospinal fluid leak and rhinorrhea
Inappropriate ADH secretion
Arachnoiditis
Meningitis
Postoperative psychosis
Local hematoma
Arterial wall damage
Epistaxis
Local abscess
Pulmonary embolism
Narcolepsy

Permanent (up to 10%)
Diabetes insipidus
Total or partial hypopituitarism
Visual loss
Inappropriate ADH secretion
Vascular occlusion
CNS damage: oculomotor palsy, hemiparesis, encephalopathy
Nasal septum perforation

Surgery-Related Mortality (up to 1%)
Brain, hypothalamic
Vascular damage
Postoperative meningitis
Cerebrospinal fluid leak
Pneumocephalus
Acute cardiopulmonary disease
Anesthesia-related
Seizure

ADH, Antidiuretic hormone; *CNS,* central nervous system; *TSH,* thyroid-stimulating hormone.
From Melmed S et al: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, WB Saunders.

- Macroadenomas, such as the nonsecretory pituitary adenoma, may also be surgically removed, but risk of recurrence is greater with these tumors and adjunctive therapy such as irradiation may also be necessary.
- Bilateral adrenalectomy has been performed in patients with Cushing disease after failure of other therapies; complications requiring lifelong hormone replacement or Nelson

syndrome (rapid enlargement of pituitary tumor due to adrenal resection) may occur.

RADIOTHERAPY:

- Radiotherapy is used primarily as adjuvant treatment. It is reserved for patients who have not responded to surgical treatment and who still have symptoms of the adenoma.
- Used with varying degrees of success in all the different pituitary adenomas.
- Radiotherapy complications include long-term hypopituitarism (40% of patients) and secondary neoplasms (1.5% of patients).

ACUTE GENERAL Rx

PROLACTINOMA:

- For prolactinomas, initial therapy is generally dopamine agonists. Bromocriptine, a dopamine analogue, is generally given orally in divided doses of 1.5 to 10 mg. Cabergoline is given once or twice weekly. It is better tolerated and more effective than bromocriptine for tumor shrinkage but more expensive.
- Side effects include orthostatic hypotension, nausea, and dizziness; avoided by beginning with low-dose therapy.
- Other compounds include pergolide mesylate, a long-acting ergot derivative with dopaminergic properties, as well as other nonergot derivatives.

ACROMEGALY:

- Somatostatin analogues: Octreotide, lanreotide administered as monthly injections.
- Cabergoline or bromocriptine can also be used. They have modest activity but can be administered orally and are less expensive than somatostatin analogues.
- Pegvisomant can also be used to normalize IGF-1 levels.

CUSHING DISEASE:

- Ketoconazole, which inhibits the cytochrome P-450 enzymes involved in steroid biosynthesis, is effective in managing mild to moderate disease in daily oral doses of 600 to 1200 mg.
- Metyrapone and aminoglutethimide can be used to control hypersecretion of cortisol but are generally used when preparing a patient for surgery or while waiting for a response to radiotherapy.

THYROTROPIN-SECRETING PITUITARY ADENOMA:

- Ablative therapy with either radioactive iodide or surgery is indicated.
- Treatment directed to the thyroid alone may accelerate growth of the pituitary adenoma.
- Octreotide has been shown to be effective in doses similar to those used for acromegaly.

NONSECRETORY PITUITARY ADENOMA:

- There is no role for medical therapy at this time.

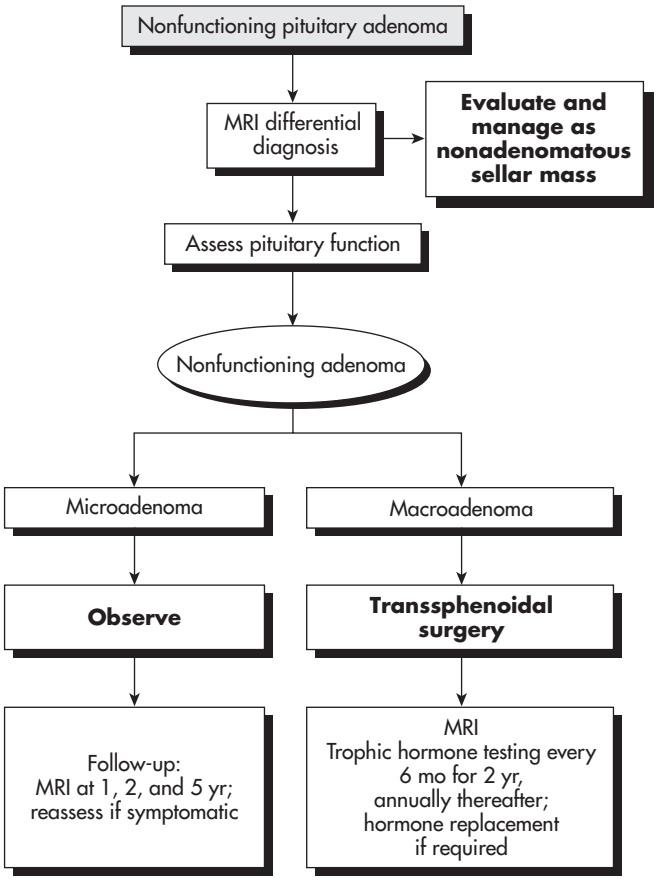

FIG. 2 Management of nonfunctioning pituitary adenomas. Skilled interpretation of magnetic resonance images is crucial to diagnosing a nonadenomatous mass such as a meningioma, aneurysm, or other sellar lesion. *MRI,* Magnetic resonance imaging. (From Melmed S et al: *Williams textbook of endocrinology*, ed 12, Philadelphia, 2011, WB Saunders.)

- Surgery and radiotherapy may be indicated. An algorithm for the management of nonfunctioning pituitary adenomas is described in Fig. 2.

CHRONIC Rx

For all pituitary adenomas:

- Careful follow-up is important. Patients undergoing transsphenoidal microsurgical resection should be seen in 4 to 6 wk to ensure that the adenoma has been completely removed and that the endocrine hypersecretion is resolved.
- If there is good clinical response, patient should be monitored yearly for recurrence and to follow the level of the hypersecreted hormone.
- Patients who have undergone irradiation should have close follow-up with backup medical therapy because response to radiotherapy may be delayed; incidence of hypopituitarism also increases with time.
- Surgical resection is not indicated in pituitary incidentalomas that are microadenomas since only 10% will experience tumor growth.

Pityriasis Rosea (PTG)

BASIC INFORMATION

DEFINITION

Pityriasis is a common self-limiting skin eruption of unknown etiology.

ICD-10CM CODE
L42 Pityriasis rosea

EPIDEMIOLOGY & DEMOGRAPHICS

- Most cases of pityriasis rosea occur between ages 10 and 35 yr; mean age is 23 yr.
- The incidence of disease is highest in the fall and spring.
- Female:male ratio is 1.5:1.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Initial lesion (herald patch), an annular pink patch with trailing scale, precedes the eruption by approximately 1 to 2 wk; typically measures 3 to 6 cm; it is round to oval in appearance and most frequently located on the trunk (Fig. E1).
- Eruptive phase follows within 2 wk and peaks after 7 to 14 days.
- Lesions are most frequently located in the lower abdominal area. They have a salmon-pink appearance in whites and a hyperpigmented appearance in blacks.
- Most lesions are 4 to 5 mm in diameter; center has a "cigarette paper" appearance; border has a characteristic ring of scale (collarette) (Fig. E2). When stretched across the long axis, the scales tend to fold across the lines of stretch, the so-called "hanging curtain sign."
- Lesions occur in a symmetric distribution and follow the cleavage lines of the trunk (Christmas tree pattern).
- An inverse pattern showing distribution along skin lines may be present (Fig. E3). The axillary area is a good site to look for orientation along skin lines, facilitating the diagnosis (Fig. E4).
- The number of lesions varies from a few to hundreds. They generally disappear spontaneously after 3 to 8 wk.
- Most patients are asymptomatic; pruritus is the most common symptom.
- History of recent fatigue, headache, sore throat, and low-grade fever is present in approximately 25% of cases.

ETIOLOGY

Unknown, possibly viral exanthem. Active replication of human herpesvirus (HHV)-6 and HHV-7 has been demonstrated in mononuclear cells of lesional skin.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Tinea corporis (can be ruled out by potassium hydroxide examination)

FIG. E1 Herald patch (pityriasis rosea). Oval lesion with finely scaled, elevated border, occasionally misdiagnosed as tinea corporis. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence*, ed 5, Philadelphia, 2016, Elsevier.)

FIG. E2 Pityriasis rosea. The collarette of scale can be subtle. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence*, ed 5, Philadelphia, 2016, Elsevier.)

FIG. E3 Pityriasis rosea. Inverse pattern showing the distribution along skin lines. Scaling may be more difficult to appreciate in intertriginous areas. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence*, ed 5, Philadelphia, 2016, Elsevier.)

FIG. E4 Pityriasis rosea. Truncal involvement with larger plaques and predominantly round papular lesions, most commonly seen in young children and African Americans. Note the peripheral scale and distribution along skin lines. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence*, ed 5, Philadelphia, 2016, Elsevier.)

- Secondary syphilis (absence of herald patch, positive serologic test for syphilis)
- Psoriasis
- Nummular eczema
- Drug eruption: Medications that may cause rashes similar to pityriasis rosea include clonidine, captopril, interferon, bismuth, barbiturates, gold, hepatitis B vaccine, and imatinib mesylate
- Other viral exanthem
- Seborrheic dermatitis
- Eczema
- Lichen planus
- Tinea versicolor (the lesions are more brown and the borders are not as ovoid)
- Erythema migrans

WORKUP

Presence of herald lesion and characteristic rash are diagnostic. Skin biopsy is generally reserved for atypical cases.

LABORATORY TESTS

Generally not necessary; serologic test for syphilis if clinically indicated

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

The disease is self-limited and generally does not require any therapeutic intervention.

ACUTE GENERAL Rx

- Use calamine lotion or oral antihistamines in patients with significant pruritus. Corticosteroid lotions or creams also provide some relief from itching.
- Use prednisone tapered over 2 wk in patients with severe pruritus.
- Direct sun exposure or use of ultraviolet light within the first wk of eruption is beneficial in decreasing the severity of disease.
- One small trial showed improvement of rash and pruritus with erythromycin 250 mg qid for 2 wk.

DISPOSITION

- Spontaneous complete resolution of the rash within 4 to 8 wk
- Recurrence rare (<2% of cases)

PEARLS & CONSIDERATIONS

COMMENTS

Reassure patient that the disease is not contagious, and its course is benign.

BASIC INFORMATION

DEFINITION

The diagnosis of placenta previa is based on sonography and requires the identification of echogenic homogeneous placental tissue over the internal cervical os. When the placental edge is <2 cm from the internal os, the placenta is called "low-lying." The historic terms "marginal" and "partial" for characterizing a placenta previa are no longer used.

One hypothesis is that the lower uterine cavity contains more vascularized decidua, which promotes implantation of trophoblast toward the cervical os. Another hypothesis is that a particularly large placental surface area increases the probability that the placenta will implant over the cervical os.

ICD-10CM CODES

O44	Placenta previa
O44.0	Complete placenta previa NOS or without hemorrhage
O44.1	Complete placenta previa with hemorrhage
O44.2	Partial placenta previa without hemorrhage
O44.3	Partial placenta previa with hemorrhage
O44.4	Low-lying placenta NOS or without hemorrhage
O44.5	Low-lying placenta with hemorrhage

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: The pooled prevalence of major placenta previa was 4.3 cases per 1000 pregnancies. Prevalence was highest among Asian studies (12.2 per 1000) and lower among studies from Europe (3.6 per 1000), North America (2.9 per 1000), and sub-Saharan Africa (2.7 per 1000).

RISK FACTORS:

- Previous placenta previa (recurs in 4% to 8% of subsequent pregnancies)
- Previous cesarean delivery (increases incidence by 47% to 60%)
- Multiparity
- Multiple gestation (increases prevalence by 40%)
- Smoking and cocaine use
- Previous intrauterine surgical procedure or Asherman syndrome
- Abnormal or large placenta

PHYSICAL FINDINGS & CLINICAL PRESENTATION

The classic presentation of placenta previa is painless vaginal bleeding, usually in the second or third trimester. 10% to 20% of women present with uterine contractions, pain, and bleeding. On physical examination, the uterus is soft and pain free. The fetus is often in breech, transverse lie, or high. Fetal distress is usually not present.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Morbidly adherent placenta (accreta, increta, percreta)
- Vasa previa
- Abruptio placentae
- Vaginal or cervical trauma
- Labor
- Local malignancy

WORKUP

- Do *not* perform a digital vaginal examination.
- Perform a speculum examination in a hospital setting to exclude any local bleeding.
- Perform a transvaginal ultrasonography to assess for placental location.
- Exclude the presence of placenta previa-accreta in patients with a history of cesarean sections. In a prospective study, the frequency of placenta accreta increased with an increasing number of cesarean deliveries: 3% for first cesarean, 11% for second cesarean, 40% for third cesarean, 61% for fourth cesarean, and up to 67% for fifth or more cesarean sections.

LABORATORY TESTS

- A complete blood count can be used to monitor hemoglobin and hematocrit.
- A Kleihauer-Betke preparation of maternal blood in all Rh-negative women and Rh-immune globulin when indicated

IMAGING STUDIES

- The simplest and safest method of placental localization is transabdominal sonography with confirmatory imaging by transvaginal ultrasonography (TVUS). Transabdominal ultrasonography alone is inaccurate in the diagnosis of placenta previa and should be used only as a screening tool. TVUS (Fig. 1) has become the gold standard for the diagnosis of placenta previa. It is safe even in the presence of active bleeding.
- MRI has also been effective in detecting placenta previa, although sonography remains the preferred method due to lower cost, widespread availability, and well-established accuracy.

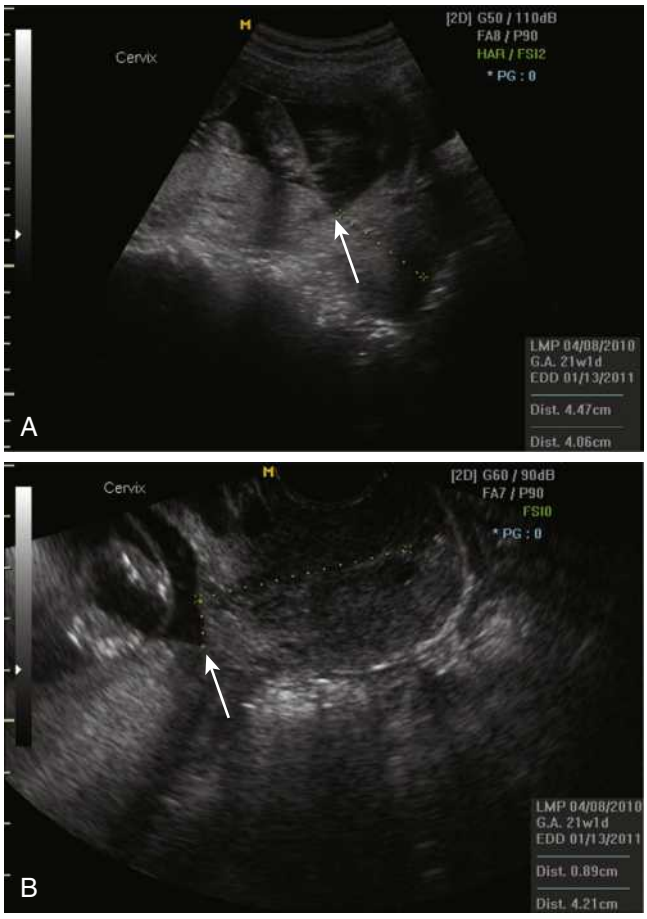

FIG. 1 Transabdominal ultrasonography and transvaginal ultrasonography of marginal placenta previa. *Arrows* identify placental edge. (Courtesy K. Francois. From Gabbe SG: *Obstetrics*, ed 6, Philadelphia, 2012, WB Saunders.)

Rx TREATMENT

MANAGEMENT OF ASYMPTOMATIC PLACENTA PREVIA

- Avoid sexual activity, digital exams, and extraneous exercise.
- Review bleeding precautions and anticipatory guidance, including the need for cesarean section and the risk for hysterectomy early in pregnancy.

Sequential assessment of placental location:

- At 32 wks, follow-up is indicated:
  1. If the placental edge is ≥2 cm from the internal os, placenta previa has resolved and no further assessment is required.
  2. If the placental edge is over or <2 cm from the internal os, placenta previa persists and repeat at 36 wks is indicated.
- At 36 wks:
  1. If the placental edge is ≥2 cm, the patient is consented for vaginal delivery.
  2. If the placental edge is over the internal os, cesarean delivery is scheduled.

Timing of delivery:

- Cesarean delivery at 36+0 to 37+6 wks in pregnancies with uncomplicated placenta previa

MANAGEMENT OF SYMPTOMATIC PLACENTA PREVIA

- Initial assessment for signs of maternal hemodynamic compromise or hemorrhagic shock; large-bore IV access with crystalloid fluid resuscitation.
- Assess fetal status and gestational age by sonogram and continuous fetal heart rate monitoring.
- Cross-matched blood should be made available during bleeding episodes.
- Tocolytic therapy should not be administered in an actively bleeding patients.
- Magnesium sulfate therapy for fetal neuroprotection should be considered in those with symptomatic preterm (less than 32 wks) placenta previa if the decision has been made to likely deliver the patient within 24 hours. Emergent delivery should not be delayed to administer magnesium.
- Cesarean delivery is indicated for active labor, nonreassuring fetal heart rate tracing, active bleeding with hemodynamic instability, and significant bleeding after 34 wks' gestation.

Expectant management after a resolved bleed:

- Antenatal corticosteroid should be administered to symptomatic women between 23+0 and 36+6 wks of gestation to enhance fetal pulmonary maturity.
- Correct anemia.
- Administer anti-D immune globulin to D-negative women.

DISPOSITION

Inpatient versus outpatient: Consider discharge for women whose bleeding has stopped for 24 hours and live in close proximity to the hospital, demonstrate compliance with medical management, can maintain bed rest, understand bleeding precautions, and have an adult companion available for transport 24 hours a day.

PEARLS & CONSIDERATIONS

COMMENTS

- Placenta previa is diagnosed by TVUS, with repeat assessment at 32 and 36 wks when indicated.
- Asymptomatic placenta previa can be managed expectantly with a planned cesarean delivery at 36+0 to 37+6 wks.
- Symptomatic placenta previa is managed by assessing hemodynamic stability, considering steroids for fetal lung maturity, magnesium sulfate for fetal neuroprotection when indicated, and cesarean delivery.

Plantar Fasciitis (PTG)

BASIC INFORMATION

DEFINITION

Despite its name, plantar fasciitis is characterized by chronic degeneration of the plantar fascia without signs of inflammation. The plantar fascia consists of longitudinal collagen fibers that extend from the anteromedial calcaneus and divide distally into five digital bands that insert in the corresponding metatarsophalangeal joints. The function of the plantar fascia is to provide dynamic shock absorption, medial longitudinal arch support, and protection to underlying anatomic structures. Over time, repetitive microtrauma to the plantar fascia causes myxoid degeneration, microtears in the fascia, collagen necrosis, and angiofibroblastic hyperplasia culminating in the clinical presentation of plantar fasciitis.

Patients with plantar fasciitis have pain that is typically elicited along the medial calcaneal tuberosity on which the medial band of the plantar fascia inserts or along the coursing of the plantar fascia (Fig. E1).

SYNONYM

Heel spur syndrome

ICD-10CM CODES

M72.2	Plantar fascial fibromatosis
M77.30	Calcaneal spur, unspecified foot
M77.31	Calcaneal spur, right foot
M77.32	Calcaneal spur, left foot

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Plantar fasciitis is the most common cause of plantar heel pain and occurs bilaterally in up to 30% of cases. In the U.S., it is estimated that greater than two million people suffer from and are treated for plantar fasciitis on an annual basis. Most patients seek their primary care physicians for initial consultation. Studies have shown that plantar fasciitis resolves in 80% of patients who do not seek any medical treatment during a 12-mo period.

PREDOMINANT SEX: Predominance of plantar fasciitis varies according to studies.

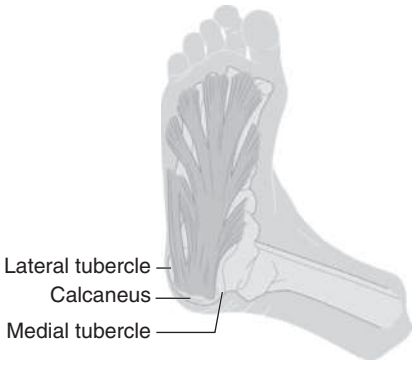

FIG. E1 Plantar view of origin and insertion of plantar fascia. (From Frontera WR: *Essentials of physical medicine and rehabilitation,* ed 2, Philadelphia, 2008, WB Saunders.)

PREDOMINANT AGE: Peak incidence ranges from ages 40 to 60 yr old but can occur at any age.

RISK FACTORS: Rapid increase in activity, weight gain, obesity, pes cavus or pes planus foot type, prolonged standing, excessive running, and abrupt change in activity, trauma, and ambulating on hard surfaces barefoot.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Pain is commonly localized to the medial tubercle of the calcaneus and may radiate along the course of the plantar fascia. Pain outside of the plantar heel should raise the suspicion of an alternative diagnosis. The pain is often described as sharp, deep, and achy. Nerve paresthesias are not common. Additionally, passive ankle dorsiflexion can cause discomfort in the proximal plantar fascia, and the plantar fascia may be thickened. Classically, patients experience poststatic dyskinesia–heel pain with the first few steps in the morning and upon standing after sitting for a prolonged period of time. Symptoms typically improve with ambulation secondary to the plantar fascia being in a relaxed position.

ETIOLOGY

- Repetitive, prolonged microtrauma to the plantar heel
- Calcaneal heel spurs may or may not be present, and are more likely an incidental finding rather than a factor related to the etiology
- Achilles tendon contracture (equinus, pseudoequinus)
- Intrinsic biomechanical factors: Forefoot varus, compensated rearfoot varus, rearfoot varus, flexible forefoot valgus, compensated forefoot valgus, tibial varum, excessive femoral anteversion
- Poor footwear
- Prolonged standing/walking occupations
- Heel pad atrophy
- Ambulating barefoot on hard surfaces
- Exercising on uneven terrain
- Overtraining
- Obesity

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Calcaneal fracture
- Tarsal tunnel syndrome
- Foreign body
- Bone cyst or bone tumor
- Bone contusion
- Posterior tibial tendon dysfunction
- Flexor hallucis longus tendonitis
- Plantar fascial fibromatosis
- Rheumatoid arthritis
- Seronegative arthropathies including reactive arthritis, psoriatic arthritis, and ankylosing spondylitis
- Plantar fascial rupture
- Bursitis of the plantar heel
- Baxter neuritis
- Piezogenic plantar papules
- L5 to S1 radiculopathy
- Disruption in the morphology of plantar fat pad

STUDIES

Additional studies play a limited role in diagnosing plantar fasciitis but may reveal alternative causes of heel pain.

- Weight-bearing x-rays—osseous abnormalities including tumors, fractures (lateral, oblique, anterior-posterior, calcaneal axial [Harris] views); however, these usually are not high yield in identifying plantar fasciitis
- MRI—soft tissue and osseous structures in greater anatomic detail without any exposure to radiation and is useful for ruling out other causes of heel pain
- CT—osseous structure abnormalities such as tarsal coalitions and osteocartilaginous lesions in greater anatomic detail
- Bone scan—stress fractures
- Ultrasound—soft tissue structure anomalies or abnormalities; therapeutic ultrasound is also an early, effective treatment modality
- Nerve conduction tests—nerve disorders such as tarsal tunnel syndrome

TREATMENT

Nonsurgical treatment is the mainstay of treatment for plantar fasciitis

- Supportive shoe gear with appropriate modifications (e.g., gel heel cup for comfort)
- Custom-molded orthotics (rearfoot posting to correct for rearfoot varus or valgus)
- Physical therapy: Ultrasound, iontophoresis, electrical stimulation (TENS unit); stretching, strengthening, and proprioception exercises
- Ice, NSAIDs, oral corticosteroids, activity reduction
- Weight reduction in those who are overweight
- Stretching before activities
- Corticosteroid injection (Caution: Can lead to plantar fascia rupture and is not routinely recommended)
- Botulin toxin injection: Inhibits the release of acetylcholine in overactive muscles
- Platelet-rich plasma injection
- Dorsiflexion night splint to maintain ankle joint at 90 degrees (stretches plantar fascia)
- Manual deep foot massage
- Heel lifts or heel cup if the etiology is Achilles equinus
- Severe cases may require a controlled ankle movement (CAM) boot or short leg cast for 4 to 6 wk of immobilization
- Recalcitrant cases may require surgical intervention
- Pulsed radiofrequency electromagnetic field therapy
- Extracorporeal shock-wave therapy (ESWT): Last option before surgical intervention in those who have failed all other conservative treatment modalities. Mechanism of action (MOA): Increases proliferation of growth factors; inhibits demyelinated plantar sensory nerves; reduces calcification within the plantar fascia; increases peripheral blood circulation, angiogenesis, and neovascularization in the degenerative tissue of the heel

DISPOSITION

Higher success rates for treating plantar fasciitis are associated with early recognition . It is imperative to recognize the biomechanical components when assessing plantar fasciitis. Pathology that is not recognized early typically involves a longer treatment course, and those cases that are recalcitrant to conservative treatment modalities tend to need surgical intervention.

REFERRAL

- For biomechanical exam, orthotics, or surgical consult (podiatric surgeon and/or foot and ankle orthopedic surgeon)
- Physical therapy can be used as an adjunct to conservative treatment measures

PEARLS & CONSIDERATIONS

COMMENTS

- Plantar fasciitis is commonly misdiagnosed. The cases that are recalcitrant to treatment need to be reevaluated to exclude other etiologies.
- A recent meta-analysis of 20 randomized trials comparing foot orthoses with sham orthoses, other treatments, or no treatment revealed that although some trials showed modest improvement with orthoses the overall results revealed no significant short- or long-term benefit for custom-made or prefabricated orthoses.[1]
- A recent systematic review and meta-analysis reveal that corticosteroid injection was no better than placebo for short-term treatment of plantar fasciitis.[2]

[1]Rasenberg N et al: Efficacy of foot orthoses for the treatment of plantar heel pain: a systemic review and meta-analysis, *Br J Sports Med* 52(16):1040-1046, 2018.

[2]Whittaker GA et al: Corticosteroid injection for plantar heel pain: a systematic review and meta-analysis, *BMC Musculoskelet Disord* 20(1):378, 2019.

PREVENTION

- Avoid sitting for prolonged periods of time without stretching.
- Avoid wearing unsupportive shoe gear.
- Avoid abrupt change and intensity in physical activity.
- Perform stretches before any exercises or strenuous activity.
- Seek early medical attention with onset of heel pain.

BASIC INFORMATION

DEFINITION

Pleural effusion is the pathologic accumulation of fluid in the pleural space, with a wide range of etiologies.

SYNONYMS

Hydrothorax
Hemothorax
Chylothorax
Empyema

ICD-10CM CODES

J90	Pleural effusion
J91.8	Pleural effusion in other conditions classified elsewhere

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Subjective symptoms include dyspnea, cough, fatigue, fever, chest pain. Box 1 summarizes signs and symptoms of pleural effusion
- Physical examination findings include dullness to percussion, decreased tactile fremitus, and decreased breath sounds
- Bedside transthoracic ultrasound can be helpful to identify characteristics of pleural effusion, including:
  1. Size, location, and laterality
  2. Presence of loculations, pleural adhesions, or implants
  3. Safe site for thoracentesis
  4. Underlying lung parenchymal pathology (e.g., pulmonary edema, consolidation, pneumothorax)

ETIOLOGY

Caused by a number of factors, including increased capillary permeability, increased vascular hydrostatic pressure, decreased vascular oncotic pressure, inflammation of the pleurae, traumatic/iatrogenic causes, and/or obstruction of normal pleural fluid efflux. Box 2 summarizes causes of pleural effusion.

BOX 1 Signs and Symptoms of Effusion

Dyspnea
Cough (dry, nonproductive)
Chest pain (pleuritic or nonpleuritic)
Chest wall discomfort
Decreased breath sounds
Dullness to percussion
Egophony, tactile fremitus
Pleural friction rub
Disease-specific signs and symptoms may include:
Orthopnea
Paroxysmal nocturnal dyspnea
Fever
Night sweats

From Adams JG et al: *Emergency medicine, clinical essentials*, ed 2, Philadelphia, 2013, Elsevier.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Transudate (pleural to serum LDH ratio <0.6 or total protein ratio <0.5)

- Congestive heart failure
- Cirrhosis (hepatic hydrothorax)
- Chronic renal insufficiency
- Hypoalbuminemia

BOX 2 Causes of Pleural Effusions

Transudates
Atelectasis (early)
Congestive heart failure
Cirrhosis
Glomerulonephritis
Hypoalbuminemia
Myxedema
Nephrotic syndrome
Peritoneal dialysis
Pulmonary embolism
Superior vena cava syndrome

Exudates
Infectious
Bacterial infection
Bronchiectasis
Fungal infection
Lung abscess
Parasitic infection
Traumatic hemothorax
Tuberculosis
Viral illness

Malignancies
Lymphoma
Mesothelioma
Primary lung cancer
Pulmonary metastasis

Connective Tissue Disease
Rheumatoid arthritis
Systemic lupus erythematosus

Abdominal/Gastrointestinal
Esophageal rupture
Pancreatic disorders
Subphrenic abscess

Other
Atelectasis (chronic)
Chylothorax
Drug reactions (amiodarone)
Postpartum state
Pulmonary infarction or embolism
Uremia

From Adams JG et al: *Emergency medicine, clinical essentials*, ed 2, Philadelphia, 2013, Elsevier.

- Constrictive pericarditis
- Superior vena cava obstruction
- Urinothorax

Exudate (defined as pleural to serum LDH ratio ≥0.6 or total protein ratio ≥0.5)

- Malignancy (secondary to metastatic cancer or primary; e.g., mesothelioma)
- Infection
  1. Uncomplicated parapneumonic effusion (pH >7.2)
  2. Complicated parapneumonic effusion (pH ≤7.2)
  3. Tuberculous effusion
  4. Viral pleurisy
- Pulmonary embolism
- Hemothorax
- Chylothorax
- Esophageal perforation
- Pleuropancreatic fistula
- Connective tissue disease

WORKUP

The Light criteria for classification of pleural effusions is summarized in Box 3. Fig. 1 illustrates a diagnostic algorithm for pleural effusions. Fig. E2 illustrates an approach to malignant pleural effusions.

LABORATORY TESTS

See Table 1.

IMAGING STUDIES

Chest radiography (Fig. 3)**:** Blunting of the costophrenic angle, ipsilateral atelectasis, contralateral shift of the mediastinum with large effusions, elevated hemidiaphragm with subpulmonic effusions, "spine sign" on lateral chest x-ray, may be free-flowing or fixed on lateral decubitus film depending on etiology.

Ultrasonography (Fig. E4): Can demonstrate size/location of effusion relative to chest wall, lung, and diaphragm. Can be used to assess for loculations, septations/adhesions, and parietal/visceral pleural implants.

Computed tomography (Fig. E5): Useful to identify loculated effusions and to assess underlying lung parenchyma to aid in establishing a diagnosis. In empyema, can demonstrate heterogeneity and gas bubbles.

TREATMENT

- Table 2 summarizes treatment options for pleural effusions.

BOX 3 Light Criteria for Classification of Pleural Effusions

In 1972, Light et al developed the currently accepted benchmark for classifying pleural fluid, as follows:
Pleural fluid protein to serum protein ratio >0.5:1
Pleural fluid lactate dehydrogenase (LDH) to serum LDH ratio >0.6:1
Pleural fluid LDH greater than two thirds the upper limit of normal for serum LDH (a cutoff value of 200 IU/L was used previously)
Pleural fluid is classified as an exudate if it meets any of the aforementioned criteria. Conversely, if all three characteristics are absent, the fluid is classified as a transudate. These researchers achieved a diagnostic sensitivity of 99% and a specificity of 98% for classification of an exudate.

From Adams JG et al: *Emergency medicine, clinical essentials*, ed 2, Philadelphia, 2013, Elsevier.

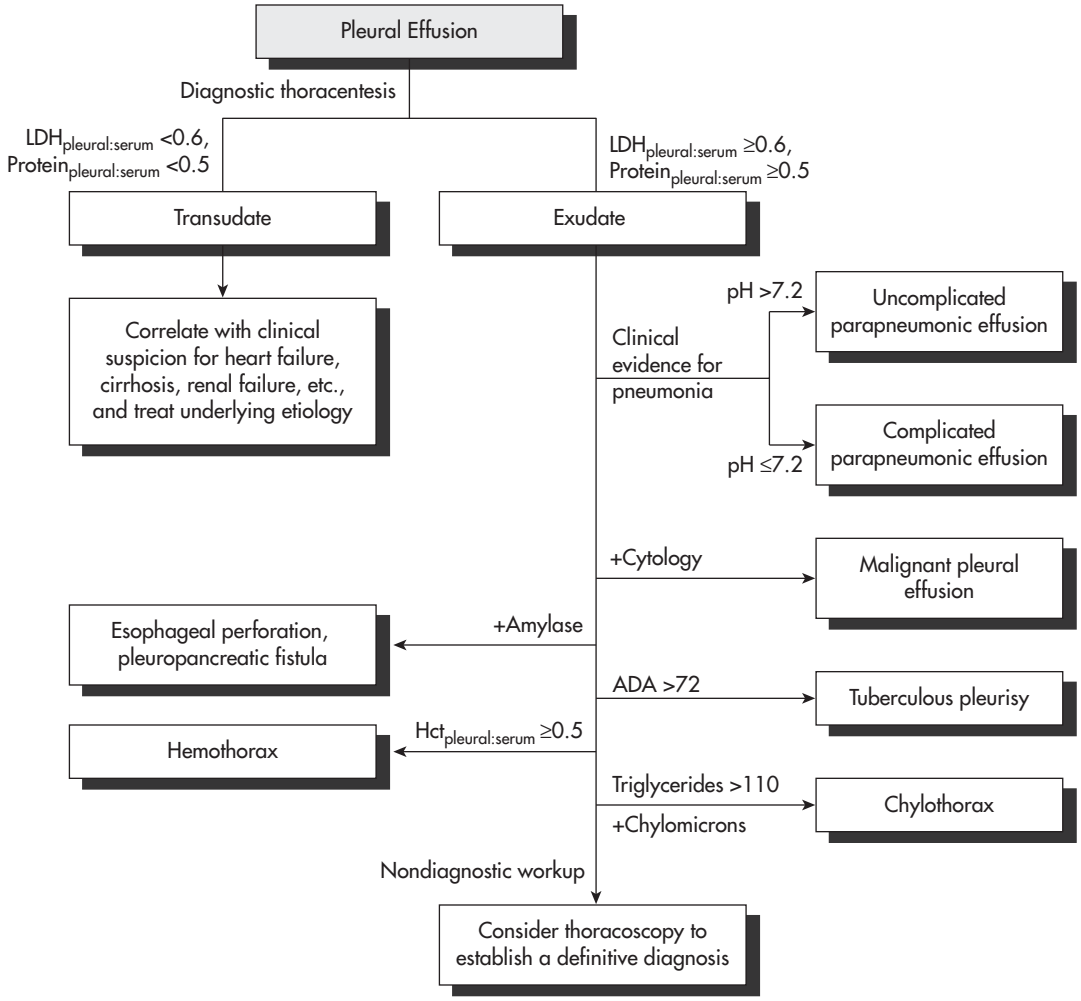

FIG. 1 Diagnostic algorithm. *ADA,* Adenosine deaminase; *Hct,* hematocrit; *LDH,* lactate dehydrogenase.

TABLE 1 Selected Laboratory Tests Used to Diagnose Pleural Effusion

Test	Diagnostic Utility	Comments
Adenosine deaminase (ADA)	>40 IU/L suggestive of tuberculous pleurisy	Values >72 IU/L highly specific for tuberculosis, with improved yield with pleural biopsy and PCR
Albumin	Pleural: serum albumin ratio <0.83 more consistent with transudate	Can be used to corroborate mixed findings from LDH and protein ratios
Amylase	Esophageal perforation, pancreatitis	
Cell count	**Lymphocyte** predominance suggestive of tuberculosis, lymphoma, other pleural malignancy, pulmonary embolism **Neutrophil** predominant effusions seen with bacterial infection, occasionally with malignancy (20%)	Helpful in distinguishing causes of exudative effusions
Chylomicrons	Positive finding adds to specificity of triglycerides for establishing chylothorax	Consider thoracic duct defect (due to malignancy, trauma or iatrogenic)
Creatinine	Pleural:serum creatinine >1 suggests urinothorax	
Culture	Positive findings used to narrow therapy	Should be sent from every suspected parapneumonic effusion to guide antimicrobial selection
Cytology	Sensitivity for malignancy of ~65%	Modest increment in diagnostic yield with up to three serial samples
Glucose	<60 mg/dl suggests complicated parapneumonic effusion, malignancy, tuberculous pleurisy or rheumatoid effusion	
Hematocrit	Pleural fluid hematocrit >50% peripheral blood hematocrit consistent with hemothorax	Pleural fluid with relatively low hematocrit can appear bloody on gross exam, does not necessarily represent hemothorax
Lactate dehydrogenase (LDH)	Pleural to serum LDH ratio >0.6 or pleural LDH >2/3 the upper limit of normal serum LDH suggests exudate	
NT-proBNP	>1500 pg/ml suggests heart failure even if effusion meets criteria for exudate	Chronic pleural effusions related to heart failure in patients on diuretic therapy may appear exudative
pH	≤7.2 with clinical suspicion highly suggestive of complicated parapneumonic effusion	Can also have low pH with malignant pleural effusions and esophageal perforation
Triglycerides	Triglycerides >110mg/dl seen with chylothorax	Absent triglycerides w/high suspicion for chylothorax can be confirmed with pleural chylomicrons

NT-proBNP, N-terminal pro b-type natriuretic peptide; *PCR,* polymerase chain reaction.

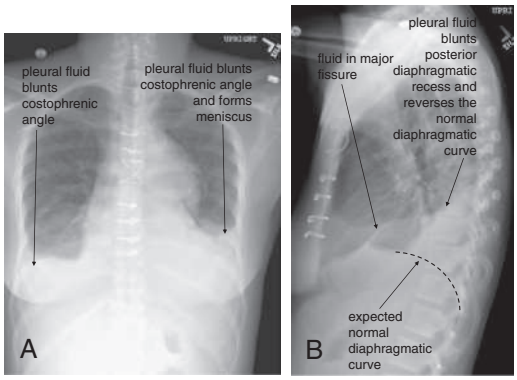

FIG. 3 Pleural effusions. A, Posterior-anterior upright view in which a pleural effusion is most evident on this patient's left side. Both costophrenic angles are blunted. The pleural effusion forms a meniscus against the left lateral chest wall. **B,** Lateral upright view shows two meniscus densities, suggesting bilateral pleural effusions. The posterior diaphragmatic recess is filled with pleural fluid, which forms a meniscus with the posterior chest wall. (From Broder JS: *Diagnostic imaging for the emergency physician*, Philadelphia, 2011, Saunders.)

TABLE 2 Treatment Options for Pleural Effusion

Thoracentesis	Site selection should be guided by ultrasonography whenever possible; evacuation of pleural fluid can be limited when the lung cannot fully re-expand, including central airway obstruction, chronic atelectasis, and the presence of extensive pleural adhesions; aspiration in these circumstances can lead to pneumothorax ex vacuo
Tube thoracostomy	Consider when ongoing drainage will be needed, especially for empyema or hemothorax
Indwelling tunneled pleural catheter	A cuffed pleural drainage catheter tunneled through subcutaneous tissue, drained regularly on an outpatient basis, most commonly used to manage malignant pleural effusions
Pleurodesis	Instillation of a chemical irritant under direct thoracoscopic visualization (e.g., talc poudrage) or via tube thoracostomy to adhere the visceral and parietal pleurae
Pharmacotherapy	Based on underlying etiology (e.g., diuretics, antimicrobials, chemotherapy)

- Fig. E6 describes a treatment approach to malignant pleural effusions.

REFERRAL

Negative diagnostic workup after initial pleural fluid sampling should be followed by referral to a pulmonologist for further evaluation (including consideration for thoracoscopy for pleural biopsy).

PEARLS & CONSIDERATIONS

- One-time drainage of pleural effusions alone is seldom a definitive therapy. Early identification of the underlying etiology of new effusions should be pursued.
- Managing patients with malignant pleural effusion can be challenging. A recent trial showed that, among patients with malignant pleural effusion, outpatient administration of talc via an indwelling tunneled pleural catheter resulted in a higher rate of pleurodesis than placement of a tunneled catheter alone.[1]
- In patients with malignant pleural effusion near the end of life, simple thoracentesis, repeated as needed, is a reasonable strategy.

[1]Bhatnagar R et al: Outpatient talc administration by indwelling pleural catheter for malignant effusion, *NEJM* 378:1313–1322, 2018.

BASIC INFORMATION

DEFINITION

Pleurisy refers to the inflammation of the parietal pleura. This inflammation results in pleuritic chest pain that is characteristically worsened with respiration or movement.

SYNONYM

Pleuritis

ICD-10CM CODE
R09.1 Pleurisy

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: One of the most common causes of pleuritic chest pain is viral pleurisy. However, there are a variety of disorders that may result in pleurisy. Infectious diseases, rheumatologic disorders, thromboembolic events, and trauma may all lead to pleural inflammation. Therefore, the incidence of pleurisy varies in accordance with the underlying etiology.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- The defining characteristic of pleurisy is chest pain that worsens with respiration, coughing, or sneezing.
- Pleuritic chest pain is typically described as sharp or stabbing. However, pleuritic chest pain may also be described as dull pain, burning pain, or a "catch" while breathing.
- Movements of the trunk or chest wall may exacerbate pain. Patients with pleurisy may locate the position of minimal discomfort and remain still in that position.
- Dyspnea may be associated with pleurisy.
- Physical exam may be remarkable for a pleural friction rub.
- Decreased breath sounds, rales, or egophony may be appreciated if pneumonia is the underlying etiology of the patient's pleurisy.

ETIOLOGY

- Pleurisy is caused by inflammation of the parietal pleura. The visceral pleura is not innervated by nociceptors. However, injury or inflammation at the periphery of the lung parenchyma often results in inflammation of the overlying parietal pleura. The parietal pleura, which lines the rib cage and the lateral portion of each hemidiaphragm, is innervated by intercostal nerves; therefore pain is localized to the cutaneous distribution of those nerves (over the chest wall). The parietal pleura of the central diaphragm is innervated by fibers that travel with the phrenic nerve; therefore pain associated with inflammation in this area is referred to the ipsilateral shoulder or neck.
- Various underlying etiologies may result in pleurisy, including the following:
  1. Thromboembolism (pulmonary embolism)
  2. Viral infection (coxsackieviruses, respiratory syncytial virus [RSV], cytomegalovirus [CMV], adenovirus, Epstein-Barr virus [EBV], parainfluenza, influenza)
  3. Bacterial infection (pneumonia or tuberculous pleuritis)
  4. Fungal infection (coccidioidomycosis, histoplasmosis)
  5. Rheumatologic disease (rheumatoid arthritis, systemic lupus erythematosus [SLE])
  6. Medications
  7. Malignancy of the lung or pleura
  8. Trauma (rib fracture)
  9. Hereditary (familial Mediterranean fever, sickle cell disease)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cardiac: Myocardial infarction, ischemia, pericarditis
- Intraabdominal process: Pancreatitis, cholecystitis
- Thromboembolic: Pulmonary embolism, infarction of lung parenchyma
- Traumatic/mechanical: Rib fracture or pneumothorax
- Viral infection: Viral infections may lead to epidemic pleurodynia (also known as Bornholm disease). Implicated viruses include coxsackieviruses, RSV, CMV, adenovirus, EBV, parainfluenza, influenza. Of note, viral pleurisy is a diagnosis of exclusion
- Bacterial infection: Pneumonia or tuberculous pleurisy
- Fungal infection: Coccidioidomycosis, histoplasmosis
- Rheumatologic disease: Rheumatoid arthritis, SLE
- Medications: Drug-induced lupus
- Hereditary causes: Familial Mediterranean fever, sickle cell disease
- Malignancy: Malignancy affecting the lung or pleura
- Uremia

WORKUP

- A thorough history and physical exam of all patients presenting with pleuritic chest pain should be taken. The time course of the patient's symptoms can provide valuable diagnostic clues. Acute onset of symptoms is suggestive of traumatic injuries, spontaneous pneumothorax, pulmonary embolism, or myocardial infarction. Subacute onset of symptoms suggests a potential infectious, rheumatologic, or medication-induced cause. Viral pleurisy is often associated with prodromal symptoms of upper respiratory infection. Chronic or recurrent symptoms suggest a potential malignant, tuberculous, or hereditary cause.
- Chest x-ray to evaluate for pneumonia, pneumothorax, or pleural effusion.
- ECG to evaluate for infarction, ischemia, or pericarditis.
- Evaluation for pulmonary embolism should be undertaken if clinical suspicion exists.

LABORATORY TESTS

- Laboratory testing varies based on suspected underlying etiology. Consider CBC, Chem 7, and D-Dimer testing depending on clinical presentation.
- If a pleural effusion is present, diagnostic thoracentesis may provide valuable diagnostic clues to the underlying etiology.

IMAGING STUDIES

- Chest x-ray
- ECG
- CT chest in selected patients

TREATMENT

- Treatment of pleurisy consists of pain control as well as treating the underlying condition.
- NSAIDs are the preferred first-line agent to control pain associated with pleurisy. Human studies have been limited to trials using indomethacin for pain control, although an NSAID class effect is presumed.
- Indomethacin 50 mg orally up to three times a day has been found to be effective in relieving pain and is associated with an improvement in mechanical lung function.

AUTHOR: **Chakravarthy Reddy, MD**

BASIC INFORMATION

DEFINITION

Pneumonia is defined as inflammation of the pulmonary parenchyma caused by an infectious agent (in this case, bacteria). It can be further categorized as community-acquired or health care-associated. The definition of community-acquired pneumonia (CAP), traditionally referred to alveolar infection that develops in the outpatient setting or within 48 hours of admission, now includes patients previously categorized as having health care-associated pneumonia (HCAP) since the microbiology and treatment is similar. Hospital-acquired pneumonia (HAP) is pneumonia occurring ≥48 hours after hospital admission and not incubating at the time of admission.

SYNONYMS

Community-acquired pneumonia
CAP

ICD-10CM CODES

J15.9	Unspecified bacterial pneumonia
J13	Pneumonia due to *Streptococcus pneumoniae*
J15.1	Pneumonia due to *Pseudomonas*
J15.20	Pneumonia due to staphylococcus, unspecified
J15.0	Pneumonia due to *Klebsiella pneumoniae*
J14	Pneumonia due to *Haemophilus influenzae*
J15.211	Pneumonia due to methicillin-susceptible *Staphylococcus aureus*
J15.212	Pneumonia due to methicillin-resistant *Staphylococcus aureus*
J15.6	Pneumonia due to other aerobic gram-negative bacteria
J15.7	Pneumonia due to *Mycoplasma pneumoniae*

EPIDEMIOLOGY & DEMOGRAPHICS

- The annual incidence of pneumonia in the U.S. is 24.8 cases per 10,000 adults, with the highest rates among adults between 65 and 79 yr of age (63 cases per 10,000 adults) and those 80 yr or older (164.3 cases per 10,000 adults). Health care expenditures for CAP exceed $10 billion annually.
- Hospitalization rate for pneumonia is 15% to 20%. Incidence is highest among the oldest adults.
- In 2014, the eighth leading cause of mortality in the U.S. reported by the National Center for Health Statistics was influenza and pneumonia together.
- Globally, *Streptococcus pneumoniae* (pneumococcus) is the most common pathogen causing community-acquired pneumonia.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Fever, tachypnea, chills, tachycardia, cough; pleurisy in the case of pleural effusion.
- Presentation varies with the cause of pneumonia, the patient's age, and the clinical situation:
  1. Patients with streptococcal pneumonia usually present with high fever, chills, atypical chest pain, cough, and copious production of rusty-appearing purulent sputum. Pleurisy in the setting of parapneumonic effusions can also occur. Potential complications include bacteremia, empyema, and distant infections (e.g., meningitis).
  2. *Mycoplasma pneumoniae:* Insidious onset; headache; dry, paroxysmal cough that is worse at night; myalgias; malaise; sore throat; extrapulmonary manifestations (e.g., erythema multiforme, aseptic meningitis, urticaria, erythema nodosum) may be present.
  3. *Chlamydia pneumoniae:* Persistent, nonproductive cough, low-grade fever, headache, sore throat.
  4. *Legionella pneumophila:* High fever, mild cough, mental status change, myalgias, diarrhea, respiratory failure.
  5. MRSA pneumonia: Often preceded by influenza, may present with shock and respiratory failure.
  6. Elderly or immunocompromised hosts with pneumonia may initially present with only minimal symptoms (e.g., low-grade fever, confusion); respiratory and nonrespiratory symptoms are less commonly reported by older patients with pneumonia.
  7. In general, auscultation of patients with pneumonia reveals crackles and diminished breath sounds.
  8. Dullness on percussion may be an indication that pleural effusion is present.
  9. The clinical impression of pneumonia has an overall sensitivity of 70% to 90%; specificity ranges from 40% to 70%.

ETIOLOGY

- Table 1 summarizes common pathogens causing CAP
- *Streptococcus pneumoniae* (5% to 15% of hospitalized CAP cases): Incidence has been declining due to widespread use of pneumococcal vaccination and reduced rate of cigarette smoking
- *Haemophilus influenzae* (3% to 10% of CAP cases)
- *L. pneumophila* (1% to 5% of adult pneumonias) (2% to 8% of CAP cases)
- *Klebsiella pneumoniae, Pseudomonas aeruginosa, Escherichia coli*
- *Staphylococcus aureus* (3% to 5% of CAP cases)
- Atypical organisms such as *Mycoplasma pneumoniae, Chlamydia pneumoniae,* and *Legionella pneumophila* implicated in up to 40% of cases of CAP
- Influenza infection is one of the important predisposing factors to *S. pneumoniae* and *S. aureus* pneumonia; gram-negative organisms cause >80% of nosocomial pneumonias
- Predisposing factors (Table 2 and Table 3):
  1. Chronic obstructive pulmonary disease: *H. influenzae, S. pneumoniae, Legionella, Moraxella catarrhalis*
  2. Seizures: Aspiration pneumonia
  3. Compromised hosts: *Legionella*, gram-negative organisms
  4. Alcoholism: *K. pneumoniae, S. pneumoniae, H. influenzae*
  5. HIV: *S. pneumoniae*
  6. IV drug addicts with right-sided bacterial endocarditis: *S. aureus*
  7. Older patient with comorbid diseases: *C. pneumoniae*

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Viral pneumonias: Viral pneumonias/pneumonitis are on the rise. Several viruses alone or in combination can cause pneumonias in adults. Influenza is the predominant virus, but respiratory syncytial virus (RSV), parainfluenza viruses, adenoviruses, rhinoviruses, coronaviruses, and human metapneumovirus are all possible etiologies. The diagnosis is based on clinical suspicion, negative bacterial workup, and/or respiratory cultures, serologies, or rapid PCR testing
- Exacerbation of chronic bronchitis
- Pulmonary embolism or infarction
- Lung neoplasm
- Bronchiolitis
- Sarcoidosis
- Hypersensitivity pneumonitis
- Pulmonary edema
- Drug-induced lung injury
- Fungal pneumonias
- Parasitic pneumonias
- Atypical pneumonia
- Tuberculosis

WORKUP

Diagnostic testing for CAP is summarized in Table 4. Useful tools for assessing severity of illness are the *CURB-65* (see "Disposition") and *Pneumonia Severity Index* (Fig. 1 and Box 1). Poor prognostic indicators are hypotension (SBP <90 or DBP <60), respiratory rate >30/min, fever (>40° C; 104° F), or hypothermia (<35° C; 95° F). None of these indices is as valuable as clinical judgment.

LABORATORY TESTS

- Complete blood count with differential; white blood cell count is elevated, usually with left shift or the presence of bandemia
- Blood cultures (hospitalized patients only): Positive in approximately 20% of cases of pneumococcal pneumonia
- Pneumococcal urinary antigen test can be used to detect the C-polysaccharide antigen of *S. pneumoniae* (70% sensitivity). It is a useful tool in the treatment of hospitalized adult patients with CAP
- When suspecting *Legionella,* a respiratory specimen culture on special media and/or a urinary antigen should be requested

TABLE 1 Common Pathogens Causing Community-Acquired Pneumonia

Inpatient, with No Cardiopulmonary Disease or Modifying Factors

Streptococcus pneumoniae, Haemophilus influenzae, Mycoplasma pneumoniae, Chlamydophila pneumoniae, mixed infection (bacteria plus atypical pathogen), viruses (including influenza), *Legionella* spp., and others (*Mycobacterium tuberculosis*, endemic fungi, *Pneumocystis jirovecii*)

Inpatient, with Cardiopulmonary Disease and/or Modifying Factors

All of the above, but drug-resistant *S. pneumoniae* (DRSP) and enteric gram-negative organisms are more of a concern

Severe Community-Acquired Pneumonia, with No Risks for *Pseudomonas Aeruginosa*

S. pneumoniae (including DRSP), *Legionella* spp., *H. influenzae*, enteric gram-negative bacilli, *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), *M. pneumoniae*, respiratory viruses (including influenza), others (*C. pneumoniae, M. tuberculosis*, endemic fungi)

Severe CAP, with Risks for *P. Aeruginosa*

All of the pathogens above plus *P. aeruginosa*

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

TABLE 2 Risk Factors for Developing Severe Community-Acquired Pneumonia

Advanced age
Comorbid illness (e.g., chronic respiratory illness, cardiovascular disease, diabetes mellitus, neurologic illness, renal insufficiency, malignancy)
Cigarette smoking
Alcohol abuse
Absence of antibiotic therapy before hospitalization
Failure to contain infection to its initial site of entry
Immune suppression
Genetic polymorphisms in the immune response

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

TABLE 3 Clinical Associations with Specific Pathogens

Condition	Commonly Encountered Pathogens
Alcoholism	*Streptococcus pneumoniae* (including penicillin-resistant), anaerobes, gram-negative bacilli (possibly *Klebsiella pneumoniae)*, tuberculosis
Chronic obstructive pulmonary disease/current or former smoker	*S. pneumoniae, Haemophilus influenzae, Moraxella catarrhalis*
Residence in nursing home	*S. pneumoniae*, gram-negative bacilli, *H. influenzae, Staphylococcus aureus, Chlamydophila pneumoniae;* consider *M. tuberculosis.* Consider anaerobes, but these are less common
Poor dental hygiene	Anaerobes
Bat exposure	*Histoplasma capsulatum*
Bird exposure	*Chlamydophila psittaci, Cryptococcus neoformans, H. capsulatum*
Rabbit exposure	*Francisella tularensis*
Travel to southwestern United States	*Coccidioidomycosis;* hantavirus in selected areas
Exposure to farm animals or parturient cats	*Coxiella burnetii* (Q fever)
Postinfluenza pneumonia	*S. pneumoniae, S. aureus* (including the community-acquired strain of methicillin-resistant *S. aureus*), *H. influenzae*
Structural disease of the lung (e.g., bronchiectasis, cystic fibrosis)	*Pseudomonas aeruginosa, Pseudomonas cepacia,* or *S. aureus*
Sickle cell disease, asplenia	Pneumococcus, *H. influenzae*
Suspected bioterrorism	Anthrax, tularemia, plague
Travel to Asia	Severe acute respiratory syndrome, tuberculosis, melioidosis

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

- Serologic testing for HIV in selected patients
- Serum electrolytes (hyponatremia in suspected *Legionella* pneumonia), BUN, creatinine
- Test for and treat influenza during flu season[1]

[3]Metlay JP et al: Diagnosis and Treatment of Adults with Community-acquired Pneumonia. An Official Clinical Practice Guideline of the American Thoracic Society and Infectious Diseases Society of America, *Am J Respir Crit Care Med* 200:e45–e67, 2019 .

- Serum procalcitonin level: Often used to distinguish pneumonia from heart failure in patients presenting to the emergency department with acute dyspnea. The procalcitonin level is significantly higher in patients with pneumonia than in those without.[1] However, serum procalcitonin should not be used to determine initiation or duration of antibiotic therapy in patients with radiographically confirmed CAP unless antibiotic therapy is being extended beyond 5 to 7 days. Recent trials regarding procalcitonin-guided use of antibiotics for lower respiratory tract infections did not result in less use of antibiotics than did usual care among patients with suspected lower respiratory tract infection[2]
- Pulse oximetry or arterial blood gases: Hypoxemia with partial pressure of oxygen <60 mm Hg while the patient is breathing room air, a standard criterion for hospital admission
- Fig. 2 illustrates an algorithm for the diagnosis and treatment of nosocomial pneumonia

IMAGING STUDIES

Chest x-ray (PA and lateral) (Fig. 3): Findings vary with the stage and type of pneumonia and the hydration of the patient:

- Classically, pneumococcal pneumonia presents with a segmental lobe infiltrate.
- Diffuse infiltrates on chest x-ray can be seen with *L. pneumophila* (Fig. 4), *M. pneumoniae,* viral pneumonias, *P. jirovecii (carinii),* miliary tuberculosis, aspiration, aspergillosis.
- An initial chest x-ray is also useful to rule out the presence of any complications (pneumothorax, empyema, abscesses).

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Avoidance of tobacco use
- Oxygen to maintain partial oxygen pressure in arterial blood >60 mm Hg or oxygen saturation >88% in COPD patients and >92% in non-COPD patients
- IV hydration, correction of dehydration
- Assisted ventilation in patients with significant respiratory failure

ACUTE GENERAL Rx

- Antibiotic therapy should be based on clinical, radiographic, and laboratory evaluation. Empiric therapy regimens for severe community-acquired pneumonia are summarized in Table 5.
- Macrolides (azithromycin or clarithromycin) or doxycycline can be used for empiric outpatient treatment of CAP as long as the patient has not received antibiotics within the past 3 mo and does not reside in a community in which the prevalence of macrolide resistance is high. Updated guidelines from the American Thoracic Society and Infectious Diseases Society of America[3] have added amoxicillin as a first-line agent for heart adult outpatients

[1]Alba GA et al: Diagnostic and prognostic utility of procalcitonin in patients presenting to the emergency department with dyspnea, *Am J Med* 129:96, 2016.

TABLE 4 Diagnostic Testing for Community-Acquired Pneumonia

Test	Sensitivity	Specificity	Comment
Chest radiograph	65%-85%	85%-95%	Computed tomography is more sensitive to infiltrates. Recommended for all patients.
Computed tomography	Gold standard	Not infection specific	Should not be performed routinely but helpful to identify cavitation and loculated pleural fluid. Recommended in the evaluation of nonresponding patients.
Blood cultures	10%-20%	High when positive	Usually shows pneumococcus (in 50%-80% of positive samples) and defines antibiotic susceptibility. Recommended in patients with severe CAP, particularly if not on antibiotic therapy at the time of testing.
Sputum Gram stain	40%-100% depending on criteria	0%-100% depending on criteria	Can correlate with sputum culture to define predominant organism and can be used to identify unsuspected pathogens. Recommended if sputum culture is obtained. May not be able to narrow empiric therapy choices.
Sputum culture			Use if suspect drug-resistant or unusual pathogen, but a positive result cannot differentiate colonization from infection. Obtain via tracheal aspirate in all intubated patients.
Oximetry or arterial blood gas			Define both severity of infection and need for oxygen; if hypercarbia is suspected, a blood gas sample is needed. Recommended in severe community-acquired pneumonia.
Serologic testing for *Legionella, Chlamydophila pneumoniae, Mycobacterium pneumoniae*, viruses			Accurate, but usually requires acute and convalescent titers collected 4 to 6 wk apart. Not routinely recommended.
Legionella urinary antigen	50%-80%		Specific to serogroup 1, but the best acute diagnostic test for *Legionella.*
Pneumococcal urinary antigen	70%-100%	80%	False positives if recent pneumococcal infection. Can increase sensitivity with concentrated urine.
Serum procalcitonin			Not a routine test, but if performed, should be measured with the highly sensitive Kryptor assay. May help guide duration of therapy and need for ICU admission.

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

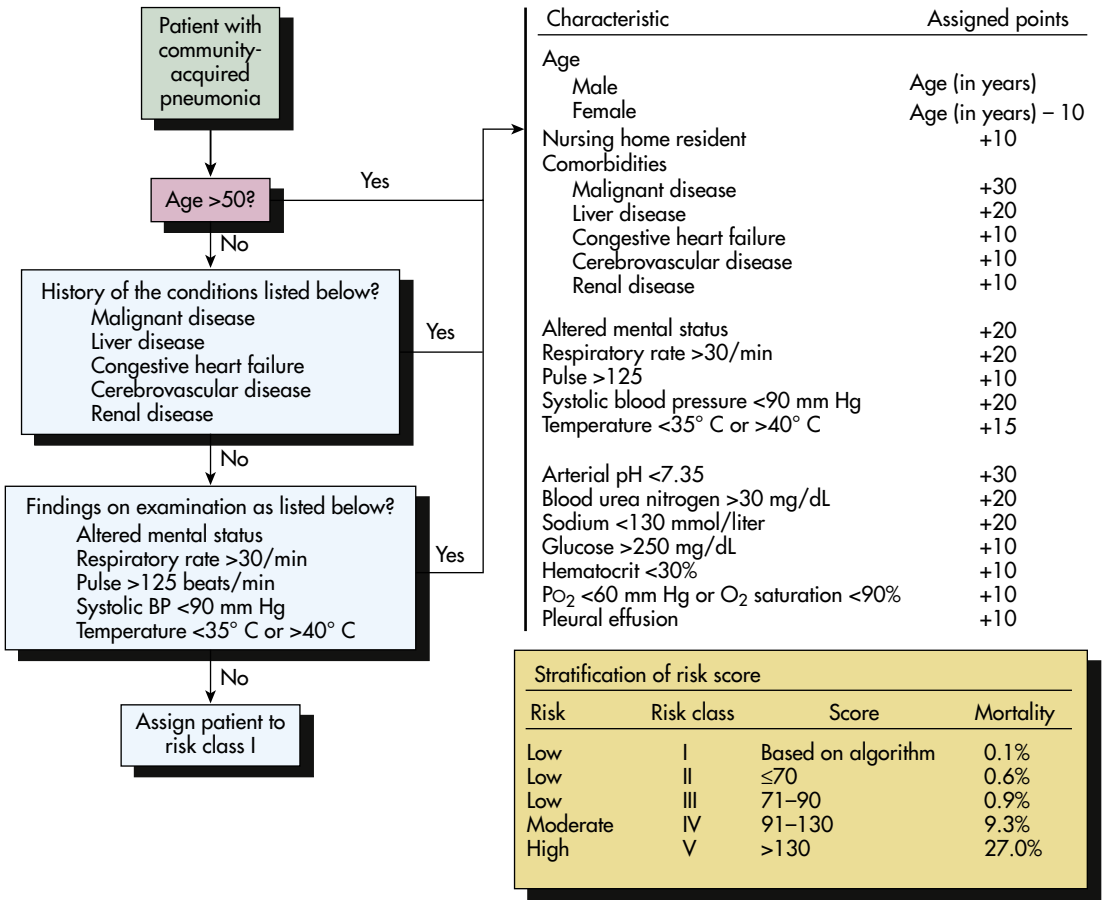

FIG. 1 The pneumonia severity index. *BP,* Blood pressure; *O_2,* oxygen; *P_{O_2},* partial pressure of oxygen. (From Sellke FW et al: *Sabiston & Spencer surgery of the chest,* ed 9, 2016, Elsevier.)

BOX 1 Severe Pneumonia: Diagnostic Criteria[1]

Major Criteria
Invasive mechanical ventilation
Use of vasopressors to maintain blood pressure

Minor Criteria
Respiratory rate ≥30 breaths/min
Multilobar infiltrates
New-onset confusion/disorientation
Uremia (BUN >20 mg/dl)
Leukopenia (WBC count <4000 cells/μL)
Pao_2/Fio_2 ratio ≥250
Thrombocytopenia (platelet count <100,000 cells/μL)
Hypothermia (core temperature <36°C; 96.8º F)
Hypotension requiring aggressive fluid resuscitation

ATS/IDSA, American Thoracic Society/Infectious Diseases Society of America; *BUN,* blood urea nitrogen; *WBC,* white blood cell.
[1]According to ATS/IDSA 2007 guidelines.
From Parrillo JE, Dellinger RP: *Critical care medicine: principles of diagnosis and management in the adult,* ed 4, Philadelphia, 2014, Saunders.

with CAP. Fig. 5 summarizes empiric therapy for CAP. The treatment of choice in suspected *Legionella* pneumonia is either a quinolone (e.g., moxifloxacin) or a macrolide (e.g., azithromycin) antibiotic. A beta-lactam antibiotic is usually added to macrolides.

- In the hospital setting, patients admitted to the general ward can be treated empirically with a second- or third-generation cephalosporin (ceftriaxone, cefotaxime, or cefuroxime) plus a macrolide (azithromycin or clarithromycin) or doxycycline. An antipseudomonal quinolone (levofloxacin or moxifloxacin) can be substituted in place of the macrolide or doxycycline.
- Empiric therapy in ICU patients: IV beta-lactam (ceftriaxone, cefotaxime, ampicillin-sulbactam) plus an IV quinolone (levofloxacin, moxifloxacin) or IV azithromycin.
- In hospitalized patients at risk for *P. aeruginosa* infection, empiric treatment should consist of an antipseudomonal beta-lactam (meropenem, doripenem, imipenem, or piperacillin-tazobactam) with or without a second antipseudomonal agent such as an aminoglycoside or an antipseudomonal quinolone.
- In patients with suspected methicillin-resistant *S. aureus,* vancomycin or linezolid is effective.
- Corticosteroids: Corticosteroids (i.e., methylprednisolone 0.5 mg/kg IV q12h for 5 days) are often administered in hospitalized adult patients presenting with severe CAP.
- Adjunctive treatment with corticosteroids improves initial clinical response and reduces length of hospital stay but does not offset mortality or clinical failure and increases readmission rate in hospitalized patients with CAP. Recent guidelines[4] do not recommend routine treatment with corticosteroids in CAP except in patients with concurrent refractory septic shock.
- Duration of treatment ranges from 5 to 14 days. Trials have shown that in adults hospitalized with CAP, stopping antibiotic treatment after 5 days in clinically stable patients is reasonable and noninferior to usual care. Hematogenous *Staphylococcus* infection, abscesses, and cavitary lesions might require prolonged antibiotic therapy, sometimes until radiological resolution is documented.

CHRONIC Rx

Parapneumonic effusion and empyema can be managed with chest tube placement for drainage. Instillation of fibrinolytic agents (streptokinase, urokinase, or, more commonly, tissue plasminogen activator [TP]) along with DNase (i.e., dornase alfa) twice a day via chest tube may facilitate the drainage of effusions not responding to chest tube drainage alone. A thoracoscopic debridement or a surgical decortication may be necessary in resistant cases.

DISPOSITION

Risk factors for a poor outcome from CAP are summarized in Table E6. Indications for hospital admission are:

- Hypoxemia (oxygen saturation <90% while patient is breathing room air)
- Hemodynamic instability
- Inability to tolerate medications
- Active coexisting condition requiring hospitalization. A criterion often used to determine hospital admission is known as the "CURB-65": **C**onfusion, B**U**N >19.6 mg/dl, **R**espiratory rate >30 breaths/min, systolic **B**P <90 mg Hg, and diastolic BP ≤60 mm Hg, age ≥**65.** Patients are generally admitted to the hospital if they fulfill 2 or more criteria and to the ICU if they have 3 or more criteria

PEARLS & CONSIDERATIONS

COMMENTS

- Use of gastric acid suppressive therapy (H_2 receptor antagonists, proton pump inhibitors [PPIs]) has been reported to increase the risk of CAP. It has been reported that PPI therapy started within the previous 30 days is associated with a risk for CAP, whereas longer-term current use is not. Recent studies have failed to confirm increased risk of CAP with PPI use and have shown that risk of CAP is higher during 30 days before PPI prescription than during the 30 days after PPI prescription.[4]
- Causes of slowly resolving or nonresolving pneumonia:
  1. Difficult to treat infections: Viral pneumonia, *Legionella,* pneumococci or staphylococci with impaired host response, tuberculosis, fungi
  2. Neoplasm: Lung, lymphoma, metastasis
  3. Congestive heart failure
  4. Pulmonary embolism
  5. Immunologic or idiopathic: Wegener granulomatosis, pulmonary eosinophilic syndromes, systemic lupus erythematosus
  6. Drug toxicity (e.g., amiodarone)
- If patients with pneumonia don't improve within a reasonable time frame, repeat films should be taken promptly. In those with complete clinical recovery, it is reasonable to wait 6 to 8 wk before repeating the imaging study to document clearing of the infiltrate. The benefit of routine radiography after pneumonia has been questioned due to the low 1-yr incidence of lung cancer. Opponents propose a selective approach limiting follow-up chest x-ray to middle-aged and older adults.
- Prevention: The 23-valent pneumococcal polysaccharides vaccine (PPSV23) and the pneumococcal conjugated vaccine (PCV13) are currently available for older adults. The ACIP recommends giving the PCV13 first to be followed after a yr by the PPSV23. This recommendation includes patients younger than 65 yr with some defined risk factors (end-stage renal disease, sickle cell disease, congenital or acquired asplenia, HIV infection, congenital or acquired immunodeficiency, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, iatrogenic immunosuppression, solid organ transplant, multiple myeloma, CSF leak, cochlear implant). The CDC no longer supports routine administration of PVC13 to older adults (≥65) and limits its administration to compromised older adults and those with cerebrospinal fluid leak or cochlear implants.
- Prevention: During the influenza season, patients should also receive influenza vaccination.

TABLE 5 Empiric Therapy Regimens for Severe Community-Acquired Pneumonia

No Pseudomonal Risk Factors

Selected beta-lactam (cefotaxime, ceftriaxone)

plus

Intravenously administered macrolide *or* quinolone (moxifloxacin or levofloxacin*)

Pseudomonal Risk Factors Present

Selected antipseudomonal beta-lactam (cefepime, piperacillin/tazobactam, imipenem, meropenem)

plus

Ciprofloxacin

or

Selected antipseudomonal beta-lactam

plus

Aminoglycoside

plus

Intravenously administered macrolide or antipneumococcal quinolone (moxifloxacin or levofloxacin*)

NOTE: Although routine methicillin-resistant *Staphylococcus aureus* (MRSA) coverage is NOT recommended for all severe community-acquired pneumonia, consider community-acquired MRSA, especially after influenza and with bilateral necrotizing pneumonia, and if suspected, treat by adding either linezolid or the combination of vancomycin and clindamycin.

*For patients with normal renal function, the recommended dose of levofloxacin is 750 mg daily.

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

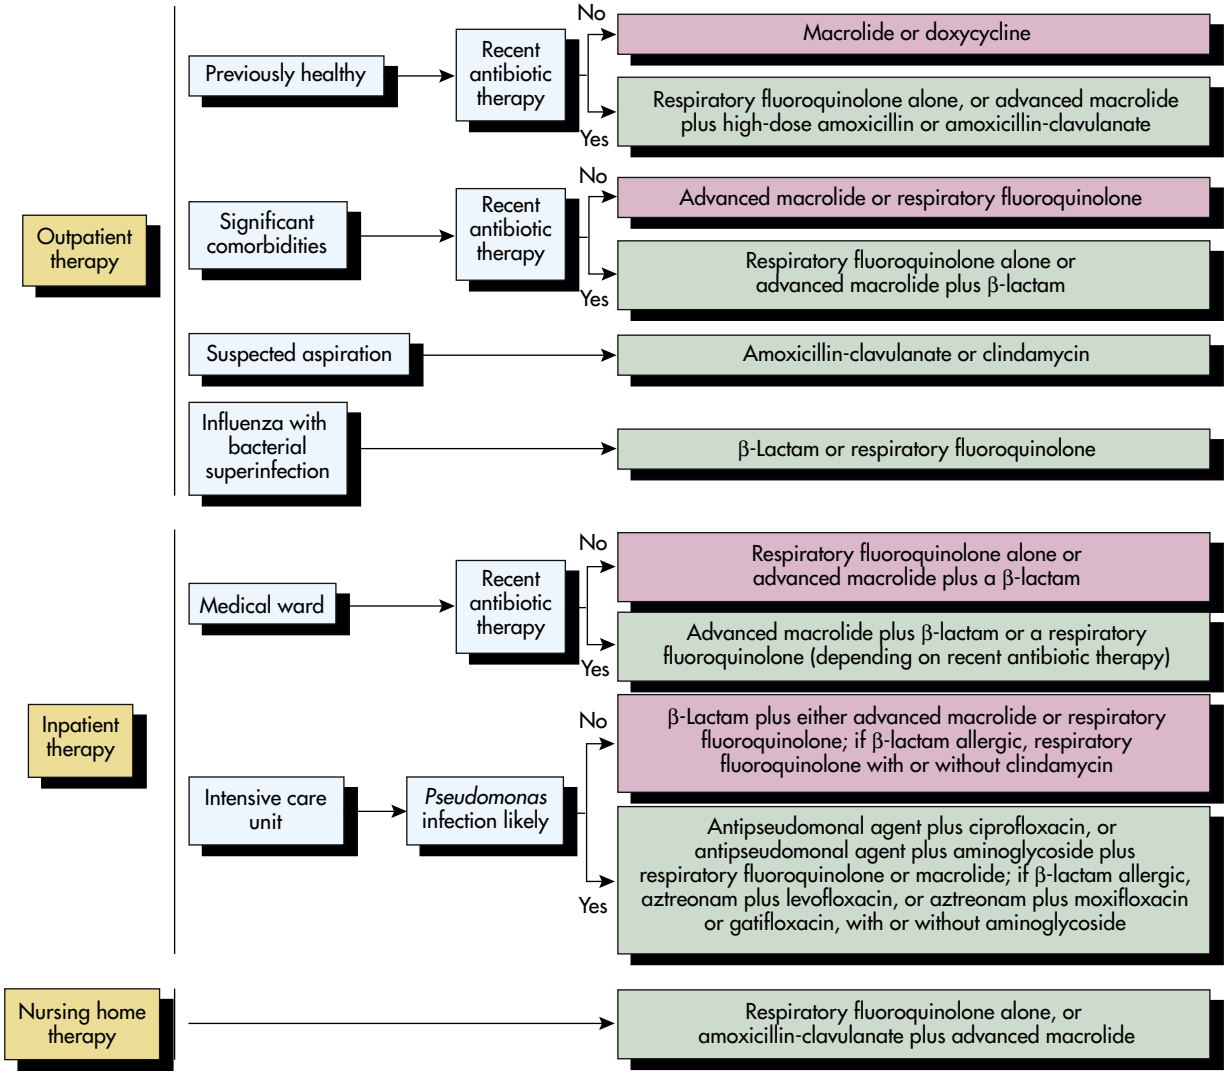

FIG. 5 Empiric therapy for community-acquired pneumonia. (From Sellke FW, del Nido PJ, Swanson SJ: *Sabiston & Spencer surgery of the chest,* ed 9, Philadelphia, 2016, Elsevier.)

TABLE E6 Risk Factors for a Poor Outcome from Community-Acquired Pneumonia

Patient-Related Factors

Male sex
Absence of pleuritic chest pain
Nonclassic clinical presentation
Neoplastic illness
Neurologic illness
Age >65 yr
Family history of severe pneumonia or death from sepsis

Abnormal Physical Findings

Respiratory rate >30 breaths/min on admission
Systolic (<90 mm Hg) or diastolic (<60 mm Hg) hypotension
Tachycardia (>125 beats/min)
High fever (>40° C; 104° F) or afebrile
Confusion

Laboratory Abnormalities

Blood urea nitrogen >19.6 mg/dl
Leukocytosis or leukopenia (<4000/mm^3)
Multilobar radiographic abnormalities
Rapidly progressive radiographic abnormalities during therapy
Bacteremia
Hyponatremia (<130 mmol/L)
Multiple organ failure
Respiratory failure
Hypoalbuminemia
Thrombocytopenia (<100,000/mm^3) or thrombocytosis (>400,000/mm^3)
Arterial pH <7.35
Pleural effusion

Pathogen-Related Factors

High-risk organisms
Type III pneumococcus, *Staphylococcus aureus*, gram-negative bacilli (including *Pseudomonas aeruginosa*), aspiration organisms, severe acute respiratory syndrome
Possibly high levels of penicillin resistance (minimal inhibitory concentration of at least 4 mg/L) in pneumococcus

Therapy-Related Factors

Delay in initial antibiotic therapy (more than 4 hours)
Initial therapy with inappropriate antibiotic therapy
Failure to have a clinical response to empiric therapy within 72 hours

From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

BASIC INFORMATION

DEFINITION

Mycoplasma pneumonia is an infection of the lung parenchyma caused by a small rod-shaped bacterium, *Mycoplasma pneumoniae.*

SYNONYMS

Primary atypical pneumonia
Eaton pneumonia
Walking pneumonia

ICD-10CM CODE

J15.7 Pneumonia due to *Mycoplasma pneumoniae*

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- It is a frequent cause of community-acquired pneumonia (CAP), accounting for up to 37% of CAP in patients treated as outpatients and 10% of pneumonia in persons requiring hospitalization. The Centers for Disease Control (CDC) estimates 2 million cases a yr with 100,000 pneumonia-related hospitalizations.
- Many cases probably resolve without coming to medical attention.
- Incidence is estimated at one case per 1000 persons annually.
- Incidence is estimated to at least triple every (approximately) 5 yr during epidemics.

PREVALENCE (IN U.S.):

- Estimated to be present in one in every five patients hospitalized for pneumonia (generally a self-limited disease, so its true prevalence is unknown)
- Estimated to cause 7% of all cases of pneumonia and approximately half the cases in those aged 5 to 20 yr

PEAK INCIDENCE:

- Some increased incidence in fall to early winter
- Seems more prevalent in temperate climates

PREDOMINANT SEX: Equal distribution

PREDOMINANT AGE:

- Most commonly affected: School-age children and young adults (ages 5 to 20 yr)
- Occurs in older adults as well, especially with household exposure to a young child
- More severe infections in affected elderly patients

GENETICS: Familial disposition:

- None known
- May be more severe in patients with sickle cell anemia
- Neonatal infection: Severe respiratory distress, sometimes requiring intubation, attributed to this disease in infants

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Nonexudative pharyngitis (common)
- Headache, otalgia common
- Fever may be mild or not present
- Rhonchi or rales without evidence of consolidation (common) in lower lung zones
- Associated with bullous myringitis (nonspecific finding; perhaps no more frequently than in other pneumonias)
- Skin rashes in up to one fourth of patients:
  1. Morbilliform
  2. Urticaria
  3. Erythema nodosum (unusual)
  4. Erythema multiforme (unusual)
  5. Stevens-Johnson syndrome (rare)
- Muscle tenderness (<50% of the patients)
- On examination (and confirmed with testing)
  1. Mononeuritis or polyneuritis
  2. Transverse myelitis
  3. Cranial nerve palsies
  4. Meningoencephalitis
- Lymphadenopathy and splenomegaly
- Conjunctivitis
- Table 1 summarizes the clinical manifestations of *Mycoplasma pneumoniae*

ETIOLOGY

- Infection is spread person-to-person via respiratory droplets or secretions with an incubation period of 1 to 4 wk. Incubation period is generally 2 to 3 wk.
- Mycoplasma are the smallest free-living organisms and lack a cell wall and are not visible after Gram staining.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- *Chlamydia* (now known as *Chlamydophila) pneumoniae*
- *Chlamydophila psittaci*
- *Legionella* spp
- *Coxiella burnetii*
- Several viral agents
- Q fever
- *Streptococcus pneumoniae*
- Pulmonary embolism or infarction

WORKUP

- Chest x-ray (Fig. 1)
- Thorough history and physical examination
- Laboratory tests
- Evaluation guided by symptoms and findings

LABORATORY TESTS

- White blood cells (WBCs):
  1. WBC count >10,000/mm^3 in approximately one fourth of patients
  2. Differential count nonspecific
  3. Leukopenia rare
- Cold agglutinins:
  1. Detected in approximately 50% to 70% of all patients within 1 to 2 wk after infection; highest in children with yield decreasing with age. Since neither sensitive nor specific, the use of cold agglutinins has come into question
  2. Also may be found in:
     a. Lymphoproliferative diseases
     b. Influenza
     c. Mononucleosis
     d. Adenovirus infections
     e. Occasionally, Legionnaires' disease
  3. Titers typically >1:64:
     a. May be detectable with bedside testing
     b. Appear between days 5 and 10 of the illness (so may be demonstrable when patient is first examined) and disappear within 1 mo
- Complement fixation testing assay specific for mycoplasma antigens of paired sera (fourfold rise) or a single titer ≥1:32 in patients with pneumonia and a compatible history:
  1. Considered diagnostic in the appropriate clinical setting
  2. Other assays include enzyme-linked immunosorbent assay (ELISA), antigen capture-enzyme immunoassay, and polymerase chain reaction (PCR); if available, is considered diagnostic test of choice on nasopharyngeal samples
- Culture of the organism from specimens
  1. Only truly specific test for infection
  2. Technically difficult and done reliably by few laboratories
  3. May require weeks to get results
- Sputum:
  1. Often no sputum produced for laboratory testing
  2. When present, Gram-stained specimens show polymorphonuclear cells without organisms
- Infection occasionally complicated by pancreatitis or glomerulitis
- Disseminated intravascular coagulation is a rare complication
- Electrocardiographic evidence of pericarditis or myocarditis may be present

TABLE 1 Clinical Manifestations of *Mycoplasma pneumoniae* Infection

Respiratory tract	Pharyngitis, laryngitis, acute bronchitis, bronchopneumonia
Skin and mucosa	Maculopapular and vesicular exanthema, urticaria, purpura, erythema nodosum, erythema multiforme, Stevens-Johnson syndrome
Central nervous system	Meningitis, meningoencephalitis, acute psychosis, cerebellitis, Guillain-Barré syndrome*
Parenchymatous organs	Pancreatitis, diabetes mellitus, nonspecific reactive hepatitis, subacute thyroiditis*
Miscellaneous	Hemorrhagic bullous myringitis, hemolytic anemia, pericarditis, thromboembolism*

*Some association remains uncertain.
From Cohen J, Powderly WG: *Infectious diseases,* ed 2, St Louis, 2004, Mosby.

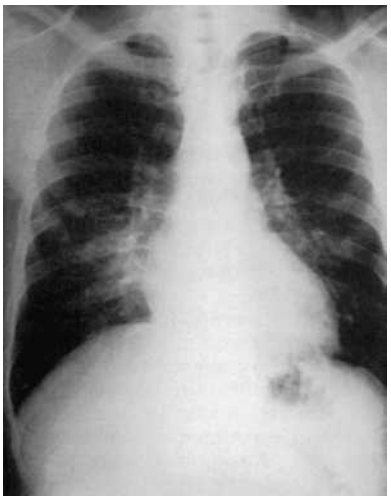

FIG. 1 Radiographic findings in *Mycoplasma pneumoniae* pneumonia are nonspecific. Bilateral bronchopneumonia occurred in this patient. (From Mason RJ et al: *Murray and Nadel's textbook of respiratory medicine*, ed 5, Philadelphia, 2010, WB Saunders.)

FIG. 2 Localized airspace opacification resulting from *Mycoplasma pneumoniae*. (From Specht N [ed]: *Practical guide to diagnostic imaging,* St Louis, 1998, Mosby.)

IMAGING STUDIES

- Predilection for lower lobe involvement (upper lobes involved in less than a fourth), with radiographic abnormalities frequently out of proportion to those on physical examination (Fig. 2)
- Small pleural effusions in approximately 30% of patients
- Large effusions: Rare
- Infiltrates: Patchy, unilateral, and with a segmental distribution, although multilobar involvement may be seen
- Evidence of hilar adenopathy on chest radiographs in 20% to 25%
- Rare cases reported:
  1. Associated lung abscess
  2. Residual pneumatoceles
  3. Lobar collapse
  4. Hyperlucent lung syndrome

Rx TREATMENT

ACUTE GENERAL Rx

- Therapy: Azithromycin 500 mg qd × 3 or 500 mg initially, then 250 mg daily for 4 days for adults. For children: 10 mg/kg in one dose on first day, then 5 mg/kg in one dose for 4 days or clarithromycin: 500 mg bid for 10 days in adults, 15 mg/kg per day in two divided doses for 10 days in children. Alternatives include erythromycin (500 mg qid) for adults or 30 to 40 mg/kg per day in four divided doses in children or doxycycline: 2 to 4 mg/kg per day in one or two divided doses for 10 days, maximum daily dose: 100 to 200 mg, but this agent cannot be used in young children or women of childbearing age. Respiratory fluoroquinolones such as Levaquin or moxifloxacin are alternative agents for treatment in adults but should not be used in young children.
- Therapy shortens the duration and severity of symptoms and may hasten radiographic clearing, but the disease is self-limiting.
- Macrolide resistance is becoming a concern, starting in Asia in 2000s and then spread to Europe and North America. One study showed resistance of 5% to 13% in France and U.S.

CHRONIC Rx

- Effective antimicrobial therapy does not eliminate the organism from the respiratory secretions, which may be positive for weeks.
- Serum antibody response does not necessarily provide lifelong immunity.
- Chronic symptoms do not occur, although clinical relapses may occur 7 to 10 days after the initial response and may be associated with new areas of infiltration.

DISPOSITION

- Clinical improvement is almost universal within 10 days.
- Infiltrates generally clear within 5 to 8 wk.
- Rare deaths are likely attributable to underlying medical diseases.
- Person-to-person spread can be minimized by avoiding open coughing, especially in enclosed areas. Azithromycin prophylaxis can prevent infection in close contacts of patients.

REFERRAL

- Not responding to treatment
- Severe infection
- Severe extrapulmonary manifestations
- Multilobe involvement accompanied by respiratory embarrassment (very rare)

PEARLS & CONSIDERATIONS

COMMENTS

- Outbreaks occur in military recruits, group homes, nursing homes, and in the community. Between 2006 and 2013, the CDC investigated 17 sporadic cases, clusters, and local outbreaks in the U.S.
- Infection control: In the hospital these patients should be on droplet precautions.
- X-ray resolution complete by 8 wk in approximately 90% of patients.

BASIC INFORMATION

DEFINITION

Pneumocystis jiroveci pneumonia (PJP) is a respiratory infection caused by the fungal pathogen *P. jiroveci* (formerly known as *P. carinii*).

SYNONYMS

Pneumocystis jiroveci pneumonia
PCP
PJP

ICD-10CM CODE
B59 Pneumocystosis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):
- Approximately 95% of cases occur in HIV-infected individuals with CD4 counts <200/mm^3 who are not on prophylaxis.
- Also seen in other immunocompromised patients with severe cell-mediated immune deficiency (congenital T-cell deficiency, acute leukemia, lymphoma, bone marrow or organ transplant deficiency).
- May be associated with prednisone use (usually higher than 20 mg/day), usually in conjunction with a second immune-modulating agent.
- Rituximab use has been associated with PJP in HIV-negative patients, most of whom have hematologic cancers.

PREDOMINANT SEX: Equal incidence when adjusted for HIV status
PREDOMINANT AGE: 20 to 40 yr
PEAK INCIDENCE: Age 20 to 40 yr (parallel to AIDS epidemic)
GENETICS: Neonatal infection:
- Most frequent opportunistic infection among HIV-infected children
- Neonatal occurrence unusual

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Fever, cough, shortness of breath present in almost all cases. May be subacute or insidious in HIV patients; acute onset with rapid progression seen in non–HIV-immunocompromised patients
- Lungs frequently clear to auscultation, although rales occasionally present
- Cyanosis and pronounced tachypnea in severe cases
- Hemoptysis is unusual. Spontaneous pneumothorax is possible

ETIOLOGY

- *P. jiroveci* (formerly *P. carinii*) reclassified as a fungal organism (previously classified as a protozoan) (Fig. E1)
- Reactivation of dormant infection
- Extrapulmonary involvement rare but possible

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Other opportunistic respiratory infections:
  1. Tuberculosis
  2. Histoplasmosis
  3. Cryptococcosis
  4. Mycobacterium avium complex (MAC)
- Nonopportunistic infections:
  1. Bacterial pneumonia
  2. Viral pneumonia
  3. Mycoplasma pneumonia
  4. *Legionella*
- Occurs almost exclusively in the setting of profound depression of cellular immunity

WORKUP

- Chest x-ray (Fig. 2) or chest CT (Fig. E3).
- Arterial blood gases.
- Because *Pneumocystis* cannot be cultured, diagnosis relies on detection of the organism by cytologic stains, direct immunofluorescent antibody test, or PCR.
- Sputum examination for cysts of PJP and to exclude other pathogens.
- Bronchoscopy with bronchoalveolar lavage or lung biopsy for diagnosis if sputum examination is negative or equivocal. PCR on lavage is very sensitive but less specific.
- Serum beta-D glucan has good negative predictive performance (very sensitive, less specific).
- Fig. 4 describes an algorithm for the diagnostic evaluation and management of patients with suspected *Pneumocystis* pneumonia.

LABORATORY TESTS

- Arterial blood gas monitoring
- Elevated lactate dehydrogenase in majority of cases
- HIV antibody test and CD4 cell count if cause of underlying immune deficiency state is unclear
- Beta-D-glucan testing may be positive (92% sensitivity, 86% specificity)

IMAGING STUDIES

PJP may appear as diffuse, unilateral, bilateral, or interstitial infiltrates on chest x-ray. CT with mixed alveolar-interstitial patterns, often with sparing of the periphery. Pneumatoceles, which may cause pneumothorax, are common.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Supplemental oxygen
- Ventilation support if needed
- Prompt chest tube placement if pneumothorax develops

ACUTE GENERAL Rx

For confirmed or suspected PJP:
- Trimethoprim-sulfamethoxazole (15 to 20 mg/kg trimethoprim and 75 to 100 mg/kg sulfamethoxazole qd) PO or IV per day divided and given q6 to 8h
- Pentamidine (4 mg/kg IV qd) (severe cases with a contraindication to trimethoprim/sulfamethoxazole). Careful monitoring is required, can cause nephrotoxicity, numerous electrolyte disturbances, and cardiac arrhythmias
- Either regimen with prednisone (40 mg PO bid):
  1. If arterial oxygen pressure <70 mm Hg
  2. If arterial-alveolar oxygen pressure difference >35 mm Hg
  3. Dose tapered to 20 mg bid after 5 days and 20 mg qd after 10 days
- Therapy continued for 3 wk
- Alternative therapies available for patients unable to tolerate conventional therapy:
  1. Dapsone/trimethoprim
  2. Clindamycin/primaquine
  3. Atovaquone
- Table 1 summarizes causes of deterioration in an HIV-infected patient receiving treatment for PJP

CHRONIC Rx

- After completion of therapy, prophylaxis should be maintained with trimethoprim-sulfamethoxazole (one single-strength tablet PO qd or double-strength three times weekly) until the CD4 cell count is >200 for 3 mo.

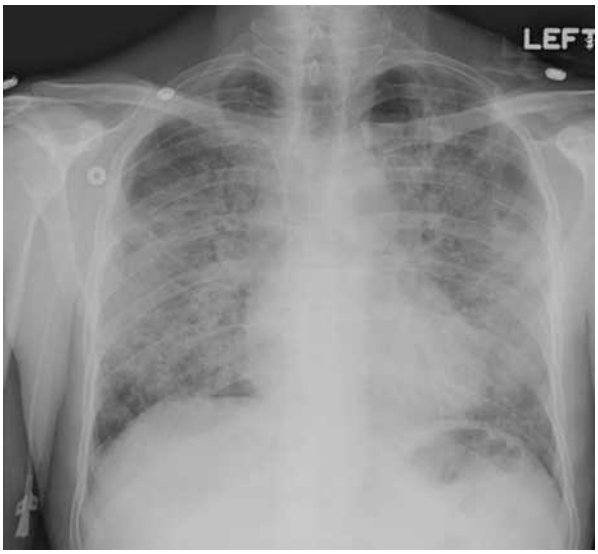

FIG. 2 Chest radiograph showing diffuse interstitial infiltrate in a patient with *Pneumocystis jiroveci* pneumonia. (From Firestein GS et al [eds]: *Kelly's textbook of rheumatology,* ed 9, Philadelphia, 2013, WB Saunders.)

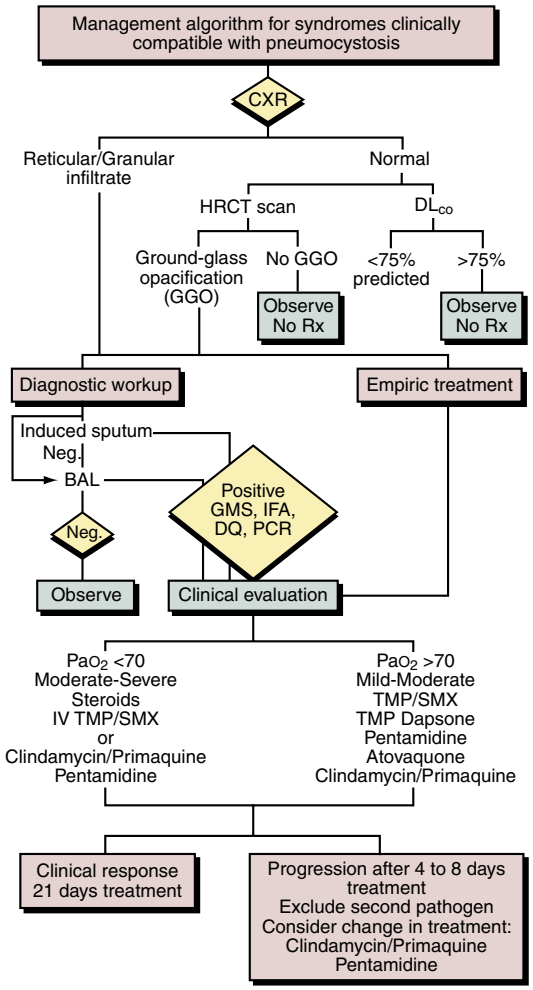

FIG. 4 Algorithm for the diagnostic evaluation and management of patients with suspected *Pneumocystis* pneumonia *BAL*, Bronchoalveolar lavage; *CXR*, chest x-ray; DL_{CO}, single-breath diffusing capacity for carbon monoxide; *DQ*, Diff-Quik (stain); *GGO*, ground-glass opacities; *GMS*, Gomori methenamine silver (stain); *HRCT*, high-resolution computed tomography; *IFA*, immunofluorescent antibody (stain); *IV*, intravenous; *Neg.,* negative; PaO_2, partial pressure of oxygen in arterial blood; *PCR*, polymerase chain reaction; *Rx*, treatment; *TMP/SMX*, trimethoprim-sulfamethoxazole. (Bennett JE et al: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases*, ed 8, Philadelphia, 2015, WB Saunders.)

TABLE 1 Causes of Deterioration in an HIV-Infected Person Receiving Treatment for PJP

Etiology	Explanation
Severe Progressive PJP	
Iatrogenic	Pulmonary edema due to IV fluid overload when giving TMP-SMX IRIS following early initiation of ART
Side effects of therapy	Anemia (e.g., caused by TMP-SMX), methemoglobinemia (e.g., caused by dapsone, primaquine)
Inadequate therapy	Incorrect dosage or route of administration Adjuvant glucocorticoids not given for treatment of moderate or severe PJP
Postbronchoscopy	Sedation Pneumothorax
Pneumothorax	Spontaneous Associated with intubation and positive pressure ventilation
Copathology in lung	Bacterial infection Pulmonary Kaposi sarcoma Intercurrent pulmonary embolism
Wrong diagnosis	Empiric diagnosis of PJP, and correct diagnosis is another pathology (e.g., bacterial pneumonia)

ART, Antiretroviral therapy; *HIV*, human immunodeficiency virus; *IRIS*, immune reconstitution inflammatory syndrome; *IV*, intravenous; *PJP*, *Pneumocystis jiroveci* pneumonia; *TMP-SMX*, trimethoprim-sulfamethoxazole.
Bennett JE et al: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases*, ed 8, Philadelphia, 2015, WB Saunders.

- Patients intolerant of this therapy should be treated with dapsone (100 mg PO qd) or atovaquone (1500 mg PO qd).
- Inhaled pentamidine (300 mg monthly by standardized nebulizer) is less effective and is reserved for patients intolerant to other forms of prophylaxis.

DISPOSITION

After completion of therapy, long-term ambulatory follow-up is mandatory to provide secondary prevention of PJP (see "Chronic Rx" previously) and management of the underlying immunodeficiency syndrome.

REFERRAL

- To pulmonologist for bronchoscopy if diagnosis cannot be confirmed by sputum examination
- To an infectious disease specialist if case is severe or difficult to manage and to evaluate underlying immune deficiency

PEARLS & CONSIDERATIONS

COMMENTS

- All patients, especially those with severe infection or intolerant of conventional therapy, should be followed by a physician experienced in the management of PJP and, if appropriate, in the long-term management of HIV infection or other underlying disease.
- Severe and life-threatening hypoglycemia may occur 1 or 2 wk after start of IV pentamidine. Monitor closely and advise the patient of symptoms of hypoglycemia.

BASIC INFORMATION

DEFINITION

Viral pneumonia is a lung infection caused by any of a large number of viral pathogens. The most important viruses are discussed in this chapter.

SYNONYMS

Viral pneumonia
Nonbacterial pneumonia

ICD-10CM CODES
J12.9 Viral pneumonia, unspecified
J12.89 Other viral pneumonia

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- Influenza virus:
  1. 10% to 20% of population in temperate zones infected during 1 to 2 mo epidemics occurring yearly during winter mos.
  2. Up to 50% infected during pandemics.
  3. Secondary bacterial pneumonia develops in a small percentage of infected persons.
- Incidence of other important viral pathogens that cause pneumonia can vary widely depending on setting, geography, and testing modalities. With the more widespread use of rapid molecular testing of respiratory secretions, an increase in the detection of viral pathogens has been observed. However, drawing conclusions as to causality of the identified virus to the actual pneumonia remains challenging because respiratory viruses remain detectable for several wks after initial infection, and the pneumonia may be due to secondary bacterial infection.

PREVALENCE (IN U.S.):

- Often related to immune status of the population or presence of an epidemic
- Normal hosts (estimates):
  1. 86% of cases of pneumonia resulting in hospitalization in American adults
  2. 16% of pediatric pneumonias managed as outpatients
  3. 49% of hospitalized infants with pneumonia
- Important problem in hosts with impaired immunity

PREDOMINANT SEX:

- Equal predominance.
- Male sex may predispose to more severe respiratory disease in RSV infection.

PREDOMINANT AGE:

- Influenza:
  1. Overall incidence greatest at age 5 yr
  2. Lower incidence with increasing age
  3. The most serious sequelae in those with chronic medical illnesses, especially cardiopulmonary disease
  4. Hospitalizations greatest in infants and adults aged >64 yr
- RSV and parainfluenza virus:
  1. Young children (as the major cause of pneumonia)
  2. Occurs throughout life
- Adenoviruses:
  1. Young children
  2. Adults, primarily military recruits
- Varicella:
  1. Approximately 16% of adults (not infected in childhood) who contract chickenpox
  2. Acute varicella during pregnancy more likely to be complicated by severe pneumonia
  3. 90% of reported varicella pneumonia cases are in adults (highest incidence ages 20 to 60 yr)
- Measles:
  1. Young adults and older children who received a single vaccination (5% failure rate)
  2. Measles during pregnancy more likely to be complicated by pneumonia
  3. Underlying cardiopulmonary diseases and immunosuppression predispose to serious pneumonia complicating measles
  4. Before availability of measles vaccine, 90% of pneumonias in those <10 yr
  5. Currently more than one third of patients >14 yr in the U.S.
  6. 3% to 50% of measles cases are complicated by pneumonia
- CMV:
  1. Neonatal through adult
  2. Immunosuppression is key predisposing factor
- Human metapneumovirus:
  1. Children: Peak incidence 11 mo
  2. Increasingly detected in adults (bronchitis, chronic obstructive pulmonary disease [COPD] exacerbation, pneumonia)
  3. Frequent cause of lower respiratory tract infection (LRTI) in lung transplant recipients

PEAK INCIDENCE:

- Influenza:
  1. Winter mos for influenza A
  2. Yr-round for influenza B
  3. Peak of pneumonia seen wks into the outbreak of infection
- Respiratory syncytial virus (RSV) and parainfluenza virus: Winter and spring
- Adenovirus: Endemic (military)
- Varicella: Spring in temperate zones
- Measles: Yr-round
- Cytomegalovirus (CMV): Yr-round
- Human metapneumovirus: Winter mos

GENETICS: Familial disposition:

- Close contact, not genetics, is important in acquisition
- Congenital anomalies and immunosuppression worsen course of RSV pneumonia

Congenital infection:

- CMV is the most common intrauterine infection in the U.S.
- Pneumonia occurs occasionally in infants with symptomatic congenital infection

Neonatal infection:

- Severe RSV pneumonia
- Adenovirus pneumonia
  1. 5% to 20% mortality rate
  2. Can lead to residual restrictive or obstructive functional abnormalities
- "Varicella neonatorum"
  1. Disseminated visceral disease including pneumonia
  2. May develop in neonates whose mothers develop peripartum chickenpox
- CMV pneumonia
  1. Generally fatal
  2. Associated with severe cerebral damage in this population

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Influenza:
  1. Fever, cough, or sore throat (referred to as influenza-like illness [ILI])
  2. Uncomfortable or lethargic appearance
  3. Prominent dry cough (rarely hemoptysis)
  4. Flushed integument and erythematous mucous membranes
  5. Rales or rhonchi
- RSV, parainfluenza, and human metapneumovirus:
  1. Fever
  2. Tachypnea
  3. Prolonged expiration
  4. Wheezes and rales
- Adenoviruses:
  1. Hoarseness
  2. Pharyngitis
  3. Tachypnea
  4. Cervical adenitis
- Measles:
  1. Conjunctivitis
  2. Rhinorrhea
  3. Koplik spots (white lesions on the buccal mucosa)
  4. Exanthem (maculopapular rash that starts on the head, then moves down to rest of body)
  5. Pneumonitis
     a. May occur as a complication in 3% to 4% of adolescents and young adults
     b. Coincident with rash
     c. May also develop after apparent recovery from measles
  6. Fever
  7. Dry cough
- Varicella:
  1. Fever
  2. Maculopapular or vesicular rash (all lesions at the same stage)
     a. Becomes encrusted
     b. Pneumonia typical 1 to 6 days after rash appears
     c. Pneumonia (Fig. 1) accompanied by cough and occasionally hemoptysis
  3. Few auscultatory abnormalities noted on examination of the lungs
- CMV:
  1. Fever
  2. Paroxysmal cough
  3. Occasional hemoptysis
  4. Diffuse adenopathy when pneumonia occurs after transfusion

ETIOLOGY

Viral infection can lead to pneumonia in both immunocompetent and immunocompromised hosts.

FIG. 1 This chest radiograph demonstrates bilateral nodular and interstitial pneumonia characteristic of varicella pneumonia. The patient, a 27-yr-old gravida 6, para 2, abortus 3, was exposed to varicella infection in her two children. Characteristic skin vesicles of varicella occurred several days before the development of pulmonary symptoms. She required endotracheal intubation and mechanical ventilation for 6 days. She was treated with intravenous acyclovir and ceftazidime for possible superimposed infection. The patient recovered fully and delivered a healthy infant at term. (From Gabbe SG: *Obstetrics*, ed 6, Philadelphia, 2012, WB Saunders.)

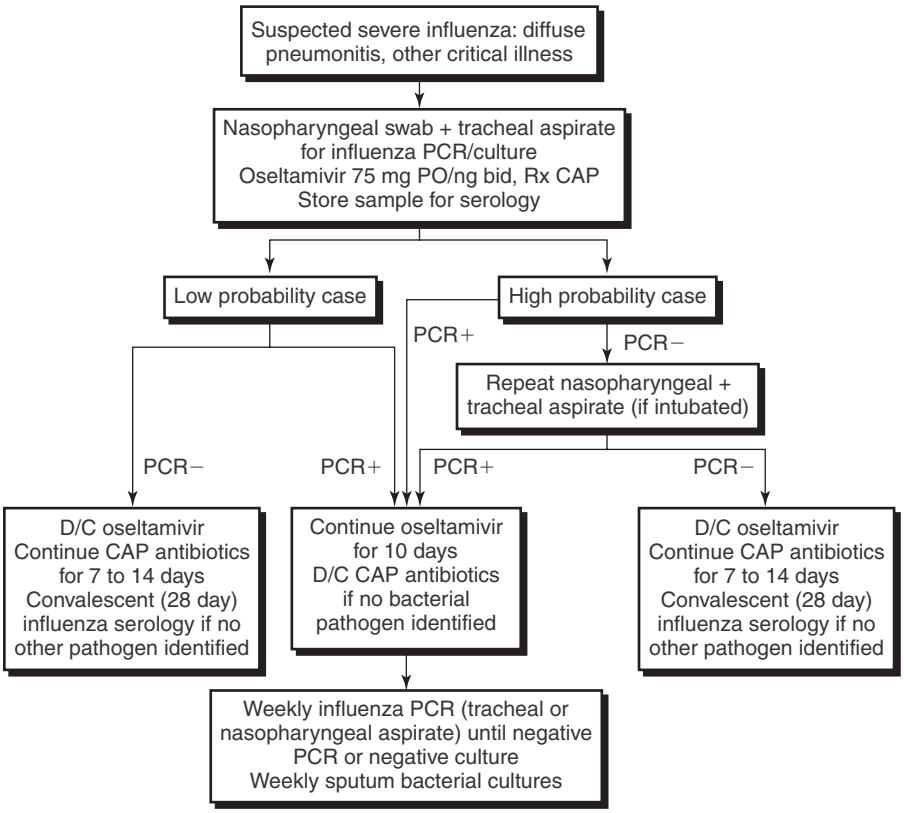

FIG. 2 Suggested algorithm in the workup and management of suspected severe influenza pneumonia in the critical care unit. *CAP,* Community-acquired pneumonia; *D/C,* discontinue; *PCR,* polymerase chain reaction; *PO,* by mouth; *Rx*, prescription. (From Vincent JL et al: *Textbook of critical care,* ed 6, Philadelphia, 2011, WB Saunders.)

Dx DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Bacterial pneumonia, which frequently complicates (i.e., can follow or be simultaneous with) viral pneumonia
- Other causes of atypical pneumonia:
  1. *Mycoplasma* spp.
  2. *Chlamydia* spp.
  3. *Coxiella* spp.
  4. Legionnaires' disease

  In certain patient populations (e.g., immunocompromised), consider fungal infections, tuberculosis, or atypical mycobacterium.
- Acute respiratory distress syndrome (ARDS)
- Physical findings and associated hypoxemia confused with pulmonary emboli

WORKUP

- Information about the current prevalent strain of influenza virus can be obtained from local health departments or from the Centers for Disease Control and Prevention.
- Influenza and other viruses may be cultured from respiratory secretions during the initial few days of the illness (special media and techniques necessary).
- Respiratory viral panels that use PCR-based assays to test for a variety of viruses are extremely sensitive and are becoming the test of choice.
- Rapid flu tests have a 50% sensitivity in diagnosing influenza (a negative test does not mean the patient does not have influenza).
- Measles and adenovirus pneumonia are usually diagnosed clinically and can be confirmed with serology.
- CMV may be grown in culture or PCR amplified from bronchoalveolar lavage samples. An algorithm for the workup and management of suspected severe influenza pneumonia in the critical care unit is described in Fig. 2. Open lung biopsy is required for a definite diagnosis of CMV pneumonia.

LABORATORY TESTS

- Sputum Gram stain (usually produced in scanty amounts) typically shows few polymorphonuclear leukocytes and few bacteria.
- White blood cell count may vary from leukopenic to modest elevation, usually without a leftward shift.
- Disseminated intravascular coagulation occasionally complicates adenovirus type 7 pneumonia.
- Multinucleated giant cells on Tzanck preparation of an unroofed vesicular lesion are useful in diagnosing varicella in a patient with an infiltrate (also found in herpes simplex).
- Severe immunosuppression is associated with symptomatic CMV pneumonia (usually reactivation of latent infection or in previously seronegative recipients from the donor).
- Hypoxemia may be profound.
- Cultures may be helpful in identifying superinfecting bacterial pathogens.
- When they occur, parapneumonic pleural effusions are exudative.

IMAGING STUDIES

- Chest radiographs may demonstrate a spectrum of findings from ill-defined, patchy, or generalized interstitial infiltrates, which can be associated with ARDS.
- A localized dense alveolar infiltrate suggests a superimposed bacterial pneumonia.
- Small calcified nodules may develop as a radiographic residual of varicella pneumonia.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

General:

- Measures to diminish person-to-person transmission
- Modified bed rest
- Maintenance of adequate hydration
- Possible ventilation support for severe pneumonia or ARDS

Influenza:

- Yearly prophylactic strain-specific influenza vaccination can be given to prevent infection.
- Live, attenuated influenza vaccines administered by nose drops as effective as injected inactivated viral vaccines.

RSV:

- Isolation techniques are important in limiting spread of RSV infections.

- Immunoglobulins with a high RSV-neutralizing antibody titer are beneficial in treatment.

Adenoviruses:
- Intestinal inoculation of respiratory adenoviruses has been used to successfully immunize military recruits.
- Although they produce no disease in recipients, the viruses may be shed chronically and may infect others at a later date.
- These vaccines are not available for civilian populations.

Varicella:
- Live, attenuated varicella vaccine has been successfully used in clinical trials.
- Varicella-zoster immune globulin should be administered within 4 days of exposure to prevent or modify the disease in susceptible persons.
- Nonimmunized persons exposed to varicella are potentially infectious between 10 and 21 days after exposure.

Measles:
- Effective measles vaccine is available.
  1. The vaccine should be administered at age 15 mo.
  2. A second dose should be administered at the time of school entry.
- Live, attenuated vaccine or gamma-globulin can prevent measles in unvaccinated persons if administered early after exposure.
- Vitamin A given PO for 2 days reduces morbidity and mortality rates from measles in exposed children.

ACUTE GENERAL Rx

- General: Administer appropriate antibiotics for bacterial superinfections.
- Influenza:
  1. Amantadine and rimantadine for influenza A (not active against influenza B). Early use can speed recovery from small airway dysfunction, but whether it influences the development or course of pneumonia is uncertain.
  2. The neuraminidase inhibitors oseltamivir and zanamivir are effective if given in the first 48 hours of symptoms of influenza; their efficacy in established influenza pneumonia is unclear.
  3. Aerosolized ribavirin or amantadine may have a role in treating severe influenza pneumonia, but they have not been approved for this indication.
- RSV and parainfluenza:
  1. Ribavirin aerosol may be effective for severe RSV pneumonia.
  2. There is no approved antiviral therapy for parainfluenza virus pneumonia.
- Adenoviruses: No effective agent; some case reports of cidofovir use but unproved.
- Varicella:
  1. Varicella pneumonia can be treated with IV acyclovir.
  2. Adults who develop chickenpox should be considered for acyclovir treatment, which may prevent the development of pneumonia.
- Measles: No effective antimeasles agent.
- CMV:
  1. Acyclovir can prevent CMV infection in renal transplant recipients.
  2. Ganciclovir and foscarnet, with or without CMV hyperimmune globulin, show promise in the treatment of serious CMV infection, including pneumonia, in compromised hosts.
- Human metapneumovirus: No specific treatment available

DISPOSITION

- Supportive therapy is useful.
- Death is possible during acute illness.
- Residual functional abnormalities may be persistent or develop into or predispose to chronic respiratory diseases in later life.
- Morbidity and mortality rates after most viral pneumonias are increased by bacterial superinfection.

REFERRAL

- Uncertainty about the diagnosis in a compromised host.
- Symptoms or findings are progressive.
- Severe respiratory compromise, diffuse infiltrates, or the development of ARDS.

PEARLS & CONSIDERATIONS

COMMENTS

- Influenza spreads by close contact and by small droplets transmitted by cough.
- RSV is effectively transmitted by fomites and by direct contact (little by aerosol).
- Varicella is transmitted by direct contact or by aerosol.
- Of the three major forms of parainfluenza viruses (types 1 to 3), type 3 is the most common cause of viral pneumonia; types 1 and 2 primarily cause laryngotracheitis.
- Human metapneumovirus is a recently identified common cause of upper respiratory infections and pneumonia.

AUTHOR: **Sebastian G. Kurz, MD**

Pneumothorax, Spontaneous ALG PTG

BASIC INFORMATION

DEFINITION

A spontaneous pneumothorax (SP) is defined as air in the pleural space, collapsing the lung without a precipitating event. This can be primary SP (otherwise healthy people without any obvious underlying lung disease) or secondary SP (with underlying lung disease).

SYNONYMS

Primary spontaneous pneumothorax (PSP)
Secondary spontaneous pneumothorax (SSP)
SP
PSP
SSP

ICD-10CM CODES	
J93.0	Spontaneous tension pneumothorax
J93.11	Primary spontaneous pneumothorax
J93.12	Secondary spontaneous pneumothorax
J93.81	Chronic pneumothorax
J93.83	Other pneumothorax
J93.9	Pneumothorax, unspecified
J95.811	Postprocedural pneumothorax
P25.1	Pneumothorax originating in the perinatal period
S27.0XXA	Traumatic pneumothorax, initial encounter
S27.0XXD	Traumatic pneumothorax, subsequent encounter
S27.0XXS	Traumatic pneumothorax, sequela

EPIDEMIOLOGY & DEMOGRAPHICS

- Approximately 20,000 new cases of SP occur each yr in the U.S.
- SP is more common in men than women (6:1).
- Incidence of primary SP is 7.4 per 100,000 in men and 1.2 per 100,000 in women.
- Incidence of secondary SP is 6.3 per 100,000 in men and 2.0 per 100,000 in women.
- SP is commonly seen in tall, thin young men aged 20 to 40 yr.
- Risk factors include smoking, family history, Marfan syndrome, homocystinuria, and thoracic endometriosis.
- Anorexia nervosa is thought to be a risk factor due to pulmonary parenchymal consequences of malnutrition.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Sudden onset of pleuritic chest pain (90%), usually at rest and no relationship between the onset of pneumothorax and physical activity, which often becomes dull after a few hours
- Pain is usually unilateral and can be sharp and agonizing and associated with considerable apprehension
- Dyspnea (80%), which often resolves within 24 hr, despite persistence of pneumothorax
- Cough (10%)
- Asymptomatic (5%); may take up to 7 days to come to medical attention
- Tachycardia
- Hypoxemia
- Hypercapnia is rare because the alveolar ventilation is maintained by the contralateral lung
- Decreased chest excursion on the affected side (Fig. 1)
- Diminished breath sounds
- Subcutaneous emphysema may be present
- Hyperresonance on percussion

ETIOLOGY

- In primary SP, rupture of small blebs and bullae, usually located near the apex of the upper lobes, is a common cause.
- In secondary SP, chronic obstructive pulmonary disease is the most common cause, but it can also be associated with pneumonia, bronchogenic carcinoma, mesothelioma, sarcoidosis, tuberculosis, cystic fibrosis, and many other lung diseases. Causes of secondary spontaneous pneumothorax are summarized in Box 1.

DIAGNOSIS

Established by the chest x-ray (CXR) (Fig. 2)

DIFFERENTIAL DIAGNOSIS

- Pleurisy
- Pulmonary embolism
- Myocardial infarction
- Pericarditis
- Asthma
- Pneumonia

WORKUP

CXR

LABORATORY TESTS

Arterial blood gases may show hypoxemia and hypocapnia as a result of hyperventilation.

IMAGING STUDIES

- SP is usually confirmed by upright CXR:
  1. A white visceral pleural line. The absence of vessel markings peripheral to this line helps differentiate from mimicking conditions such as an overlying skin fold. A lateral width of 1 cm corresponds to 27% pneumothorax, and 2 cm occupies 49% of the hemithorax.
  2. The left lateral decubitus position is the most sensitive and the supine position the least sensitive. Inspiratory and expiratory films have equal sensitivities.
  3. As little as 50 ml of air can be detected on upright film.
- Tension pneumothorax (Fig. 3) is a medical emergency and should be suspected when the patient is hemodynamically unstable or with contralateral tracheal and mediastinal deviation and ipsilateral flattening or inversion of the diaphragm on the CXR (Fig. 4).
- CT scan is considered acceptable for a patient with recurrent pneumothorax or persistent air leak, and for planning surgery.
- Lung ultrasound has emerged as a rapid and accurate screening tool for pneumothorax.

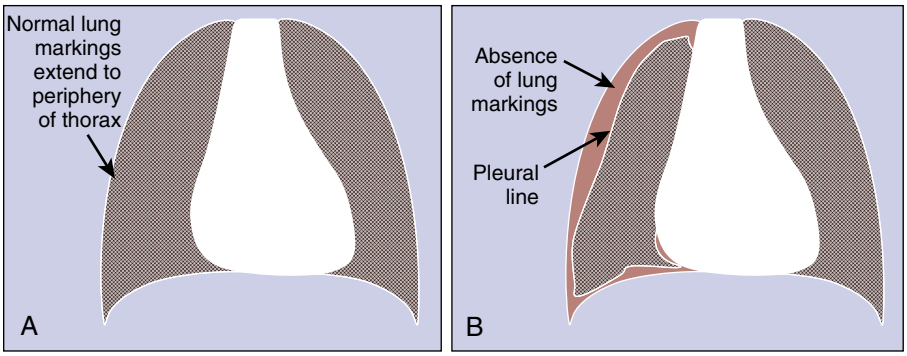

FIG. 1 Pneumothorax. A, Schematic of normal lung. **B,** Schematic of pneumothorax. Pneumothoraces can range in size from tiny to massive. Because of the variability in their size and location, pneumothoraces can be difficult to detect on chest x-ray. For example, a pneumothorax that is anterior or posterior rather than lateral may be hidden on frontal chest x-ray, particularly one taken in the supine position. An upright chest x-ray should be obtained if possible. An expiratory film is thought to be more sensitive, because the lung and thorax decrease in size during expiration, but air trapped in the pleural space remains the same size and thus appears relatively larger. Subtle pneumothoraces may not be visible on chest x-ray. In some cases, subcutaneous air may be the only visible clue to underlying lung injury. CT is extremely sensitive for pneumothorax, although controversy remains over the proper management of pneumothoraces seen only on CT. Ultrasound is also thought to be more sensitive than chest x-ray for detection of pneumothorax, although, again, the management of pneumothorax seen only on ultrasound is uncertain because this is a relatively newly described method of detection. The chest x-ray findings of pneumothorax include a lack of the normal lung markings, which should be visible to the periphery of the chest wall. Sometimes a line marking the boundary of the lung and visceral pleura is visible, although this can be confused with ribs and with the medial margin of the scapula. Depending on the degree of pneumothorax and lung collapse, the lung parenchyma may appear denser than the opposite side. In extreme cases of tension pneumothorax, the pressure exerted by the air in the pleural space may begin to displace other structures, including the diaphragm and mediastinum. In tension pneumothorax, the hyperinflated hemithorax may also have abnormally positioned ribs, with a position more horizontal than usual. (From Broder JS: *Diagnostic imaging for the emergency physician,* Philadelphia, 2011, WB Saunders.)

The lung point sign, a sonographic representation of the point of the chest wall where the pleural layers re-adhere, is 100% specific to confirm the diagnosis.

Rx TREATMENT

INITIAL MANAGEMENT

- 100% oxygen administration reduces the partial pressure of nitrogen in pleural capillaries, consequently quadrupling the rate of pneumothorax absorption, and should be administered to all patients with pneumothorax.
- Further treatment is based on the size of the pneumothorax.
  1. If the pneumothorax is small (<2 cm between lung and chest wall on CXR) and the patient is asymptomatic, the patient can be treated with observation alone. Repeat imaging should be performed to ensure stability/resorption of the pneumothorax. Some studies have shown that using a cutoff of 35 mm for deciding which patients can be managed with observation is reasonable in selected patients with nonoccult traumatic pneumothoraces after consultation with trauma consultants.
  2. If the pneumothorax is large (>2 cm), or if the patient is symptomatic with chest pain and dyspnea, initial management should focus on removing air from the pleural space. Needle aspiration is the treatment of choice in the clinically stable patient.
- Needle aspiration can be done at the bedside using a large-bore angiocatheter needle or commercially available catheter aspiration kit. The needle is introduced in the second intercostal space midclavicular line. The catheter is left in place and attached to a three-way stopcock and a large syringe. Air is aspirated until resistance is met or the patient experiences significant coughing. Repeat CXR is done immediately after aspiration and again in 4 to 24 hours to document reexpansion of the lung. If the pneumothorax fails to resolve with aspiration, repeated aspiration is reasonable for primary spontaneous pneumothorax.
- If there is improvement but not complete resolution of pneumothorax after the aspiration, the catheter can be attached to a Heimlich (one-way) valve to allow further lung expansion. Some stable patients can be discharged home with this device in place if close follow-up monitoring can be obtained. Chest tube insertion has been recommended for patients with primary SP who are unsuccessful in controlling symptoms by simple aspiration or catheter aspiration. Most patients can be managed with small chest tubes (<12 Fr). The chest tube can be connected to a water seal device, with or without suction, and left in position until the pneumothorax has resolved.
- An algorithmic approach to the treatment of primary spontaneous pneumothorax is outlined in Fig. 5.

PREVENTION

- Approximately 25% to 50% of patients with primary SP with have a recurrence within 5 yr. Recurrence rate is higher in patients with secondary spontaneous pneumothorax.
- Prevention of spontaneous pneumothorax is surgical intervention or instillation of sclerosing agents through a chest tube.
- Indication for the surgical intervention is second ipsilateral SP, first contralateral SP, simultaneous bilateral SP, persistent air leak (>5 to 7 days), failure of lung reexpansion by the chest tube, and professions at risk (e.g., pilots, divers).
- The current recommended surgical approach is the use of video-assisted thoracoscopy (VATS) with bullectomy and pleurodesis. Surgical chemical pleurodesis is best achieved with sterile talc. The overall recurrence rate is estimated at <5% after VATS.
- Instillation of a sclerosing agent through a chest tube: Doxycycline and talc slurry are the preferred agents; minocycline is considered to be an acceptable agent. The recurrence rates for the instillation of sclerosing agents (minocycline 5 mg/kg in 50 ml of normal saline or doxycycline 500 mg in 50 ml of normal saline) are higher than for VATS-guided therapy (<25%). Therefore this mode of therapy should be reserved for patients who are poor surgical candidates.

DISPOSITION

- Smoking cessation should be advised.
- Death from primary SP is uncommon. In patients with secondary SP and chronic obstructive pulmonary disease, mortality rates range from 1% to 16%.

REFERRAL

A pulmonary specialist and surgical consultation are recommended.

PEARLS & CONSIDERATIONS

- The rate of pleural air absorption is approximately 1.25% of the volume of the hemithorax per day. Therefore the interval for complete resolution of pneumothorax with observation can be estimated.

BOX 1 Causes of Secondary Spontaneous Pneumothorax

Airway Disease
- Chronic obstructive pulmonary disease
- Asthma
- Cystic fibrosis

Infections
- Necrotizing bacterial pneumonia, lung abscess
- *Pneumocystis jirovecii* pneumonia
- Tuberculosis

Interstitial Lung Disease
- Sarcoidosis
- Idiopathic pulmonary fibrosis
- Lymphangiomyomatosis
- Tuberous sclerosis
- Pneumoconioses

Neoplasms
- Primary lung cancers
- Pulmonary or pleural metastases

Miscellaneous
- Connective tissue diseases
- Pulmonary infarction
- Endometriosis, catamenial pneumothorax

From Marx JA et al: *Rosen's emergency medicine*, ed 8, Philadelphia, 2014, Elsevier.

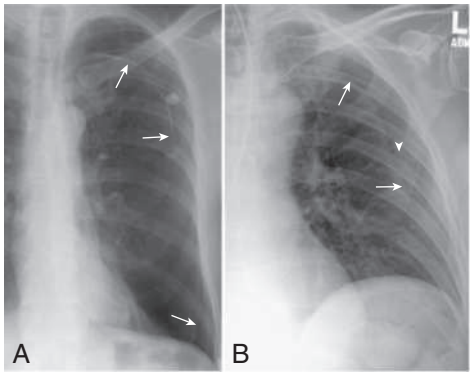

FIG. 2 A, Chest radiograph of a pneumothorax. The pleural line has lucency on either side, representing air in the pleural space on one side of the line and air in the lung on the other. The line is sharply demarcated and can be traced along its course *(lower arrow)*. No blood vessels can be seen beyond the superior *(upper arrow)* and lateral *(middle arrow)* extent of the line. **B,** Chest radiograph of a skinfold *(arrows)* that could be mistaken for a pneumothorax. The border is more of an edge, with lucency on only one side. The edge is poorly defined and cannot be followed continuously *(lower arrow)*. Blood vessels can be traced beyond the border of the fold *(arrowhead)*. (Courtesy Michael B. Gotway, MD, Scottsdale Medical Imaging, and the Department of Radiology, University of California, San Francisco. From Mason RJ et al: *Murray & Nadel's textbook of respiratory medicine*, ed 5, Philadelphia, 2010, WB Saunders.)

[1]Aspler A et al: Double-lung point sign in traumatic pneumothorax, *Am J Emerg Med* 32:819, 2014.

- Catamenial pneumothorax is a rare condition characterized by recurrent SP coinciding with the onset of menses. It usually affects the right lung and is believed to be caused by endometriosis with involvement of the diaphragm and/or pleura. It is believed to be hormonally related, and treatment is aimed at endometrial suppression.
- Air travel should be avoided until complete resolution of pneumothorax.
- Scuba diving is contraindicated. It may be considered on a case by case basis in patients who have had surgical pleurectomy.

COMMENTS

- A recent trial revealed that conservative management of spontaneous pneumothorax is safe and effective and noninferior to interventional management and it also has a lower risk of serious adverse events.[2]
- Patients with AIDS and *Pneumocystis jirovecii* infection have a high incidence of SP. Treatment typically requires chest tube placement and either thoracoscopy or open thoracotomy.

[2]Brown SGA et al: Conservative versus interventional treatment for spontaneous pneumothorax, *N Engl J Med* 382(5):405-415, 2020.

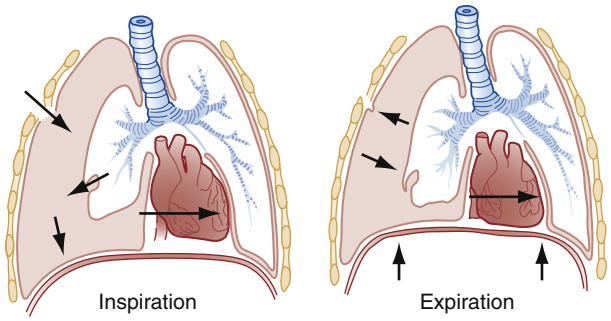

FIG. 3 Tension pneumothorax with total collapse of the right lung and shift of mediastinal structures to the left. Air is forced into the pleural space during inspiration and cannot escape during expiration. (From Marx JA et al: *Rosen's emergency medicine,* ed 8, Philadelphia, 2014, Elsevier.)

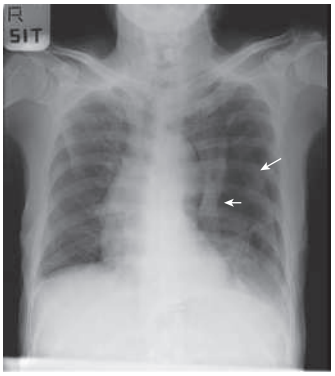

FIG. 4 Chest radiograph showing left pneumothorax with shift of the mediastinum and trachea to the right side *(white arrows).* The left lung is not completely collapsed, suggesting the presence of a loculated tension pneumothorax. (From Chan SSW: Tension pneumothorax managed without immediate needle decompression, *Am J Emerg Med* 36[3]:242-245, 2009.)

Poison Ivy Dermatitis PTG

BASIC INFORMATION

DEFINITION

Poison ivy dermatitis is a contact dermatitis caused by exposure to urushiol, the oil of plants of the genus *Toxicodendron,* which includes poison ivy, poison oak, and poison sumac.

SYNONYMS

Rhus dermatitis
Toxicodendron dermatitis

ICD-10CM CODE
L23.7 Allergic contact dermatitis due to plants, except food

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: Affects 10 million to 40 million Americans annually.
PREVALENCE: From 50% to 75% of the adult population is clinically sensitive to these plants. Sensitivity rates are lower in urban areas. (Tolerance is found in 10% to 15% of the population.)
PREDOMINANT SEX AND AGE: Sensitization occurs most commonly between ages 8 and 14 yr. Sensitivity wanes with age, especially in individuals with limited exposure or prior mild reactions.
PEAK INCIDENCE: More frequent in mos when outdoor activity is more common.
GENETICS: There is thought to be a genetic susceptibility to sensitivity; however, the rash occurs in all ethnicities and skin types.
RISK FACTORS: Firefighters, forestry workers, farmers, and outdoor workers in general, as well as those who participate in outdoor recreation. These plants are indigenous to the U.S., Canada, and Mexico, and cases are most common in these areas.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients typically present with intense pruritus and rash. The patient may not be aware of exposure to the plant.
- Symptoms typically peak from 1 to 14 days after exposure, depending on the degree of exposure and thickness of affected skin.
- Dermatitis may initially present as erythema and may develop into papules, vesicles, and bullae.
- Lesions may be found in the classic linear configuration, typically in exposed areas likely to have been in contact with plants (Fig. E1). Atypical appearance or location of dermatitis is more common with secondary exposure, such as through pets or infected tools or clothing.
- Face and genital involvement may present with significant edema.
- Inhalation of urushiol aerosolized by fire can cause significant respiratory tract inflammation. This can be a particular occupational hazard of forest firefighters.
- Postinflammatory hyperpigmentation may occur, more commonly in dark skin types. This usually resolves with treatment.

FIG. E1 Allergic contact dermatitis to *Rhus*. A, The classic appearance of allergic contact dermatitis is illustrated in this patient, who came into contact with poison oak. The lesions are linear but not following Blaschko lines. The eruption is microvesicular and extremely pruritic. **B,** *Rhus* dermatitis. Linear bullae are characteristic of an allergic contact dermatitis. (Courtesy O. Dale Collins III. From White GM, Cox NH [eds]: *Diseases of the skin, a color atlas and text,* ed 2, St Louis, 2006, Mosby.)

ETIOLOGY

- Initial contact with oil of plants in this genus, which is released with damage to plant parts, causes a classic T-lymphocyte–mediated delayed-type allergic reaction.
- Contact with any part of the plant, including leaves, stems (vines), and roots, can cause dermatitis. Even minimal damage is enough to release the oil.
- Subsequent exposures cause a cell-mediated cytotoxic immune response.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Allergic contact dermatitis from other plants or nonplant substances
- Irritant contact dermatitis
- Nummular dermatitis
- Arthropod reactions, including scabies and bedbug bites

WORKUP

Typically not needed. Diagnosis is based on characteristic rash and possibly history of exposure.

TREATMENT

Prevention is the most effective treatment.

NONPHARMACOLOGIC THERAPY

- After known exposure, patients should remove contaminated clothing and wash the skin gently with soap and water. Washing after appearance of dermatitis does not prevent further lesions.
- Calamine lotion, cool compresses, baking soda, or colloidal oatmeal baths may provide symptomatic relief.
- Keep nails short and clean to help prevent secondary bacterial infection.
- Exposed clothing, as well as tools, pets, and equipment, should be washed with soap and water to prevent secondary exposure.

ACUTE GENERAL Rx

- Topical steroids are generally not helpful. They may be effective for symptom management in mild, early cases with erythema and pruritus but no vesiculation.
- Topical antibiotics should be avoided.
- Use of antihistamines for associated pruritus may be effective, but this has not been extensively studied.
- Systemic corticosteroids offer significant relief in moderate to severe *Rhus* dermatitis, including generalized rash or severe facial or genital involvement.
- Effective dosing of oral prednisone is 1 mg/kg/day over 7 to 10 days (maximum 60 mg initial dose), with tapering over an additional 7 to 10 days.
- Inadequate doses or too-rapid tapering of systemic steroids may cause symptom rebound.
- Intramuscular (IM) treatment with long-acting triamcinolone suspension may be considered for patients intolerant of oral therapy.

CHRONIC Rx

- Recurrence may be caused by repeated exposure to fomites, including contaminated clothing, equipment, or pets.
- Secondary bacterial infection of the skin is the most common complication of *Rhus* dermatitis. Staph and strep are the most common pathogens. Methicillin-resistant *Staphylococcus aureus* (MRSA) must be considered.

DISPOSITION

Untreated *Rhus* dermatitis will resolve in 1 to 3 wk.

REFERRAL

Refer to dermatology if there is diagnostic confusion.

PEARLS & CONSIDERATIONS

PREVENTION

- Patients should be educated regarding identification and avoidance as well as washing to remove the oil after known exposure.
- Total avoidance of the plants may not be practical.
- The use of barrier creams applied before exposure to prevent dermatitis may be of some benefit, particularly in potential occupational (therefore predictable) exposure. These need to be regularly reapplied.
- Products available for postexposure prophylaxis are effective; however, equal efficacy may be obtained from less expensive liquid dishwashing soap.

- Desensitization has not been found to be effective.

PATIENT & FAMILY EDUCATION

- "Leaves of three, let it be" is a helpful reminder for patients.
- Patient education material, including access to photographs of the leaves of these plants in a variety of seasons and conditions, may be useful.

Poliomyelitis (PTG)

BASIC INFORMATION

DEFINITION

Poliomyelitis is a symptomatic infection caused by poliovirus, which is transmitted by fecal-oral route, and which (on rare occasions) may result in paralysis.

SYNONYMS

Polio
Infantile paralysis

ICD-10CM CODES

A80.0	Acute paralytic poliomyelitis, vaccine-associated
A80.1	Acute paralytic poliomyelitis, wild virus, imported
A80.2	Acute paralytic poliomyelitis, wild virus, indigenous
A80.30	Acute paralytic poliomyelitis, unspecified
A80.39	Other acute paralytic poliomyelitis
A80.4	Acute nonparalytic poliomyelitis
A80.9	Acute poliomyelitis, unspecified
B91	Sequelae of poliomyelitis

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE (IN U.S.):

- All cases in the U.S. and Western Hemisphere are now vaccine associated (because of use of the live-attenuated oral polio vaccine [OPV]).
- Before 1997, there were 6 to 10 cases per yr in the U.S. caused by OPV. Since 2000, only inactivated polio vaccine (IPV) has been used in the U.S.

PREDOMINANT AGE: Almost always infants or young children

GENETICS

NEONATAL INFECTION: Most cases occur in otherwise healthy infants who receive OPV, or their contacts.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Exposure of a nonimmune host to poliovirus usually results in asymptomatic infection.
- A small percentage of individuals may have one of three presentations after an incubation period of 7 to 14 days:
  1. Abortive poliomyelitis: A flulike illness
     a. Fever
     b. Malaise
     c. Headache
     d. Sore throat
  2. Nonparalytic poliomyelitis: An aseptic meningitis that correlates with invasion of the central nervous system (CNS)
     a. Headache
     b. Neck stiffness
     c. Change in mental status
  3. Paralytic poliomyelitis
     a. Most commonly affects the lumbar or bulbar regions
     b. Following paralysis, a period of variable degrees of recovery, the majority of which occurs in 2 to 6 mo
     c. Paralysis from involvement of motor neurons in the spinal cord
     d. Flaccid paralysis without sensory defects
     e. Postpolio syndrome late sequelae, which may occur many yr after the acute illness
     f. Functional deterioration of muscle groups that had recovered from initial paralysis thought to result from failure of reinnervation, which initially was able to restore function to weakened or paralyzed areas

ETIOLOGY

- Virus of genus *Enterovirus* (three serotypes of polio virus [types 1 to 3]).
- Classic endemic and epidemic disease caused by wild-type poliovirus.
- Due to vaccination efforts, there have been no endemic polio cases in the Western Hemisphere since 1991. Only 33 cases occurred worldwide in 2018. India and Nigeria reported their last cases of polio in 2014.
- Only two nations remain with endemic polio: Pakistan and Afghanistan.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Guillain-Barré syndrome
- Cerebrovascular accident (CVA)
- Botulism food poisoning
- Spinal cord compression
- West Nile virus
- Other nonpolio enteroviruses such as Enterovirus A71 and Enterovirus D68: The cause of acute flaccid myelitis
  1. Aseptic meningitis
  2. Paralysis (rare)

WORKUP

- Isolation of virus:
  1. Stool or a rectal swab
  2. Throat swabs
  3. Rarely cerebrospinal fluid (CSF)
- Paired sera for antibody titer determinations for each of the three serotypes, but serologic tests cannot distinguish between wild-type virus and vaccine-virus infection.
- Gold standard is now a polymerase chain reaction (PCR) on CSF.

LABORATORY TESTS

CSF:

- Aseptic meningitis
- Elevated WBCs
- Elevated protein
- Normal glucose
- PCR for enterovirus

IMAGING STUDIES

MRI may show involvement of anterior horn of the spinal cord.

TREATMENT

NONPHARMACOLOGIC THERAPY

- Maintenance of respiration and hydration
- Early mobilization and exercise once fever subsides

ACUTE GENERAL Rx

- Aimed at reduction of pain and muscle spasm
- No agent to alter the course of disease

CHRONIC Rx

Physical therapy

DISPOSITION

- In the abortive and nonparalytic forms, complete recovery
- Paralytic disease:
  1. Variable degrees of recovery
  2. 80% usually in the first 6 mo following illness

REFERRAL

Always refer to an infectious disease consultant. Cases should be reported to public health agencies.

PEARLS & CONSIDERATIONS

COMMENTS

- Risk of disease in recipients of OPV is approximately 1 in 2.5 million.
- Use of IPV is not associated with disease:
  1. Does not confer local (mucosal) immunity.
  2. Will not immunize nonvaccinated contacts.
  3. Requires boosters.
  4. Is given by injection.
- To decrease the incidence of vaccine-associated polio, the routine childhood vaccination schedule in the U.S. was changed to immunization with four doses of inactivated poliovirus vaccine at 2, 4, and 6 mo through 18 mo and 4 through 6 yr of age. Exclusive use of IPV is now recommended. OPV use is limited to unvaccinated persons with plans for imminent (<4 wk) travel to polio-endemic areas but is not available in the U.S.
- Postpolio syndrome (PPS): Consists of new or progressive muscle weakness and disability of unclear etiology decades after development of acute poliomyelitis.
- Acute flaccid myelitis (AFM): A polio-like illness was described in the U.S. in 2014 to 2015 and starts as a febrile or respiratory illness followed by limb weakness, variable cranial nerve abnormalities, and MRI evidence of gray matter involvement of spinal cord. AFM appears to be temporally related to an enterovirus D68 infection.

Polyarteritis Nodosa

BASIC INFORMATION

DEFINITION

Polyarteritis nodosa (PAN) is a systemic vasculitic syndrome involving medium-sized to small arteries, characterized histologically by necrotizing inflammation of the arterial media and inflammatory cell infiltration. It is not associated with antineutrophil cytoplasmic antibodies (ANCA).

SYNONYMS

Periarteritis nodosa
PAN
Necrotizing arteritis

ICD-10CM CODE
M30.0 Polyarteritis nodosa

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence is 1/100,000 persons annually
- Increased incidence in patients with hepatitis B surface antigen or hepatitis C virus
- There is no gender predilection
- Commonly occurs between age 40 to the mid-60s
- Can also occur in children
- No racial predilection is observed
- Prevalence is 2 to 33/1,000,000
- Is also associated with hairy cell leukemia

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Typical presentation is subacute in >90% of cases
- Weight loss
- Nausea, vomiting, headache
- Testicular pain or tenderness (more commonly seen in hepatitis B infection)
- Myalgias, weakness, or leg tenderness in 24% to 80% of cases
- Neuropathy (mononeuritis multiplex), foot drop
- Cutaneous manifestations like tender nodules, livedo reticularis, palpable purpura, ulceration of digits
- Abdominal pain after meals, hematemesis, hematochezia, occasionally with diarrhea and gastrointestinal bleeding in severe cases
- Liver function abnormalities
- Asymmetric polyarthritis (tending to involve large joints of lower extremities); true synovitis occurs only in a minority of patients
- Presence of lung vasculitis suggests other causes
- Fever (PAN is often a cause of fever of unknown origin) can range from intermittent, low-grade fevers to high fevers with chills
- Chest pain secondary to ischemic infarcts in the coronary arteries, pericarditis, cardiomyopathy, and arrhythmias are seen with cardiac involvement
- Tachycardia is common and often striking
- Hypertension secondary to renal ischemia, perirenal hematomas

ETIOLOGY

- Unknown.
- Hepatitis B virus (HBV)–associated PAN appears to be an immune complex–mediated disease.
- Hepatitis C, hairy cell leukemia, and human immunodeficiency virus are also associated in some cases.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Cryoglobulinemia
- Systemic lupus erythematosus
- Infections (e.g., subacute bacterial endocarditis, trichinosis, *Rickettsia*)
- Blood dyscrasias (hyperviscosity syndrome)
- Henoch-Schönlein purpura (immunoglobulin A [IgA] vasculitis)
- Granulomatosis with polyangiitis (Wegener granulomatosis)
- Microscopic polyangiitis
- Kawasaki disease
- Eosinophilic granulomatosis with polyangiitis (EGPA)
- Giant cell arteritis
- Human immunodeficiency virus
- Drug-induced vasculitis
- Ergot toxicity
- Occupational hazards

WORKUP

Laboratory evaluation, arteriography, and biopsy of small or medium-sized arteries can confirm diagnosis. Clinical manifestations are variable and depend on the arteries involved and the organs affected (e.g., kidney involvement occurs in >80% of cases). Table E1 summarizes investigations for patients with suspected PAN.

The presence of any three of the following 10 items allows the diagnosis of PAN with a sensitivity of 82% and a specificity of 86%:

1. Weight loss >4 kg
2. Livedo reticularis
3. Testicular pain or tenderness

TABLE E1 Investigations for Patients with Suspected Polyarteritis Nodosa (PAN)

Test	Supports Diagnosis of PAN	Supports an Alternative Diagnosis	Comment
Elevated C-reactive protein	+		Supports the presence of systemic inflammation
Elevated sedimentation rate	+		Supports the presence of systemic inflammation
Elevated serum creatinine	+/–	+/–	Raised serum creatinine, typically without hematuria or proteinuria on urinalysis, may indicate renal ischemia or infarction. Significant proteinuria or hematuria (especially red cell casts) would suggest glomerular disease, which is *not* a feature of PAN
Abnormal liver function tests	+		May suggest hepatitis, either from HBV or as a result of ischemic hepatitis from PAN affecting the hepatic arteries
Positive HBV serology	+		Seen in HBV PAN
Anemia	+		Due to chronic inflammation or from gastrointestinal blood loss
Positive ANCA		+	A positive ANCA would suggest an alternative type of vasculitis such as granulomatosis with polyangiitis or MPA
Elevated creatine kinase	+/–	+/–	Normal or mildly elevated, despite any muscle involvement
Blood cultures		+	To exclude endocarditis or other infective mimic of vasculitis
Positive HCV serology and cryoglobulins		+	HCV associated with a skin limited manifestation of PAN, but typically it is associated with a small vessel vasculitis related to cryoglobulinemia
Positive rheumatoid factor and ACPA		+	To rule out rheumatoid arthritis, especially in the context of a patient presenting predominantly with arthritis
Positive ANA and anti-dsDNA		+	In patients with clinical features consistent with SLE or other connective tissue disease
HIV positive		+	

ACPA, Anticitrullinated protein antibody; *ANA,* antinuclear antibody; *ANCA,* antineutrophil cytoplasm antibody; *dsDNA,* double-stranded deoxyribonucleic acid; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *MPA,* microscopic polyangiitis; *SLE,* systemic lupus erythematosus.

4. Myalgias, weakness, or leg tenderness
5. Neuropathy
6. New-onset diastolic blood pressure >90 mm Hg
7. Elevated blood urea nitrogen (BUN) or creatinine
8. Positive test for hepatitis B virus
9. Arteriography revealing small or large aneurysms and focal constrictions between dilated segments
10. Biopsy of small or medium-sized artery containing necrotizing inflammatory infiltrate

LABORATORY TESTS

- Elevated BUN or creatinine, positive test for hepatitis B virus or hepatitis C.
- Elevated erythrocyte sedimentation rate and C-reactive protein, anemia, elevated platelets, eosinophilia, proteinuria, hematuria.
- Biopsy of small or medium-sized artery of symptomatic sites (muscle, nerve) is >90% specific. Biopsy of the gastrocnemius muscle and sural nerve is commonly performed.
- Circumferential or segmental vessel wall involvement with necrotizing mixed cell inflammation with fibrinoid necrosis is characteristic lesion of active PAN.
- Assays for antinuclear antibody and rheumatoid factor are negative; however, low, nonspecific titers may be detected.
- Serum and urine immunofixation electrophoresis for monoclonal gammopathy and human immunodeficiency virus should also be tested for alternative diagnoses.

IMAGING STUDIES

Arteriography can be done in patients with negative biopsies or if there are no symptomatic sites. Mesenteric angiography will reveal aneurysmal dilation of the renal, mesenteric (Fig. E1), or hepatic arteries. Less invasive techniques, such as computed tomography (CT) and MRI angiography, also help evaluate the extent and resolution of the disease.

Nerve conduction studies are useful in patients with neuropathy suggesting PAN, helping to evaluate nerves or muscles to biopsy.

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

Low-sodium diet in hypertensive patients

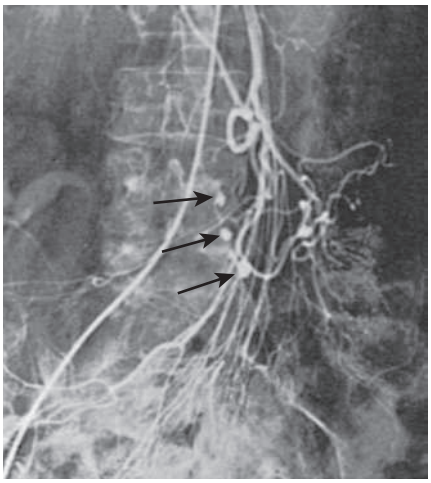

FIG. E1 Superior mesenteric arteriogram in patients with polyarteritis. Several small aneurysms *(arrows)* are present in branches of superior mesenteric artery. (Courtesy Dr. A.W. Stanson. From Harris ED et al: *Kelley's textbook of rheumatology,* ed 7, 2005, WB Saunders.)

ACUTE GENERAL Rx

- Prednisone 1mg/kg/day with higher doses initially, then tapering the doses slowly with overall course of average 9 mo or longer.
- Patients with isolated cutaneous involvement may be treated with steroids alone or in combination with methotrexate or azathioprine.
- Severe PAN with multi-organ involvement treated with a combination of cyclophosphamide 1.5 to 2 mg/kg per day and glucocorticoids has shown good disease outcomes. Once patient achieves stable remission, transition to a less toxic immunomodulatory therapy such as methotrexate or azathioprine, along with tapering doses of oral prednisone, is indicated for chronic therapy.
- In conditions where the disease is resistant to cyclophosphamide glucocorticoids, pulse steroids for few months then switching to alternate agents such as mycophenolate, azathioprine, or methotrexate is tried.
- If hepatitis B is identified, then appropriate antiviral treatment (interferon alpha-2b or lamivudine with or without plasma exchange) is initiated.
- Plasma exchange has been shown to have a limited role in treatment of severe forms of acute hepatitis B–associated PAN.

CHRONIC Rx

Monitoring for infections and potential complications such as thrombosis, infarction, or organ necrosis. Hypertension in patients with renal involvement in PAN is treated with angiotensin-converting enzyme inhibitor.

DISPOSITION

The 5-yr survival is <15% in untreated patients. Treatment with corticosteroids increases survival to approximately 50%. Use of both corticosteroids and immunosuppressive drugs may increase 5-yr survival to >80%. Poor prognostic signs are severe renal or gastrointestinal involvement. Prognosis is better in patients with cutaneous PAN without systemic involvement and in hepatitis B virus (HBV)–associated PAN than for non–HBV-associated disease. Patients on cyclophosphamide should have regular white cell count monitoring for leukopenia. Cyclophosphamide can cause increased risk of infertility, myelodysplasia, lymphoma, bladder malignancy, and when given in combination of high-dose corticosteroids can predispose patients to infection with *Pneumocystis jiroveci (carinii)* pneumonia. Therefore, close follow-up and PCP prophylaxis are recommended.

REFERRAL

Patients with suspected diagnosis of PAN should be immediately referred to a rheumatologist.

PEARLS & CONSIDERATIONS

- After treatment, patients should be followed up closely for relapse throughout their lifetime.
- Smoking cessation, exercise, and lifestyle modifications should be discussed to decrease vascular complications.

AUTHORS: **Sarah Aziz, DO Candidate,** and **Syeda M. Sayeed, MD**

BASIC INFORMATION

DEFINITION

Polycystic ovary syndrome (PCOS) is characterized by an accumulation of incompletely developed follicles in the ovaries due to anovulation and associated with ovarian androgen production. In its complete form, it is associated with polycystic ovaries, amenorrhea, hirsutism, and obesity. Criteria for PCOS according to published definitions are described in Table 1.

SYNONYMS

Polycystic ovarian syndrome
Stein-Leventhal syndrome
PCOS

ICD-10CM CODE
E28.2 Polycystic ovarian syndrome

EPIDEMIOLOGY & DEMOGRAPHICS

- 6% to 25% of reproductive-age women (most common endocrine disorder in this population).
- Symptoms usually begin around the time of menarche, and the diagnosis is often made during adolescence or young adulthood.
- Increased risk of endometrial and ovarian cancers.
- PCOS is the most common cause of anovulatory infertility.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Oligomenorrhea or amenorrhea
- Dysfunctional uterine bleeding
- Infertility
- Hirsutism
- Acne, alopecia, acanthosis nigricans (Fig. E1)
- Obesity (40% only), predominantly abdominal obesity
- Insulin resistance (type 2 diabetes mellitus)
- Hypertension

ETIOLOGY & PATHOGENESIS

Elevated serum luteinizing hormone (LH) concentrations and an increased serum LH/follicle-stimulating hormone (FSH) ratio result either from an increased gonadotropin-releasing hormone hypothalamic secretion or less likely from a primary pituitary abnormality. This results in dysregulation of androgen secretion and increased intraovarian androgen, the effect of which in the ovary is follicular atresia, maturation arrest, polycystic ovaries, and anovulation. Hyperinsulinemia is a contributing factor to ovarian hyperandrogenism, independent of LH excess. A role for insulin growth factor (IGF) receptors has been postulated for the association of PCOS and diabetes. Fig. E2 illustrates the pathologic mechanisms in PCOS.

DIAGNOSIS

The diagnosis of PCOS excludes secondary causes (androgen-producing neoplasm, hyperprolactinemia, adult-onset congenital adrenal hyperplasia).

Clinical:

- The symptoms, signs, and biochemical features of PCOS vary greatly among women and may change over time.
- PCOS is the most common cause of chronic anovulation with estrogen present. A positive progesterone withdrawal test establishes the presence of estrogen. Medroxyprogesterone (Provera) 10 mg qd is administered for 5 days and bleeding occurs if estrogen is present.
- The presence of oligomenorrhea, hirsutism, obesity, and documented polycystic ovaries establishes the diagnosis.

DIFFERENTIAL DIAGNOSIS

Causes of amenorrhea:

- Primary (unusual in PCOS):
  1. Genetic disorder (Turner syndrome)
  2. Anatomic abnormality (e.g., imperforate hymen)
- Secondary:
  1. Pregnancy
  2. Functional (cause unknown, anorexia nervosa, stress, excessive exercise, hyperthyroidism, less commonly hypothyroidism, adrenal dysfunction, pituitary dysfunction, severe systemic illness, drugs such as oral contraceptives, estrogens, or dopamine agonists)
  3. Abnormalities of the genital tract (uterine tumor, endometrial scarring, ovarian tumor)

LABORATORY TESTS

- Glucose tolerance test at the initial presentation and every 2 yr thereafter (rule out diabetes mellitus). Impaired glucose tolerance is very common, occurring in approximately 30% of women with PCOS
- Fasting lipid panel (rule out dyslipidemia), alanine aminotransferase, aspartate aminotransferase (rule out hepatic steatosis)
- Elevated LH/FSH ratio >2.5
- Prolactin level elevation in 25%
- Elevated androgens (testosterone [free and total levels], DHEA-S) (rule out androgen-secreting tumor)
- Other: Thyroid-stimulating hormone (rule out hypothyroidism), 17-hydroxyprogesterone (rule out congenital adrenal hyperplasia), 24-hr urine for cortisol and creatinine (rule out Cushing syndrome)
- TSH
- Table 2 summarizes laboratory testing to exclude other causes of ovulatory dysfunction and hyperandrogenism

IMAGING STUDIES

Pelvic ultrasound (Fig. E3) reveals the presence of twofold to fivefold ovarian enlargement with a thickened tunica albuginea, thecal hyperplasia, and 20 or more subcapsular follicles from 1 to 15 mm in diameter. It is important to note that having polycystic ovaries alone does not make the diagnosis of PCOS because 20% of women with polycystic ovaries have no symptoms.

TREATMENT

The goal is to interrupt the self-perpetuating abnormal hormone cycle:

- Reduction of ovarian androgen secretion by laparoscopic ovarian wedge resection. Laparoscopic ovarian surgery (laparoscopic ovarian drilling [LOD]) is a useful alternative that does not trigger ovarian hyperstimulation.

TABLE 1 Criteria for Polycystic Ovary Syndrome According to Published Definitions

	NICHD/NIH/1990	Rotterdam 2003	AE-PCOS/2009
Diagnostic criteria	Requires simultaneous presence of: • Clinical and/or biochemical hyperandrogenism • Menstrual dysfunction	Requires the presence of at least two criteria: • Clinical and/or biochemical hyperandrogenism • Ovulatory dysfunction • PCOM	Requires the presence of: • Hyperandrogenism and/or hyperandrogenemia • Ovarian dysfunction: Oligoovulation or anovulation and/or polycystic ovaries
Exclusion criteria	Congenital adrenal hyperplasia, androgen-secreting tumors, Cushing syndrome, and hyperprolactinemia	Congenital adrenal hyperplasia, androgen-secreting tumors, and Cushing syndrome	21-hydroxylase-deficient nonclassic adrenal hyperplasia, androgen-secreting neoplasms, androgenic–anabolic drug use or abuse, the hyperandrogenic-insulin resistance-acanthosis nigricans syndrome, thyroid dysfunction, and hyperprolactinemia
Clinical traits	Hirsutism, acne, and alopecia	Hirsutism, acne, and androgenic alopecia	Hirsutism
PCOM	Not included	At least one ovary showing either: • Twelve or more follicles of 2-9 mm in diameter • Ovarian volume, 10 ml	At least one ovary showing either: • Twelve or more follicles of 2-9 mm in diameter • Ovarian volume, 10 ml

TABLE 2 Laboratory Testing to Exclude Other Causes of Ovulatory Dysfunction and Hyperandrogenism

Lab	Evaluation for:	Comment
Total and/or bioavailable testosterone	Androgen-secreting tumor	Measure if there are symptoms concerning for an androgen-secreting tumor or if biochemical evidence of hyperandrogenism is needed to make the diagnosis of polycystic ovary syndrome. Rapid progression or a total testosterone >200 ng/dl should prompt a workup for an androgen-secreting tumor.
Dehydroepiandrosterone sulfate	Androgen-secreting tumor	Measure if there are symptoms concerning for an androgen-secreting tumor. Although modest elevations in dehydroepiandrosterone sulfate can be seen in polycystic ovary syndrome, rapid progression or greater elevations should prompt a workup for an adrenal androgen-secreting tumor.
Morning 17-hydroxyprogesterone	Late-onset congenital adrenal hyperplasia	This disorder is caused by a partial adrenal enzyme defect that leads to impaired cortisol production, compensatory elevation in adrenocorticotropic hormone, and subsequent excess androgen production. Symptoms may mimic polycystic ovary syndrome. Normal values <200 ng/dl. If higher than this, adrenocorticotropic hormone stimulation test recommended.
24-hour urine for cortisol and creatinine; dexamethasone suppression test; salivary cortisol	Cushing syndrome	Consider ruling out Cushing syndrome in women with an abrupt change in menstrual pattern, later-onset hirsutism, or other evidence of cortisol excess such as hypertension, facial plethora, supraclavicular fullness, hyperpigmented striae, and fragile skin.
Prolactin	Hyperprolactinemia	May be accompanied by galactorrhea. Consider ruling this out in all women with irregular menstrual cycles.
Thyroid function studies	Hyperthyroidism or hypothyroidism	Consider ruling out thyroid dysfunction in all women with irregular menstrual cycles.

From Setji TL, Brown AJ: Polycystic ovary syndrome: update on diagnosis and treatment, *Am J Med* 127:912-919, 2014.

- Reduction of ovarian androgen secretion by using oral contraceptives or LH-releasing hormone (LHRH) analogs.
- Weight reduction for all obese women with PCOS. Loss of abdominal fat seems to be crucial to restore ovulation.
- FSH stimulation with clomiphene HMG or pulsatile LHRH.
- Urofollitropin (pure FSH) administration.
- Metformin improves ovulation, insulin sensitivity, and possibly hyperandrogenemia.

Choice of treatment:

- The management of hirsutism without risking pregnancy includes oral contraceptives, glucocorticoids, LHRH analogs, or spironolactone (an antiandrogen). Finasteride and flutamide may be similarly effective in reducing hirsutism as spironolactone.
- Pregnancy can be achieved with clomiphene (alone or with glucocorticoids, human chorionic gonadotropin, or bromocriptine), HMG, urofollitropin, pulsatile LHRH, or ovarian wedge resection. Metformin may also induce ovulation. Recent trials comparing the aromatase inhibitor letrozole to clomiphene for infertility have shown higher live-birth and ovulation among infertile women with PCOS treated with letrozole. When considering in vitro fertilization (IVF), the transfer of fresh embryos is generally preferred over the transfer of frozen embryos; however, a recent trial among infertile women with PCOS undergoing IVF revealed that frozen-embryo transfer is associated with a higher rate of live birth, a lower risk of the ovarian hyperstimulation syndrome, and a higher risk of preeclampsia after the first transfer than with fresh-embryo transfer.[1]
- Psychological screening for depression is recommended. Women with PCOS are fourfold more likely to have abnormal depression scores.
- Table 3 describes a mnemonic for assessment and management of PCOS.

[1] Chen ZJ et al: Fresh versus frozen embryos for infertility in the polycystic ovary syndrome, *N Engl J Med* 375:523-533, 2016.

Abnormal Uterine Bleeding (Related Key Topic)

AUTHOR: **Fred F. Ferri, MD**

TABLE 3 MY PCOS: Mnemonic for Assessment and Management of Polycystic Ovary Syndrome (PCOS)

	Assessment	Management
Metabolic	2-hour glucose tolerance test with 75 grams oral glucose, measuring serum glucose at time 0 and 120 min. Lipid profile Liver function tests (if other risk factors for nonalcoholic fatty liver disease)	Lifestyle intervention: Diet, exercise, and weight loss (if overweight or obese) Metformin for abnormal glucose tolerance not controlled with lifestyle Statin therapy if patient meets criteria (Adult Treatment Panel-III or American College of Cardiology/American Heart Association guidelines)
Cycle control	Ask about menstrual pattern; normal cycle length is 28 days (range 21-35)	If amenorrhea for 3 months or more, induce withdrawal bleed with progesterone (after negative pregnancy test) Hormonal therapy Examples: • Estrogen-containing oral contraceptives (monthly cycling, seasonal cycling, continuous use) • Vaginal ring • Patch • Progestin-only pill (smokers, hypertension) • Progestin-eluting intrauterine device (Mirena) • Progesterone prn to induce withdrawal bleeding (medroxyprogesterone acetate 10 mg daily for 10-14 days, micronized progesterone 400 mg daily for 10-14 days) • Metformin (second-line therapy)
Psychosocial	Screen for depression, disordered eating Affirm that polycystic ovary syndrome is an important medical issue; provide nonjudgmental support Discuss stress management Reinforce self-care behaviors	Mental health referral and/or antidepressant therapy may be warranted if depression or disordered eating is identified
Cosmetic	Ferriman-Gallwey score as guide to assess hirsutism Evaluate for acne and male pattern hair loss Serum androgen levels if uncertain about degree of hirsutism or atypical symptoms	Estrogen-containing hormonal contraception Antiandrogens such as spironolactone or finasteride. Teratogenic; only use with contraception Cyproterone acetate (not available in the U.S.) Eflornithine hydrochloride 13.9% cream Laser or electrolysis Topical treatment for acne Minoxidil 2.5% or 5% for male pattern hair loss
Ovulation and fertility	Counsel that fertility is reduced in polycystic ovary syndrome, but patients typically not infertile Assess fertility goals	If subfertility is an issue, consider referral to Reproductive Endocrine for possible clomiphene citrate therapy Metformin has limited role
Sleep apnea	Screen for sleep apnea: Daytime somnolence, morning headache, reflux symptoms, snoring, observed interrupted breathing	Refer for sleep study Continuous positive airway pressure therapy recommended if sleep apnea diagnosed

PCOS, Polycystic ovary syndrome.
From Setji TL, Brown AJ: Polycystic ovary syndrome: Update on diagnosis and treatment, *Am J Med* 127:912-919, 2014.

TABLE 4 Metabolic Complications in Polycystic Ovary Syndrome

Abnormal glucose tolerance (impaired glucose tolerance or type 2 diabetes)	30% of obese polycystic ovary syndrome women have impaired glucose tolerance, and 10% have type 2 diabetes by age 40. In thin women with polycystic ovary syndrome, 10% have impaired glucose tolerance, and 1.5% have type 2 diabetes.
Obesity	Prevalence of obesity varies considerably in women with polycystic ovary syndrome. Previously, prevalence rates of obesity were estimated based on populations of women with polycystic ovary syndrome seeking care. A recent study comparing patients presenting for care in a polycystic ovary syndrome clinic with an unselected population evaluated during a preemployment physical suggests that obesity and overweight may not be more common in polycystic ovary syndrome. In that study, 63.7% of polycystic ovary syndrome clinic patients were obese, compared with 28% of unselected women with polycystic ovary syndrome identified during screening, and 28% of nonpolycystic ovary syndrome controls. Polycystic ovary syndrome symptoms, including hyperandrogenism and oligo-ovulation, are exacerbated by obesity.
Metabolic syndrome	33%-50% of U.S. women with polycystic ovary syndrome have metabolic syndrome compared to only 12% in a similarly aged National Health and Nutrition Examination Survey population. In contrast, only 8.2% of women with polycystic ovary syndrome in Italy met criteria for metabolic syndrome. Thus, metabolic syndrome varies by geographic location, a finding likely related to different body mass index, though other causes including genetics and diet could also be playing a part.
High blood pressure	Data have been conflicting, but a large Kaiser Permanente study demonstrated that hypertension or elevated blood pressure was more than twice as common in women with polycystic ovary syndrome (27% vs. 12%).
Dyslipidemia	Dyslipidemia is more prevalent in women with polycystic ovary syndrome compared to controls (15% vs. 6%). In a meta-analysis, triglyceride values were 26 mg/dl higher (95% CI 17-35), low-density lipoprotein cholesterol was 12 mg/dl higher (95% CI 10-16), and high-density lipoprotein-cholesterol was 6 mg/dl lower (95% CI 4-9) in women with polycystic ovary syndrome compared with controls. Women with polycystic ovary syndrome also have higher concentrations and proportions of small, dense low-density lipoprotein cholesterol.
Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis	Nonalcoholic fatty liver disease and nonalcoholic steatohepatitis have recently been recognized as a potential complication in women with polycystic ovary syndrome. Prevalence of fatty liver disease in polycystic ovary syndrome women has been estimated to be 15%-55%, depending on the diagnostic parameter used (level of serum alanine aminotransferase or ultrasound). Individuals that may be at higher risk of nonalcoholic fatty liver disease including nonalcoholic steatohepatitis include those with metabolic syndrome, insulin resistance, and possibly hyperandrogenemia.
Cardiovascular disease	Many studies demonstrate abnormal surrogate markers of cardiovascular disease in women with polycystic ovary syndrome. However, data regarding cardiovascular disease risk are conflicting with some studies suggesting an increased risk in women with polycystic ovary syndrome, whereas other studies have not found this difference in cardiovascular risk. While it is important to recognize and treat cardiovascular risk factors in this population, further research of cardiovascular risk and complications is still needed to clarify the long-term risk.

CI, Confidence interval.

From Melmed S et al: *Williams textbook of endocrinology,* ed 12, Philadelphia, 2011, Saunders.)

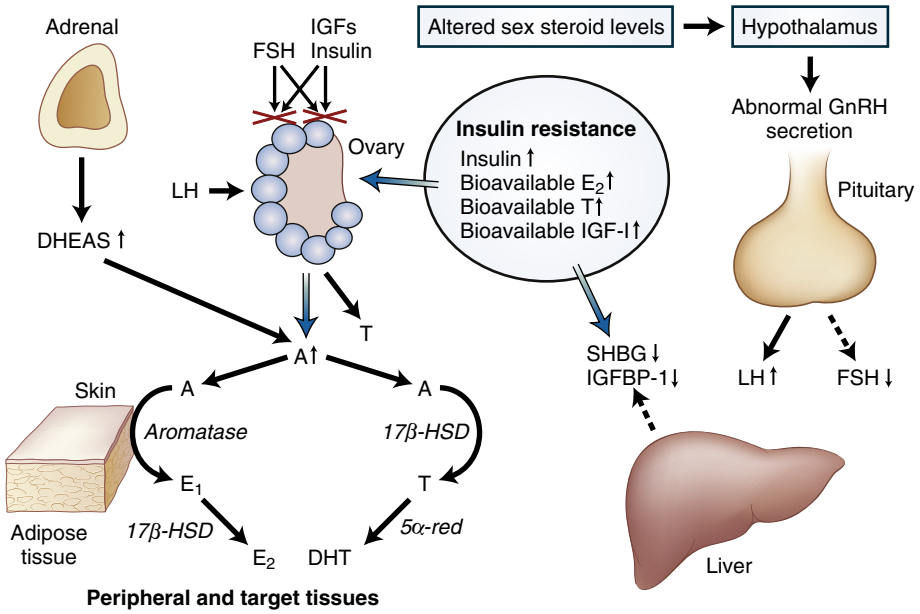

FIG. E2 Pathologic mechanisms in polycystic ovary syndrome (PCOS). A deficient in vivo response of the ovarian follicle to physiologic quantities of follicle-stimulating hormone *(FSH),* possibly because of an impaired interaction between signaling pathways associated with FSH and insulin-like growth factors *(IGFs)* or insulin, may be an important defect responsible for anovulation in PCOS. Insulin resistance associated with increased circulating and tissue levels of insulin and bioavailable estradiol *(E2),* testosterone *(T),* and IGF1 gives rise to abnormal hormone production in a number of tissues. Oversecretion of luteinizing hormone *(LH)* and decreased output of FSH by the pituitary, decreased production of sex hormone–binding globulin *(SHBG)* and IGF-binding protein 1 *(IGFBP-1)* in the liver, increased adrenal secretion of dehydroepiandrosterone sulfate *(DHEAS),* and increased ovarian secretion of androstenedione *(A)* all contribute to the feed-forward cycle that maintains anovulation and androgen excess in PCOS. Excessive amounts of E_2 and T arise primarily from the conversion of A in peripheral and target tissues. T is converted to the potent steroids estradiol or DHT (dihydrotestosterone). Reductive 17β-hydroxysteroid dehydrogenase (17β-HSD) enzyme activity may be conferred by protein products of several genes with overlapping functions; 5α-reductase (5α-red) is encoded by at least two genes, and aromatase is encoded by a single gene. *GnRH,* Gonadotropin-releasing hormone. BASIC INFORMATION

DEFINITION

Polycythemia vera is a clonal disorder of aberrant myeloid/erythroid stem cells resulting in erythropoietin-independent proliferation of erythrocytes.

SYNONYMS

PV
Primary polycythemia

ICD-10CM CODE
D45 Polycythemia vera

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE:

- 1 case per 100,000 persons
- Occurs most commonly in patients ages 50 to 75 yr
- Mean age at onset is 60 yr; men are affected more often than are women

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Polycythemia vera has a latent, proliferative, and spent phase. The patient generally comes to medical attention because of symptoms associated with increased blood volume and viscosity or impaired platelet function:

- Impaired cerebral circulation resulting in headache, vertigo, blurred vision, dizziness, transient ischemic attack, cerebrovascular accident
- Fatigue, poor exercise tolerance
- Pruritus, particularly after bathing (caused by overproduction of histamine)
- Bleeding: Epistaxis, upper gastrointestinal bleeding (increased incidence of peptic ulcer disease)
- Abdominal discomfort from splenomegaly; hepatomegaly may be present
- Hyperuricemia may result in nephrolithiasis and gouty arthritis
- Up to 40% of patients experience arterial or venous thrombosis during the course of their disease. Cerebral and splanchnic thrombotic events occur commonly and can be presenting events.

The physical examination may reveal:

- Facial plethora, congestion of oral mucosa, ruddy complexion
- Enlargement and tortuosity of retinal veins
- Erythromelalgia—painful redness, swelling, and warmth of the skin of the hands and feet
- Splenomegaly (found in >75% of patients)

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Smoking:

- Polycythemia is caused by increased carboxyhemoglobin, resulting in left shift in the hemoglobin (Hgb) dissociation curve.
- Laboratory evaluation shows increased hematocrit (Hct), RBC mass, erythropoietin level, and carboxyhemoglobin.
- Splenomegaly is not present on physical examination.

Hypoxemia (secondary polycythemia):

- Living for prolonged periods at high altitudes, pulmonary fibrosis, congenital cardiac lesions with right-to-left shunts.
- Laboratory evaluation shows decreased arterial oxygen saturation and elevated erythropoietin level.
- Splenomegaly is not present on physical examination.

Erythropoietin-producing states:

- Renal cell carcinoma, hepatoma, cerebral hemangioma, uterine fibroids, polycystic kidneys.
- The erythropoietin level is elevated in these patients, and the arterial oxygen saturation is normal.
- Splenomegaly may be present with metastatic neoplasms.

Stress polycythemia (Gaisböck syndrome, relative polycythemia):

- Laboratory evaluation demonstrates normal RBC mass, arterial oxygen saturation, and erythropoietin level; plasma volume is decreased.
- Splenomegaly is not present on physical examination.

Hemoglobinopathies associated with high oxygen affinity:

- An abnormal oxyhemoglobin-dissociation curve (P50) is present.

WORKUP

The revised 2016 WHO diagnostic criteria for PV use a hemoglobin/hematocrit level exceeding 16.5 g/dl/49% in men or 16 g/dl/48% in women after secondary causes have been excluded. Initial myelofibrosis (present in up to 20% of patients) can only be detected by performing a biopsy, and this finding may predict a more rapid progression to overt post-polycythemia myelofibrosis.

Janus kinase 2 *(JAK2)* gene mutations are detected in approximately 99% of patients with polycythemia vera and can be used for diagnostic purposes. The exon 14 JAK2V617F mutation is seen in 97% cases and the remainder 3% of JAK2 mutations are spread across exons 12, 13, and 14. Testing for the *JAK2 V617F* mutation with polymerase chain reaction assay is routine. In patients with high hematocrit (>52% in men or >48% in women) and in the absence of coexisting secondary erythrocytosis, the presence of a *JAK2* mutation is sufficient for the diagnosis of polycythemia vera.

The World Health Organization diagnostic criteria for polycythemia vera are described in Table 1.

LABORATORY TESTS

- Elevated RBC count (>6 million/mm^3), elevated Hgb (>18.5 g/dl in men, >16.5 g/dl in women), elevated Hct (<54% in men, <49% in women)
- Increased white blood cell count (often with basophilia; basophilia is a strong predictor of PV instead of a reactive state); thrombocytosis is found in the majority of patients
- Elevated leukocyte alkaline phosphatase, serum vitamin B_{12}, and uric acid levels were used previously but have been supplanted by molecular testing
- Low serum erythropoietin level
- Peripheral blood smear: May reveal basophils or immature myeloid forms
- Bone marrow aspiration revealing RBC hyperplasia and absent iron stores

TREATMENT

NONPHARMACOLOGIC THERAPY

Phlebotomy to keep Hct >45% in men and >42% in women is the mainstay of therapy. Phlebotomy, however, has no effect on the development of myelofibrosis.

TABLE 1 World Health Organization 2016 Diagnostic Criteria for Polycythemia Vera

Major Criteria

- Hemoglobin (Hgb) >16.5 g/dl (men), >16.0 (women); *or* Hematocrit (Hct) >49% (men), >48% (women); *or* elevated red cell mass (>25% above mean normal predicted value)
- BM biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic, mature megakaryocytes (differences in size)
- Presence of *JAK2 V617F* or similar mutation

Minor Criterion

- Subnormal serum erythropoietin level

1. Diagnosis of PV requires meeting either all three major criteria, or the first two major criteria and the minor criterion
2. BM biopsy may not be required in cases with sustained absolute erythrocytosis: hemoglobin levels >18.5 g/dl in men (hematocrit, 55.5%) or >16.5 g/dl in women (hematocrit, 49.5%) if major criterion 3 and the minor criterion are present.

From Arber DA et al: *Blood,* 127(20):2391-2405, 2016.

BOX 1 Algorithm for Management of Patients with Polycythemia Vera

Low-Risk Young Patients (Age <60 Yr) and No History of Thrombosis, Platelet Count <1.5 × 106 mm–3

Phlebotomy + low-dose aspirin (81 mg/day) to maintain hematocrit lower than 45%. Aspirin should not be used in patients with histories of a hemorrhagic episode or with extreme thrombocytosis (>1.5 × 10^6 mm^{-3}) or acquired von Willebrand syndrome.

↓

Thrombosis or hemorrhage
Systemic symptoms
Severe pruritus refractory to histamine antagonists
Painful splenomegaly

↓

Hydroxyurea 15 to 20 mg/kg (unless age <40 yr, pregnant, intolerant to hydroxyurea; consider pegylated interferon [IFN])

↓

Pegylated IFN 45 to 180 μg/wk or IFN-α (3 × 10^6 units three times a week; alter dose depending on response and toxicity) or ruxolitinib 10 mg twice daily and titrate dose depending on the response. →

In a patient with a prior thrombosis or a history of bleeding due to acquired von Willebrand syndrome, normalization of platelet numbers is necessary. If platelet control is inadequate or the patient cannot tolerate interferon, one option is the use of anagrelide. In this case, supplemental phlebotomy is required to maintain hematocrit lower than 45%, and the use of hydroxyurea should be considered, especially if the patient continues to have thrombotic episodes.

↓

If the patient has increasing splenomegaly, systemic symptoms, or repeated thromboses despite adequate dose of hydroxyurea (2 to 3 g/day) or if unable to tolerate hydroxyurea, start ruxolitinib 10 mg twice daily and titrate up or down based on hematologic parameters.

For patients unable to tolerate ruxolitinib or resistant to it, start low doses of busulphan or melphalan, which should be administered until the blood counts are normalized. Therapy should be then discontinued because patients frequently enjoy drug-free prolonged remissions lasting months. Therapy should be reinstituted only at the time the blood counts begin to be elevated again. Such therapy with alkylating agents should be rarely used in young patients. It should be mentioned that the sequential use of hydroxyurea and alkylating agents may be associated with an increased risk of leukemia. Supplemental phlebotomy may be required.

Painful splenomegaly

↓

Patients should be treated with ruxolitinib
If unable to tolerate or insufficient response
Splenectomy + continued systemic therapy

↓

High-risk patients (age >60 yr), previous thrombosis, platelet count >1.5 × 10^6 mm^{-3}
Phlebotomy to hematocrit of 45%
Aspirin (81 mg/day) to be given only in patients with platelet counts <1.5 × 10^6 mm^{-2}
Myelosuppressive therapy with hydroxyurea 30 mg/kg orally for 1 week
Then 15 to 20 mg/kg

↓

If patient continues to have thrombotic episodes and has extreme thrombocytosis or cannot tolerate hydroxyurea

Consider pegylated IFN 45 to 180 μg/week, anagrelide, or ruxolitinib 10 mg twice daily, or add intermittent busulphan or melphalan (in older patients).

If on busulphan or melphalan, stop when blood counts are normalized or platelet count is lower than 300,000 mm^{-3}.

Occasional supplemental phlebotomy if hematocrit is >45%; when patient relapses (patient is symptomatic), initiate busulphan therapy again at same dose.

Patient Age >70 yr

Phlebotomy + low-dose aspirin + hydroxyurea

↓

No response or poor compliance
Ruxolitinib, melphalan, or busulfan.

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

ACUTE GENERAL Rx

- Add aspirin in patients younger than 60 yr without prior thromboembolic event.
- Hydroxyurea can be used in conjunction with phlebotomy in patients older than 60 yr to decrease the incidence of thrombotic events.
- Pegylated interferon-alpha-2b is effective in achieving non-inferior rates of complete hematologic remission compared to hydroxyurea without major side effects and is approved in Europe for initial therapy.
- Box 1 describes an algorithm for management of patients with polycythemia vera.
- Ruxolitinib, a Janus kinase (JAK) 1 and 2 inhibitor, is superior to standard therapy in controlling the hematocrit, reducing the spleen volume and improving symptoms associated with polycythemia vera.

CHRONIC Rx

- Patient education regarding need for lifelong monitoring and treatment.
- Adjunctive therapy: Treatment of pruritus with antihistamines, control of significant hyperuricemia with allopurinol, reduction of gastric hyperacidity with antacids of H_2 blockers, low-dose aspirin to treat vasomotor symptoms in patients without bleeding diathesis. Low-dose aspirin can safely prevent thrombotic complications in patients with polycythemia vera and should be given to all patients in absence of contraindications.

DISPOSITION

- The median survival time without treatment is 6 to 18 mo after diagnosis; phlebotomy extends the average survival time to 12 yr.
- Patients with polycythemia vera with a hematocrit <45% have a significantly lower rate of cardiovascular death and major thrombosis than those with hematocrit of 45% to 50%.
- Prognosis is worse in patients >60 yr and those with a history of thrombosis.

BASIC INFORMATION

DEFINITION

Polymyalgia rheumatica (PMR) is an inflammatory condition characterized by neck, shoulder, and pelvic girdle muscle pain and stiffness, which is worse in the morning, and primarily affects the elderly. PMR can occur alone or in conjunction with giant cell arteritis (GCA

SYNONYMS

Anarthritic rheumatoid syndrome
PMR

ICD-10CM CODE

M31.5 Polymyalgia rheumatica with giant cell arteritis
M35.3 Polymyalgia rheumatica

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE/PREVALENCE: In the U.S., incidence is 52.5 cases per 100,000; increases with advancing age. Prevalence is 0.5% to 0.7%. Scandinavian and Northern European populations have higher incidence.
PREDOMINANT SEX: Female:male ratio of 2:1.
PREDOMINANT AGE: Almost exclusively occurs above age 50, with peak incidence between seventh and eighth decades.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Patients with PMR often have symptoms for 1 to 3 mo before a diagnosis is made.
- Onset of symmetric muscle aching and stiffness, worse in the morning. Stiffness recurs with periods of inactivity.
- Neck, shoulders, lower back, hips, thighs, and occasionally trunk and arms are involved. Shoulders are usually affected first. Pain distribution in PMR is illustrated in Fig. 1.
- Constitutional symptoms of fatigue, malaise, weight loss, loss of appetite, and low-grade fever may accompany pain and stiffness.
- Physical exam may reveal limited range of motion of shoulder (most common), cervical spine, and hips. May have subdeltoid and subacromial bursitis and peripheral joint synovitis. Motor exam is normal, although can be limited by pain.
- High-spiking fevers, night sweats, visual disturbances, headaches, or jaw claudication should raise suspicion of giant cell arteritis and be further evaluated promptly.

ETIOLOGY

The cause is unknown, but both PMR and GCA are associated with HLA-DR4 haplotype. With both conditions, also see elevated Th17 cells and decreased Treg cells.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

See Box 1.

WORKUP

- Initial laboratory evaluation: ESR, CRP, CBC, CPK.
- ESR >40 in majority of patients. CRP elevation may be more common than high ESR.
- CBC may show a normocytic anemia and thrombocytosis.
- CPK is normal. Antibodies (ANA, RF, CCP) are typically negative.
- An algorithm for diagnosing polymyalgia rheumatica without giant cell arteritis (GCA) is described in Fig. E2, and Tables 1 and 2 describe various classification criteria for PMR.
- Ultrasonography, MRI and PET may identify bursitis or tenosynovitis, (features of the 2012 PMR classification of criteria), which increase sensitivity and specificity.

TREATMENT

- Prednisone 15 to 20 mg/day, with dramatic improvement usually within 3 days; up to one third of patients may have incomplete response at 4 weeks.
- Dose adjustment may be necessary for weight, symptom severity, and comorbidities (e.g., diabetes mellitus, hypertension, or heart failure).
- If symptoms persist after 1 week, increase dose by 5 mg. Ongoing symptoms require consideration of alternative diagnosis.
- If nighttime symptoms are bothersome, can try divided dose of prednisone.
- Initial prednisone dose should be maintained for 4 to 8 weeks. Steroid dose is then tapered every 2 to 4 weeks as tolerated to minimum amount required to remain symptom free. When dose reaches 10 mg/day, taper slowly, usually by 1 mg/month.
- Flares are typical during tapering, can manage by increasing prednisone 10% to 20%. Most require treatment for 1 to 2 yr with steroids; others are unable to taper off fully.
- Monitor both clinical response and ESR and CRP intermittently.
- Gastroprotection should be considered, and attention should be paid to bone health, with calcium and vitamin D supplementation started early. Consider prophylactic bisphosphonates if indicated.
- Routine use of adjunctive therapy is not recommended, but certain cases (refractory disease, high-risk steroid use) can consider methotrexate. TNFi has not been shown to have benefit. It has been found more recently that tocilizumab (IL6i) may be beneficial in patients with contraindications to methotrexate use, and was recently approved to treat GCA.

PEARLS & CONSIDERATIONS

Patients with PMR should be monitored closely for the development of GCA. Patients who have incomplete response to prednisone or have an evolving pattern of pain and swelling should be re-evaluated for the possibility of a different diagnosis such as rheumatoid arthritis.

- Rheumatoid arthritis
- Rotator cuff syndrome
- Osteoarthritis of shoulder and hip joints
- Fibromyalgia
- Polymyositis/dermatomyositis
- Spondyloarthritis
- Systemic lupus erythematosus
- Vasculitides
- Paraneoplastic myalgias
- Infection-associated myalgias
- RS3PE (remitting seronegative symmetric synovitis and pitting edema)
- Parkinson disease
- Hypothyroidism

TABLE 1 2012 European League Against Rheumatism/American College of Rheumatology Classification Criteria for Polymyalgia Rheumatica*

Criteria	Points With Ultrasonography	Points Without Ultrasonography
1. Morning stiffness duration >45 min	2	2
2. Hip pain or limited range of movement	1	1
3. Absence of rheumatoid factor or anticitrullinated protein antibody	2	2
4. Absence of other joint involvement	1	1
5. ≥1 shoulder with subdeltoid bursitis and/or biceps tenosynovitis and/or glenohumeral synovitis (either posterior or axillary) and ≥1 hip with synovitis and/or trochanteric bursitis	1	—
6. Both shoulders with subdeltoid bursitis, biceps tenosynovitis, or glenohumeral synovitis	1	—

*Score ≥4 without ultrasonography or ≥5 with ultrasonography is categorized as polymyalgia rheumatica.

TABLE 2 Classification Criteria for Polymyalgia Rheumatica

Chuang Criteria

1. Patients aged 50 yr or older
2. Bilateral aching and stiffness persisting for 1 month or more involving two of the following areas: Neck or torso, shoulders or proximal regions of the arms, and hips or proximal aspects of the thighs
3. ESR >40 mm/hr
4. Exclusion of other diagnoses except GCA; the presence of all these criteria defines diagnosis of PMR.

Healey Criteria (22)

1. Persistent pain (for at least 1 month) involving two of the following areas: Neck, shoulders, and pelvic girdle
2. Morning stiffness lasting >1 hr
3. Rapid response to prednisone (≤20 mg/day)
4. Absence of other diseases capable of causing the musculoskeletal symptoms
5. Age >50 yr
6. ESR >40 mm/hr

The diagnosis of PMR is made if all the above criteria are satisfied.

Bird Criteria (23)*

1. Bilateral shoulder pain and/or stiffness
2. Onset of illness within 2 wk
3. Initial ESR >40 mm/hr
4. Morning stiffness >1 hr
5. Age >65 yr
6. Depression or loss of weight
7. Bilateral upper arm tenderness

*A diagnosis of probable polymyalgia rheumatica (PMR) is made if any three or more of these criteria are fulfilled. The presence of any three or more criteria yields a sensitivity of 92% and a specificity of 80%.

ESR, Erythrocyte sedimentation rate; *GCA,* giant cell arteritis.

From Hochberg MC: *Rheumatology,* ed 7, Philadelphia, 2019, Elsevier.

Polypharmacy

BASIC INFORMATION

DEFINITION

Polypharmacy is the concomitant use of many different medications, with the most common definition being the use of five or more medications for one patient. Polypharmacy is important when the medications are inappropriate without a clear benefit to the patient. Medication errors, adverse drug reactions, drug interactions, hospitalizations, nonadherence, functional decline, worse clinical outcomes, and/or increased costs have been associated with polypharmacy. A systematic review has found that polypharmacy was associated with increased mortality.

SYNONYM

Potentially inappropriate medications (PIMs)

ICD-10CM CODE
X71.9 Counseling, unspecified

EPIDEMIOLOGY & DEMOGRAPHICS

PEAK INCIDENCE: Incidence increases with age and disease burden.
PREVALENCE: One in five Americans receives potentially inappropriate drug therapy, although prevalence may be substantially higher in specific clinical settings.
PREDOMINANT SEX, AGE, AND RACE:
- Adults aged 65 and older
- Women
- White

RISK FACTORS:
- Multiple chronic diseases, particularly hypertension and depression
- Poor health status
- Frequent hospitalizations
- Multiple providers and pharmacies
- Low educational level

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Presence of one or more drugs without a clearly defined indication
- Presence of therapeutic duplications such as multiple NSAIDs
- Unexpected response to drug therapy
- Expanded list of new medications for a patient late in life or at the end of life
- Decreased patient adherence and limited patient understanding of their drug regimen
- Presence of a "geriatric syndrome" such as falling, excessive sedation and confusion, urinary retention or incontinence, reduced oral intake, and general failure to thrive
- Decreased self-perceived health status and lower quality of life

ETIOLOGY

- Inadequate communication & coordination between providers, pharmacists, and patients
- Prescriber adherence to single-disease guidelines
- Not recognizing a new problem as an adverse effect and prescribing a second drug to treat the problem
- Continuing medications without a review of risks and appropriateness of therapy
- Under-representation of elderly in studies, leading to inadequate knowledge about the benefits and harms of a drug

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Misuse, overuse, or underuse of drug therapy

WORKUP

- Obtain a thorough medication history including prescriptions, OTC drugs, supplements, and drugs "borrowed" from other individuals.
- "Brown bag" approach: Visually verify all medication bottles for actual ingredients.
- Risk assessment tools such as the Drug Burden Index (DBI) can help guide the medication review process. The DBI estimates the use of sedative and anticholinergic medications and their associated physical and cognitive impairments.
- Use standard tools to evaluate drug regimens:
  1. **Beers criteria:** Identifies potentially dangerous or ineffective drugs for older adults, such as ketorolac, muscle relaxants, and drugs with strong anticholinergic properties.
  2. **Screening Tool of Older Persons' potentially inappropriate Prescriptions (STOPP) and Screening Tool to Alert to Right Treatment (START) criteria:** Helps detect inappropriate prescribing and underprescribing of clinically indicated medications for older adults.
  3. **Medication Appropriateness Index (MAI):** Evaluates key elements of appropriate prescribing.
     a. Is there an indication for the drug?
     b. Is the medication effective for the condition?
     c. Is the dose appropriate for the patient and the condition?
     d. Are the directions practical and correct?
     e. Are there clinically significant drug-drug or drug-disease interactions?
     f. Is there unnecessary duplication with other drugs?
     g. Is the duration of therapy appropriate?
     h. Is this drug the least expensive of the equally effective alternatives?
- Utilize informatic software programs such as Micromedex, Epocrates, and Lexi-Interact.
- Pharmacogenomic tools may be used to identify how an individual reacts to different medications and can be used to assess current prescribing and promote deprescribing if necessary.

TREATMENT

NONPHARMACOLOGIC THERAPY

Consider nonpharmacologic alternatives to drug therapy.

ACUTE GENERAL Rx

If acute drug-related problems are identified, establish priorities for safely withdrawing/tapering the offending drugs.

CHRONIC Rx

- Always assess the potential risks and benefits from each specific medication, especially in patients with multiple comorbid conditions or limited life expectancy.
- Consideration should be given to the incremental benefit from each drug added to a complex drug regimen in the frail elderly.

DISPOSITION

- Prioritize medications for deprescribing based on those with the least benefit and greatest potential harm, on the patient's willingness to stop a medication, and on the medications easiest to discontinue or least likely to cause withdrawal reactions.
- Stop medications one at a time so a specific drug may be linked to reversal of adverse reactions, withdrawal symptoms, or worsening of disease state. The site http://medstopper.com/ may be useful when withdrawing medications.
- Evidence-based algorithms for deprescribing medications such as proton-pump inhibitors are available for use (http://www.open-pharmacy-research.ca/evidence-based-ppi-deprescribing-algorithm/).
- Closely monitor for withdrawal or return of original symptoms after discontinuation.
- Notify other members of the patient's health care team when a medication has been discontinued and document the reason for discontinuing the medication.
- Ensure EHR is always up to date.

REFERRAL

Referral to a clinical pharmacist for a comprehensive drug regimen review and potentially to a geriatrician, especially for frail older adults

PEARLS & CONSIDERATIONS

COMMENTS

- The prevention and/or identification of polypharmacy should focus on the appropriateness of the medications for the *individual* person and not simply the number of medications. In addition, clinical practice guidelines for chronic diseases rarely acknowledge the presence of concomitant conditions when recommending drug therapies. Deprescribing is a patient-centered process that considers a patient's preference concerning his/her drug treatment regimen, such as maintaining quality of life versus prolonging life. The decision regarding what is "appropriate" should consider the patient's own priorities, expected risk and benefit to that individual, and the patient's life expectancy.
- The EMPOWER study showed direct-to-consumer education may help start conversations regarding deprescribing. Prescribers and pharmacists should give a consistent message about the potential benefits of deprescribing.

PREVENTION

- Multiple systems are needed to prevent inappropriate polypharmacy.
- Adverse effects and adherence problems should be assessed at each encounter.
- Consider whether a drug is needed for a new symptom and whether the symptom is actually an unrecognized adverse effect.
- Confirm whether a drug is used for symptomatic relief or to prevent future events.
- Nonpharmacologic therapies should be encouraged whenever possible and appropriate.
- Update the drug list in the EHR at each visit and every care transition against what the patient is actually taking.
- Verify patient understanding about options such as tapering or discontinuing a drug.
- Counseling at hospital discharge during which the provider ensures patient and caregiver understanding of any medication change. Written and oral instructions should be provided in the patient's preferred language and at the appropriate literacy level.
- Effective communication between health care professionals is essential, with one prescriber taking overall responsibility for drug therapy.
- Regular evaluation of how frequently "as needed" medications are being used by the patient.

PATIENT & FAMILY EDUCATION

- An up-to-date list of all drugs taken on a regular or prn basis must be maintained. The list should include all prescription and OTC drugs including eye drops, inhalers, and skin creams. Dietary supplements should also be on the list. The National Transitions of Care Coalition's "My Medicine List" is an excellent tool for patients (https://static1.squarespace.com/static/5d48b6eb75823b00016db708/t/5d48ccd81475550001d26a77/1565052120781/My_Medicine_List.pdf)
- After hospital discharge, patients and/or caregivers should compare newly prescribed drugs to their existing drugs. They should ask which drugs should be stopped, which should be continued, and which should be continued but in a different dosage or frequency.
- Patients enrolled in Medicare Part D may be eligible for Medication Therapy Management (MTM) review programs.

BASIC INFORMATION

DEFINITION

Porphyrias are rare inherited (mostly autosomal dominant) disorders due to deficiencies of heme synthesis enzymes. Table E1 classifies the various types. They are named after the Greek word *porphurus* ("purple"), after the red fluorescence of phorphyrins exposed to ultraviolet light. Table E2 summarizes the various types of porphyrias.

SYNONYMS

Acute intermittent porphyria (AIP)
Porphyria cutanea tarda (PCT)
Variegate porphyria (VP)
Hereditary coproporphyria (HCP)
Congenital erythropoietic porphyria (CEP)
Hepatoerythropoietic porphyria
Erythropoietic protoporphyria
ALA-dehydrase porphyria

ICD-10CM CODE
E80.20 Unspecified porphyria

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: 0.13 cases/million/yr (Europe) with a peak incidence in Sweden (0.51 cases/million/yr)
PREVALENCE: 1:75,000 population in Europe (1:1000 population in Sweden)
PREDOMINANT SEX AND AGE: Equal female-to-male ratio, except for AIP (female predominance). Pubertal onset is common.
GENETICS: Acute intermittent porphyria is more prevalent in northern Sweden (1:1,000); variegate porphyria is more common in descendants of Dutch settlers from South Africa (both due to founder effect).

RISK FACTORS: No risk factors are identified.
Triggers for acute crisis involve:
- Alcohol
- Barbiturates
- Sulfonamides
- Progesterone and other steroid hormones
- Emotional/physical stress
- Rapid weight loss

PHYSICAL FINDINGS & CLINICAL PRESENTATION

Porphyrias can present as skin stigmata (porphyria cutanea), neurologic symptoms (acute intermittent porphyria), or both (variegata). Skin stigmata (Figs. E1, E2, and E3) are the result of absorption of solar radiation by porphyrin and consequent blistering skin findings. Porphyrins do not cross the blood-brain barrier and only affect the autonomic and peripheral nervous systems. However, vasospasm can cause CNS findings. Neurologic symptoms in acute attacks include abdominal pain, vomiting, constipation, and urinary retention. Pain in the back or extremities is common. There is no convincing evidence that delta-aminolevulinic acid is the cause of pain in acute porphyrias. Motor neuropathy affects proximal muscles of upper extremities and the sensory component affects the trunk. Seizures associated with severe hyponatremia may occur. Hallucination, insomnia, restlessness, and psychosis are described. Porphyrias can be acute or chronic. Precipitating factors in acute porphyria are summarized in Table E3.

These disorders are in the differential of acute abdomen; however, characteristically, rebound tenderness is not present.

ETIOLOGY

Porphyrin binds to iron to form heme, the core of the hemoglobin molecule. Porphyrins are synthesized in the cytosol and mitochondria, and mutations in any of the eight enzymes involved in heme synthesis can result in porphyrias. When the defect is physiologically significant, it results in overproduction of pathway precursors preceding the defective step that enter the circulation and are excreted into urine or bile.

This metabolic pathway is limited only by iron in the red blood cell and not by its end product, heme, which therefore is used in the treatment of hepatic porphyrias, where it inhibits the ALAS enzyme. Table E4 summarizes the distribution of porphyrins in red cells, urine, and feces in different forms of porphyria.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

- Lead toxicity
- Paroxysmal nocturnal hemoglobinuria
- Acute abdomen

WORKUP

Laboratory tests:
- Screening
- 24-hour urine for delta-aminolevulinic acid (markedly elevated in AIP attacks) and porphobilinogen

Confirmatory tests:
- Plasma porphobilinogen (increased in AIP, VP, and HCP)
- Erythrocyte zinc protoporphyrin, uroporphyrin, and coproporphyrin
- Stool (coproporphyrins)

IMAGING STUDIES

- Usually performed to rule out causes of acute abdomen if the porphyria is to be diagnosed
- Imaging if localized pain or rebound tenderness is present, when a primary surgical cause may be present

TABLE E1 Porphyrias: Clinical Involvement, Enzymatic Etiology, and Chromosomal Location

Porphyria (Synonym)	Acute Attack, Skin and Organ Involvement	Enzyme of Heme Biosynthesis Affected	Chromosome Location
=	=	Hepatic, 5-aminolevulinate synthase, nonspecific, mitochondrial (ALAS1)	3p21
X-linked sideroblastic anemia	Bone marrow	5-Aminolevulinate synthase, erythroid-specific, mitochondrial (ALAS2)	Xp11.21
X-linked dominant protoporphyria	Skin, red cells, liver	5-Aminolevulinate synthase, erythroid-specific, mitochondrial (ALAS2)	Xp11.21
ALA dehydratase deficiency porphyria (plumboporphyria)	Acute liver	ALA dehydratase (porphobilinogen synthase)	9q33.1
Acute intermittent porphyria (intermittent acute porphyria)	Acute liver	Porphobilinogen deaminase (hydroxymethylbilane synthase)	11q23.3
Congenital erythropoietic porphyria (Günther disease)	Skin, red cells, bone marrow	Uroporphyrinogen III synthase	10q25.2-q26.3
Porphyria cutanea tarda (symptomatic porphyria, cutaneous hepatic porphyria)	Skin, liver	Uroporphyrinogen decarboxylase	1p34
Hereditary coproporphyria	Acute skin, liver	Coproporphyrinogen oxidase	3q12
Variegate porphyria (porphyria variegata)	Acute skin, liver	Protoporphyrinogen oxidase	1q22
Erythropoietic protoporphyria (erythrohepatic protoporphyria)	Skin red cells, liver	Ferrochelatase (heme synthase)	18q21.3

ALA, 5-Aminolevulinate.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE E2 Classification of Porphyrias

Classification	Disease	Biochemistry	Clinical Features
Acute porphyria	Acute intermittent porphyria	Increased ALA and PBG	Acute attack
	Variegate porphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	Hereditary coproporphyria	Increased ALA and PBG; increased porphyrin	Acute attack; photosensitivity
	ALA dehydratase deficiency porphyria	Increased ALA; increased porphyrin	Acute and chronic neuropathy
Nonacute porphyria	Porphyria cutanea tarda	Increased porphyrin	Photosensitivity
	Erythropoietic protoporphyria	Increased porphyrin	Photosensitivity
	Congenital erythropoietic porphyria	Increased porphyrin	Photosensitivity
	X-linked dominant protoporphyria	Increased porphyrin	Photosensitivity
Porphyrinurias	Lead, alcohol, iron deficiency anemia, liver disease	Various biochemical manifestations	Various clinical presentations

ALA, 5-Aminolevulinate; *PBG,* porphobilinogen.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

FIG. E1 Porphyria cutanea tarda. Eroded blisters and crusts. (Courtesy the Yale Residents' Collection. From Skorecki K et al: *Brenner & Rector's the kidney,* ed 10, Philadelphia, 2016, Elsevier.)

FIG. E2 Congenital erythropoietic porphyria. Vesicles, bullae, and crusts on sun-exposed areas. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence,* ed 5, Philadelphia, 2016, Elsevier.)

FIG. E3 Erythropoietic protoporphyria (EPP). Vesicular lesions are only occasionally seen in patients with EPP. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology, a textbook of skin disorders of childhood and adolescence,* ed 5, Philadelphia, 2016, Elsevier.)

Rx TREATMENT

NONPHARMACOLOGIC THERAPY

- Curative: Liver transplantation
- Acute crisis: High carbohydrate intake: 2000 kcal/24 hr daily oral or 300 kcal/day administered intravenous 10% dextrose solution

ACUTE GENERAL Rx

- Opioids: Pain
- Phenothiazines: Nausea and psychiatric manifestations
- Propranolol: Tachycardia and hypertension
- Chloral hydrate or benzodiazepines: Insomnia
- Levetiracetam: Seizures
- Hematin: Given IV 1 to 4 mg/kg once daily for 3 to 14 days
- Givosiran is an investigational RNA interference therapeutic agent that inhibits hepatic ALAS synthesis. In patients who had recurrent porphyria attacks, givosiran resulted in reductions in induced ALAS mRNA levels, nearly normalized levels of the neurotoxic intermediates delta ALA and porphobilinogen, and a lower attack rate than that observed with placebo.

CHRONIC Rx

- It is advisable to carry a medical bracelet with the name of the porphyria and for specific avoidance of substances that may trigger porphyria in medical emergency or hospital admissions for other reasons.
- Consume sufficient carbohydrates.
- Avoid alcohol and other triggers, including rapid weight loss or emotional/physical stress.

COMPLEMENTARY & ALTERNATIVE MEDICINE

Avoid herbs and toxins (alcohol) that may potentially interact with phenothiazines or cause hepatic interactions.

DISPOSITION

Admit all patients in acute attacks for hematin infusion.

TABLE E3 Changes in Porphyrins and Their Precursors in the Porphyrias, Porphyrinurias, and Hereditary Sideroblastic Anemia

Porphyrias and Other Conditions	ALA	PBG	Urine Uroporphyrin	Urine Coproporphyrin	Feces Coproporphyrin	Feces Protoporphyrin	Erythrocyte Protoporphyrin
Acute Porphyrias							
Acute intermittent porphyria	Raised, very high in attack	Raised, very high in attack	Usually raised[a]	Sometimes raised	Sometimes raised	Sometimes raised	Normal
Variegate porphyria	Raised in attack	Raised in attack	Usually raised in attack	Usually raised in attack	Raised	Raised	Normal
Hereditary coproporphyria	Raised in attack	Raised in attack	Sometimes raised in attack	Usually raised, always in attack	Raised	Usually normal	Normal
ALA dehydratase–deficiency porphyria	Raised in attack	Normal	Normal	Usually raised in attack	Normal	Normal	Occasionally raised
Nonacute Porphyrias							
Porphyria cutanea tarda	Normal	Normal	Raised (7-/8-carboxylate porphyrin levels very high in attack)	Slightly raised	Isocoproporphyrin raised in remission	Raised in remission	Normal
Erythropoietic protoporphyria	Normal	Normal	Normal	Normal	Normal	Usually raised	Raised, usually very high
Congenital erythropoietic porphyria	Usually normal	Usually normal	Raised, isomer I	Raised, isomer I	Normal	Usually raised	Usually raised
X-linked dominant protoporphyria	Normal	Normal	Normal	Normal	Normal	Usually raised	Raised, usually very high
Other Conditions							
Hereditary sideroblastic anemia	Normal	Normal	Normal	Normal	Normal	Normal	Occasionally raised
Lead poisoning	Raised	Normal	Normal	Sometimes raised	Normal	Normal	Raised when blood lead level >2 μM
Hereditary tyrosinemia	Raised	Normal	Normal	Normal	Normal	Normal	Normal
Iron deficiency anemia	Normal	Normal	Normal	Normal	Normal	Normal	Raised

ALA, 5-Aminolevulinate; *PBG,* porphobilinogen.
From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

TABLE E4 Precipitating Factors in Acute Porphyria

Drugs	Other stimuli
Alcohol	Fasting or dieting
Barbiturates	Hormones, stress
Angiotensin-converting enzyme (ACE) inhibitors	Smoking
Anticonvulsants	
Antidepressants	
Calcium channel blockers	
Cephalosporins	
Ergot derivatives	
Erythromycin	
Steroids or anabolic steroids	
Contraceptives, hormone replacement therapy	
Sulfonamides	
Sulfonylureas	

From Hoffman R et al: *Hematology, basic principles and practice,* ed 7, Philadelphia, 2018, Elsevier.

REFERRAL

- Centers that carry hematin
- Outpatient follow-up with hematologist for education on triggers, screening of hepatocellular carcinoma, genetic counseling

PEARLS & CONSIDERATIONS

COMMENTS

- The efficacy of hemin infusion is due to its inhibition of hepatic delta-aminolevulinic acid synthase-1, the enzyme that catalyzes delta-aminolevulic acid formation.
- The inability to diagnose porphyrias puts patients at risk of unnecessary surgeries.
- Attacks are triggered by prescribed drugs, alcohol, hormonal changes, fasting, or stress and may be prevented by avoiding triggers.
- Cancer (hepatocellular carcinoma) may be diagnosed in an early stage.
- Skin biopsies are not diagnostic and may cause harm.

PREVENTION

- Zinc oxide sunscreens.
- Attacks can be prevented by avoiding triggers (see earlier).
- Screen for hemachromatosis in PCT, as increasing liver iron triggers this disease.
- Monitor for hepatocellular carcinoma with limited ultrasound of the liver (alpha-fetoprotein is not usually increased).

PATIENT & FAMILY EDUCATION

Genetic counseling may be offered. Most porphyrias are autosomal dominant with incomplete penetrance (half of carriers manifest symptoms).

BASIC INFORMATION

DEFINITION

Clinically significant portal hypertension is defined as a portal vein pressure >10 mm Hg, most commonly attributable to liver disease.

ICD-10CM CODE
K76.6 Portal hypertension

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence of portal hypertension is not known.
- Cirrhosis is the most common cause of portal hypertension in the U.S.
- Portal hypertension is developed by >90% of patients with cirrhosis.
- Alcoholic and viral liver diseases are the most common causes of cirrhosis and portal hypertension in the U.S.
- Schistosomiasis is the main cause of portal hypertension outside the U.S.
- Esophageal varices may appear when portal vein pressure rises to >10 mm Hg.
- Variceal hemorrhage is the most serious complication of portal hypertension and may occur when portal pressures rise >12 mm Hg.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Jaundice
- Ascites (Fig. 1)
- Spider angiomata
- Testicular atrophy
- Gynecomastia
- Palmar erythema
- Dupuytren contracture
- Asterixis (with advanced liver failure)
- Irritability, encephalopathy
- Splenomegaly
- Dilated veins in the anterior abdominal wall
- Venous pattern on the flanks
- Caput medusae (tortuous collateral veins around the umbilicus)
- Hemorrhoids
- Hematemesis
- Melena
- Pruritus

FIG. 1 Ascites secondary to portal hypertension. Note the dilated collateral vein running up the right side of the abdomen. (From Forbes A et al [eds]: *Atlas of clinical gastroenterology,* ed 3, Oxford, 2005, Mosby.)

ETIOLOGY

Pathophysiologically caused by:

- Conditions resulting in an increased resistance to flow:
  1. **Prehepatic** (e.g., portal vein thrombosis, splenic vein thrombosis, congenital stenosis)
  2. **Hepatic** (e.g., cirrhosis, alcoholic liver disease, primary biliary cirrhosis, schistosomiasis)
  3. **Posthepatic** (e.g., Budd-Chiari syndrome, constrictive pericarditis, inferior vena cava obstruction, cor pulmonale, tricuspid regurgitation)
- Conditions leading to increase in portal blood flow:
  1. Splanchnic arterial vasodilation accompanying portal hypertension, mediated by local release of nitric oxide
  2. Arterial-portal venous fistulae

Table 1 describes the pathophysiologic changes in portal hypertension and Table 2 summarizes the etiologies of portal hypertension.

DIAGNOSIS

- The diagnosis of portal hypertension is made on clinical grounds after a comprehensive history and physical examination.
- Noninvasive and invasive procedures confirm diagnosis and determine the severity of portal hypertension.

DIFFERENTIAL DIAGNOSIS

- Ascites from infection, neoplasm, or other inflammatory processes
- Obesity
- Abdominal organomegaly

WORKUP

The workup of portal hypertension includes blood tests and noninvasive imaging studies to determine if the cause of portal hypertension is prehepatic, hepatic, or posthepatic. Ascitic fluid analysis is a key part of the diagnosis.

LABORATORY TESTS

- Complete blood count with platelets
- Liver function tests with serum albumin
- Prothrombin and partial thromboplastin times
- Hepatitis B surface antigen and antibody
- Hepatitis C antibody
- In selected cases: Iron, total iron-binding capacity, and ferritin; antinuclear antibody, anti–smooth muscle antibodies, antimitochondrial antibody, ceruloplasmin, alpha-1 antitrypsin
- Ascitic fluid analysis: A serum-ascites albumin gradient ≥1.1 mg/dl suggests portal hypertension. Polymorphonuclear cells ≥250 cells/ml or positive Gram stain or culture suggest complicating spontaneous bacterial peritonitis (SBP)

IMAGING STUDIES

- Duplex-Doppler ultrasound is effective in screening for portal hypertension.
- Less commonly, CT/MRI/MRA scanning (Figs. E2 and E3) or liver-spleen nuclear medicine scanning can be used if the results from ultrasound are equivocal.
- Upper endoscopy is the most reliable test documenting the presence of esophageal varices.

TREATMENT

The treatment of portal hypertension is complex and involves measures to reduce the hypertension directly, minimize volume overload, correct underlying disorders, and prevent complications (most notably SBP and variceal bleeding).

TABLE 1 Pathophysiologic Changes in Portal Hypertension

Pathophysiologic Change	Specifics
Hepatic resistance	
	Passive, mechanical component: 60%-70%
	Active, dynamic component: 30%-40%
Portal hypertension	
Shunts	
Splanchnic vasodilation	
Increased portal inflow	
Decrease in effective circulating volume; redistribution total blood volume	
Increase in endogenous vasopressors (RAA, SNS, VP)	
	Increase in endothelin-1
	Angiotensin II
	Norepinephrine
	Vasopressin
	PGF-2 alpha
Decrease in NO, CO	

CO, Carbon monoxide; *NO,* nitrogen monoxide; *PGF,* prostaglandin; *RAA,* renin-angiotensin-aldosterone; *SNS,* sympathetic nervous system; *VP,* vasopressin.
From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

TABLE 2 Etiology of Portal Hypertension Grouped by Location of Insult

Site of Increased Resistance	Condition	FHVP	WHVP	HVGP	SPP
Presinusoidal (extrahepatic)	Extrahepatic portal, splenic, or mesenteric vein thrombosis	Normal	Normal	Normal	Increased
Presinusoidal (intrahepatic)	Early primary biliary cirrhosis	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Presinusoidal (intrahepatic)	PSC	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Presinusoidal (intrahepatic)	Sarcoid	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Presinusoidal (intrahepatic)	Schistosomiasis	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Presinusoidal (intrahepatic)	Congestive heart failure	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Presinusoidal (intrahepatic)	Noncirrhotic portal fibrosis	Normal	Normal/raised (?)	Normal/raised (?)	Increased
Intrahepatic sinusoidal	Cirrhosis (any etiology)	Normal	Increased	Increased	Increased
Intrahepatic sinusoidal	Alcoholic hepatitis	Normal	Increased	Increased	Increased
Intrahepatic sinusoidal	Fulminant liver failure (any etiology)	Normal	Increased	Increased	Increased
Extrahepatic postsinusoidal hypertension	Budd-Chiari syndrome	Increased	Increased	Normal	Increased
Extrahepatic postsinusoidal hypertension	Constrictive pericarditis	Increased	Increased	Normal	Increased
Extrahepatic postsinusoidal hypertension	Inferior vena cava obstruction	Increased	Increased	Normal	Increased
Extrahepatic postsinusoidal hypertension	Congenital inferior vena cava web	Increased	Increased	Normal	Increased
Extrahepatic postsinusoidal hypertension	Right heart failure	Increased	Increased	Normal	Increased

FHVP, Free hepatic venous pressure; *HVPG,* hepatic venous pressure gradient; *PSC,* primary sclerosing cholangitis; *SPP,* systolic pulse pressure; *WHVP,* wedged hepatic venous pressure.
From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

TABLE 3 Indications, Contraindications, and Complications of the TIPS Procedure

Indications	Relative Contraindications	Contraindications	Acute Complications	Chronic Complications
Upper GI bleeding	Pulmonary hypertension	Right-sided heart failure	Neck hematoma	Congestive heart failure
Ascites	Severe liver failure	Biliary tract obstruction	Arrhythmia	Portal vein thrombosis
Hepatic hydrothorax	Portal vein thrombosis	Uncontrolled infection	Stent displacement	Progressive liver failure
	Multiple hepatic cysts	Chronic recurrent disabling hepatic encephalopathy	Hemolysis	Chronic recurrent encephalopathy
		Hepatocellular carcinoma involving hepatic veins	Bilhemia	Stent dysfunction
			Hepatic vein obstruction	TIPSitis
			Shunt thrombosis	
			Hemoperitoneum	
			Hemobilia	
			Liver ischemia	
			Cardiac failure	
			Sepsis	

GI, Gastrointestinal; *TIPS,* transjugular intrahepatic portosystemic shunt.
From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

NONPHARMACOLOGIC THERAPY

Dietary sodium restriction to generally 2000 mg/day forms the basis of therapy to limit fluid overload.

ACUTE GENERAL Rx

- For tense ascites, serial large-volume paracentesis (LVP) is generally recommended. The use of albumin infusion (8 to 10 g/L of ascites fluid removed) during LVP >5 L has been shown to reduce the incidence of postparacentesis circulatory dysfunction, although its use remains somewhat controversial.
- IV diuretics, typically furosemide and spironolactone, are used to achieve natriuresis and net negative salt and water balance. Renal function and serum electrolytes are monitored frequently, with transition to an oral regimen for long-term therapy.
- SBP is treated with IV antibiotics directed against enteric bacteria.
- Acute variceal hemorrhage is treated with crystalloid and blood product resuscitation, IV octreotide, terlipressin/vasopressin or somatostatin, and urgent upper endoscopy, often with sclerotherapy or band ligation. Patients with acute variceal hemorrhage should receive empiric antibiotic therapy for SBP.
- Traditionally, a transjugular intrahepatic portosystemic shunt (TIPS) or surgical shunt placement may be considered in patients not responding to above measures. However, recent data show *early* TIPS placement improved outcomes in acute variceal hemorrhage. Table 3 summarizes indications, contraindications, and complications of the TIPS procedure.
- Table 4 compares treatment modalities for portal hypertension.

CHRONIC Rx

- Dietary sodium restriction in combination with diuretics: The typical ratio of furosemide

TABLE 4 Comparison of Treatment Modalities

Treatment Modality	No (%), N = 77	Age, Yr (Mean)	Female %	Initial Meld (Mean, Range)	Child-Pugh Score (N = 74)	Ascites Size	Death (No, %) (N = 44)	Days from Presentation Until Death or End of Study
Medical management	64/77 (83%)	52	23/64 (36%)	16 (4-46)	A = 1 B = 31	None: 6 Small: 34 Moderate: 16 Large: 8	40/64 (63%)	321 ± 463
TIPS	8/77 (10%)	56	5/8 (63%)	12 (7-28)	A = 0 B = 5 C = 2	None: 1 Small: 3 Moderate: 3 Large: 1	4/8 (50%)	845 ± 407
Transplant	5/77 (7%)	54	0	21 (10-40)	A = 1 B = 1 C = 1	Large: 1	0	1896 ± 1752

TIPS, Transjugular intrahepatic portosystemic shunt.
From Vincent JL et al: *Textbook of critical care,* ed 7, Philadelphia, 2017, Elsevier.

40 mg to spironolactone 100 mg retains normal serum potassium levels in most patients.
- Nonselective beta-blockers (propranolol and nadolol) in dosages sufficient to reduce the resting heart rate by 25% have been shown to be effective in primary prophylaxis for first-time variceal bleeding and for preventing recurrent variceal bleeding. Dosages are usually given bid and decreased if heart rate falls to <55 beats/min or systolic blood pressure drops to <90 mm Hg. The addition of a long-acting nitrate (e.g., isosorbide-5-mononitrate) has been shown to improve portal hemodynamics. Findings of a prospective trial of beta-blockers to prevent the formation of varices were negative. The combination of beta-blockade plus endoscopic esophageal variceal banding is superior to either intervention alone.
- Intermittent LVP may be needed in "diuretic-resistant" patients.
- Patients with prior SBP merit lifelong antibiotics for secondary prevention.
- Abstinence from alcohol or treatment for hepatitis B or hepatitis C. Vaccination for hepatitis A and B as appropriate.
- Hepatic transplantation is an option in selected patients.

DISPOSITION

- The most common complication associated with portal hypertension is variceal bleeding. The risk of bleeding from varices is approximately 15% at 1 yr.
- Development of the hepatorenal syndrome (HRS) is associated with high near-term mortality. In particular, HRS may complicate SBP, which emphasizes the importance of making the diagnosis of SBP and instituting appropriate prophylaxis.

REFERRAL

Consultation with a gastroenterologist is recommended in all patients with portal hypertension to screen for esophageal varices.

PEARLS & CONSIDERATIONS

Splanchnic arterial vasodilation is increasingly recognized as an important component of the pathophysiology of portal hypertension and ascites. There may be vasodilation in other capillary beds as well; of note, pulmonary arteriolar vasodilation can create a significant shunt fraction and resultant hypoxemia in the absence of chest radiograph or CT chest evidence of parenchymal disease. The diagnosis is suspected when otherwise unexplained hypoxia arises in a patient with cirrhosis, along with platypnea (dyspnea worse when sitting upright) and orthodeoxia (desaturation with upright posture). The diagnosis is confirmed by echocardiography with agitated saline, in which there is delayed appearance of bubbles in the left heart after injection into a peripheral vein.

COMMENTS

Portal hypertension and its complications carry significant morbidity and mortality rates. Emphasize ethanol abstinence, provide vaccinations and prophylactic therapy where indicated, and consider early referral to a specialist for assistance with management and consideration for hepatic transplantation.

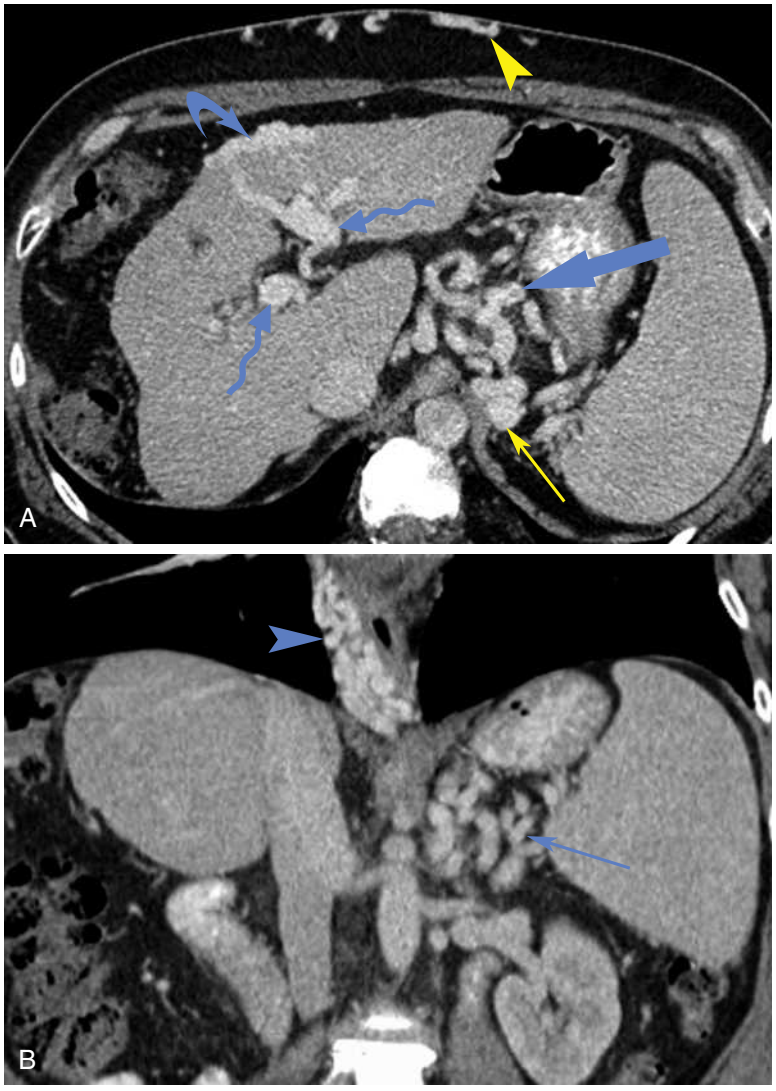

FIG. E3 Portal hypertension. A, Axial postcontrast computed tomography (CT) reveals signs of advanced portal hypertension. The right and left portal veins *(blue squiggly arrows)* are enlarged, measuring 15 mm. Dilated and tortuous cardinal veins *(fat straight blue arrow)* are seen in the gastrohepatic ligament and retroperitoneum *(skinny straight yellow arrow).* Paraumbilical collateral veins are patent and dilated, extending through the fissure of the ligamentum teres and falciform ligament *(blue curved arrow)* and as subcutaneous collaterals *(arrowhead).* Visualization of the patent paraumbilical collateral veins is the most specific CT sign of portal hypertension. **B,** Coronal CT image of the same patient reveals dramatic paraesophageal varices *(arrowhead)* and a tangle of retroperitoneal and perigastric collaterals *(arrow).* (From Webb WR et al: *Fundamentals of body CT,* ed 4, Philadelphia, 2015, WB Saunders.)

Portal Vein Thrombosis

BASIC INFORMATION

DEFINITION

Portal vein thrombosis (PVT) is thrombotic occlusion of the portal vein. The thrombus can also involve segments of the mesenteric veins and/or the splenic vein.

SYNONYMS

Pylethrombosis
PVT

ICD-10CM CODE
I81 Portal vein thrombosis

EPIDEMIOLOGY & DEMOGRAPHICS

- Occurs with equal frequency in children (peak age: 6 yr) and adults (peak age: 40 yr)
- Occurs in 8% to 25% of patients with decompensated cirrhosis

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Acute PVT may present with sudden onset of fever and abdominal pain (when there is mesenteric extension).
- Upper gastrointestinal hemorrhage (hematemesis and/or melena) caused by esophageal varices.

ETIOLOGY & PATHOPHYSIOLOGY

In children: Umbilical sepsis (pathophysiology unknown). In adults:

- Hypercoagulable states:
  1. Antiphospholipid syndrome
  2. Neoplasm (common cause)
  3. Paroxysmal nocturnal hemoglobinuria
  4. Myeloproliferative diseases
  5. Oral contraceptives
  6. Polycythemia vera
  7. Pregnancy
  8. Protein S or C deficiency
  9. Sickle cell disease
  10. Thrombocytosis
- Inflammatory diseases:
  1. Crohn disease
  2. Pancreatitis
  3. Ulcerative colitis
- Complications of medical intervention:
  1. Ambulatory dialysis
  2. Chemoembolization
  3. Liver transplantation
  4. Partial hepatectomy
  5. Sclerotherapy
  6. Splenectomy
  7. Transjugular intrahepatic portosystemic shunt
- Infections:
  1. Appendicitis
  2. Diverticulitis
  3. Cholecystitis
- Miscellaneous:
  1. Cirrhosis (common cause)
  2. Bladder cancer

Pathophysiology: PVT results in portal hypertension, leading to esophageal and gastrointestinal varices. The liver sustained by the hepatic artery maintains normal function.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Causes of upper gastrointestinal hemorrhage and abdominal pain are described in Section II.

WORKUP

- Abdominal ultrasound with Doppler (Fig. 1) or MRI may show the PVT. Abdominal ultrasound color Doppler imaging has a 98% negative predictive value and is considered the imaging modality of choice in diagnosing PVT.
- Determination of underlying cirrhosis of the liver should be the foremost step. It is crucial to differentiate acute from chronic PVT because chronic PVT does not require treatment.
- Esophagogastroscopy typically shows esophageal varices.
- Laboratory evaluation for hypercoagulable state is not cost-effective in patients with cirrhosis.

TREATMENT

- Anticoagulation data on thrombolytic therapy are inconclusive and there is no formal recommendation for or against anticoagulation in acute PVT. However, anticoagulation is generally recommended for patients with extension of PVT into the superior mesenteric vein to prevent intestinal infarction. In patients with chronic PVT and concomitant cirrhosis, long-term anticoagulation is generally not recommended.
- Variceal sclerotherapy or banding.
- Surgical mesocaval or splenorenal shunt.
- The roles of thrombolysis and transjugular intrahepatic portosystemic shunt continue to evolve.

REFERRAL

- To surgeon to rule out intestinal infarction
- To gastroenterologist

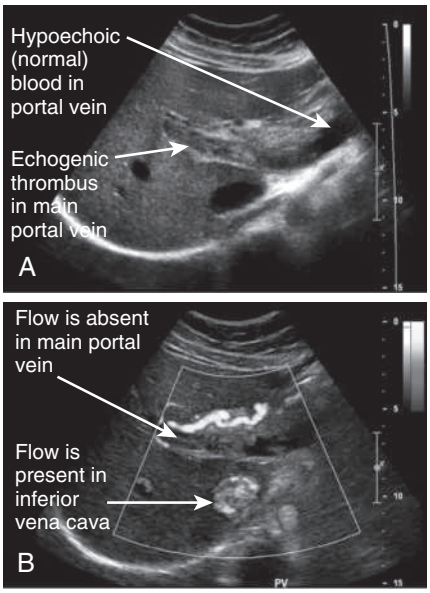

FIG. 1 Portal vein thrombosis: Ultrasound. This 22-yr-old female, 2 mo postpartum, presented with 1 wk of right upper quadrant pain. Ultrasound was performed to evaluate for suspected cholecystitis or symptomatic cholelithiasis. Instead, portal vein thrombosis was discovered. The postpartum state is a risk factor for this condition. Hypercoagulable states and inflammatory or neoplastic abdominal conditions, including pancreatitis and abdominal malignancies, also can result in portal vein thrombosis. **A,** Ultrasound gray scale image showing thrombus in the main portal vein. **B,** Doppler ultrasound showing no flow within the portal vein. BASIC INFORMATION

DEFINITION

Postconcussion syndrome (PCS) refers to nonspecific neurologic, cognitive, and psychological symptoms that result from traumatic brain injury (TBI) and persist beyond the expected recovery period. There is no consensus regarding the duration of symptoms to make the diagnosis, but symptoms usually manifest or significantly worsen within a few days following head trauma and persist for wks to mos. PCS can also follow moderate and severe brain injury, although it is more commonly associated with mild brain injury or concussion. Concussion is an acute trauma-induced alteration of mental function lasting <24 hours, with or without preceding loss of consciousness.

SYNONYMS

PCS
Postconcussive syndrome
Posttraumatic nervous instability or brain injury
Postcontusion syndrome or encephalopathy
Status post commotio cerebri

ICD-10CM CODE
F07.81 Postconcussional syndrome

EPIDEMIOLOGY & DEMOGRAPHICS

- Incidence is approximately 27 cases per 100,000 persons/yr.
- From 30% to 80% of patients with mild to moderate brain injury will experience some symptoms of PCS.
- Usually reported in the young, ages 20 to 30 yr old.
- Risk factors include female sex, low socioeconomic status, anxiety sensitivity, previous TBI, severe bodily injury from TBI, headaches, and unsettled court cases.
- Acute post-injury symptoms such as headache, dizziness, photophobia, diplopia, or tinnitus are associated with development of persistent symptoms.

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- Symptoms start within a few days to wks after the head injury and usually persist after 3 mo. 15% of patients will have persistent symptoms 1 yr later.
- At least three of the following symptoms after TBI are required to meet ICD-10 criteria:
  1. Headache (usually of frontooccipital location and showing characteristics of tension or migraine headache). The International Headache Society suggests that coding and attribution of headaches with characteristics of primary headaches but in the setting of an inciting event should be attributed to the event, unless there was a known history of the headache and the inciting event was seen as aggravating/initiating the preexisting migraine/tension headache
  2. Fatigue
  3. Dizziness and/or vertigo
  4. Impaired memory
  5. Difficulty in concentrating
  6. Insomnia
  7. Irritability/frustration
  8. Lowered tolerance of stress, emotion, or alcohol
- Other associated symptoms: Noise sensitivity, neck pain, nondermatomal paresthesias, interference with social role functioning.
- Focal neurologic deficits are typically absent on examination.

ETIOLOGY

- The inciting TBI may occur as a result of events such as falls, motor vehicle accidents, military injuries, and contact sports.
- The primary injury triggers a slew of pathophysiological changes at the cellular level secondary to the axonal stretching and injury, leading to alterations in membrane and intracellular physiology, thereby affecting neurotransmission. These changes are believed to be a factor in determining whether the outcome will be an apparent normal recovery or persistent postconcussion symptoms.
- Postmortem findings reveal diffuse axonal injury as the primary pathologic finding, along with small petechial hemorrhages and local edema.
- Prior history of anxiety is a strong risk factor for occurrence of PCS.

DIAGNOSIS

A careful history, a nonfocal neurologic examination, and normal neurologic testing will usually establish the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Headache (dissection of the vertebral artery, occipital neuralgia)
- Epidural hematoma
- Subdural hematoma
- Skull fracture
- Cervical spine disk disease
- Whiplash
- Cerebrovascular accident
- Depression
- Anxiety
- Posttraumatic stress disorder

WORKUP

To exclude other causes of neurologic symptoms after TBI:

- Normal results of electroencephalography
- Normal evoked potentials
- Neuropsychological testing, which often reveals difficulties in concentration, memory, language, and executive function

LABORATORY TESTS

Various biomarkers in blood and cerebrospinal fluid and genetic testing have been proposed and studied in patients with TBI, but these tests are not specific and are not routinely used.

IMAGING STUDIES

- There is no imaging modality to diagnose PCS. PCS is primarily a clinical diagnosis. The American College of Emergency Physicians' clinical policy regarding neuroimaging in adults with mild traumatic brain injury is summarized in Box 1.
- 10% of CT scans of the head following mild TBI are abnormal, showing mild subarachnoid hemorrhage, subdural hemorrhage, or contusions.

BOX 1 American College of Emergency Physicians' Clinical Policy Regarding Neuroimaging in Adults with Mild Traumatic Brain Injury

A noncontrast head CT is indicated (level one recommendation) in adults with LOC or posttraumatic amnesia only if at least one of the following is present:

- Headache
- Vomiting
- Age older than 60 yr
- Drug or alcohol intoxication
- Deficits in short-term memory
- Physical evidence of trauma above the clavicle
- Posttraumatic seizure
- GCS score below 15
- Focal neurologic deficit
- Coagulopathy

A noncontrast head CT should be considered (level two recommendation) in head trauma patients with no LOC or posttraumatic amnesia if any of the following is present:

- Focal neurologic deficit
- Vomiting
- Severe headache
- Age 65 yr or older
- Physical signs of a basilar skull fracture
- GCS score below 15
- Coagulopathy
- A dangerous mechanism (e.g., ejection from motor vehicle, pedestrian struck, fall of more than 3 feet or 5 stairs)

CT, Computed tomography; *GCS,* Glasgow Coma Scale; *LOC,* loss of consciousness.
From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice*, ed 7, Philadelphia, 2010, Mosby.

- MRI of the head after a mild traumatic brain injury (mTBI) is abnormal in 30% of patients with normal CT scans and may show irregular brain contours or old cerebral contusions.
- Recent improvements in imaging modalities, including diffuse tensor imaging (DTI) and susceptibility weighted imaging (SWI) in MRI, functional MRI (fMRI), and metabolic imaging such as magnetic resonance spectroscopy (MRS), positron emission tomography (PET), and single-photon emission computed tomography (SPECT) imaging, appear to be promising in elucidating the underlying pathophysiology of TBI and PCS, although they have not found a major role in clinical practice yet.
- None of the imaging modalities have been able to predict the occurrence of PCS in patients with mild TBI.

Rx TREATMENT

PCS must be recognized as a physiologic and psychological problem and treated accordingly. Treatment should be individualized to target the patient's particular symptoms and is typically completed on an outpatient basis. Some symptoms may be refractory to treatment.

NONPHARMACOLOGIC Rx

- Early reassurance and patient education are major components of treatment. Explanation of symptoms and expectations, combined with early follow-up with reassurance, may hasten resolution of symptoms.
- Graduated physical activity is preferred over prolonged cognitive and physical rest. Light aerobic activity that avoids risk for reinjury has been shown beneficial in mitigating refractory concussion symptoms. Physical and occupational therapy may be beneficial.
- Cognitive behavioral therapy may be effective in treating symptoms.
- Avoidance of alcohol, narcotics, and sleep deprivation.

PHARMACOLOGIC THERAPY

- Supportive symptomatic care may include the use of nonnarcotic analgesics and antiemetics.
- Amitriptyline has been widely used for posttraumatic tension-type headaches as well as for nonspecific symptoms such as irritability, dizziness, insomnia, and depression. Amantadine is also a consideration.
- Posttraumatic migraine-type headaches can be treated with a trial of propranolol or amitriptyline alone or in combination.
- Depression can be treated with selective serotonin reuptake inhibitors but may not respond as well when compared with patients without PCS who have depression.

DISPOSITION

- Most patients improve after mild TBI without any residual deficits within 3 mo, though the cognitive and emotional symptoms resolve more slowly.
- Although good improvement is typically seen within the first 6 mo, patients can continue to show improvement for up to 12 to 18 mo.
- Patients with very severe brain injuries (low Glasgow Coma Scale [GCS] score) and prolonged anterograde amnesia are at increased risk of development of some degree of permanent cognitive and personality disturbance.
- Predictors for the development of persistent PCS include:
  1. Female sex
  2. Ongoing litigation (conflicting studies)
  3. Low socioeconomic status
  4. Prior headaches
  5. Prior TBI
  6. Prior psychiatric illnesses, particularly anxiety

REFERRAL

Early consultations with psychologists, psychiatrists, neurologists, and rehabilitation specialists in an outpatient setting may be beneficial.

PEARLS & CONSIDERATIONS

- PCS starts within a few days after the injury.
- Recognizing depression and treating pain symptoms early in the course may help prevent the development of persistent PCS (>1 yr).
- The severity of the trauma does not clearly predict the risk of PCS and symptoms do not cluster in a predictable manner.
- The severity of brain injury is usually documented by initial GCS score, duration of loss of consciousness, and duration of amnesia; however, there is a move toward tests of function, such as neuropsychological testing or fMRI.

COMMENTS

- Attempts to determine how much of a role psychological and/or neurologic factors play in the PCS are important but very difficult.
- No medication at hospital discharge has been proved to change the natural course of the disease.
- Engaging in physical activity within 7 days after concussion is associated with a lower rate of persistent postconcussive symptoms.

BASIC INFORMATION

DEFINITION

Postherpetic neuralgia (PHN) is a pain syndrome that results as a complication of herpes zoster (HZ). HZ, also known as shingles, is a painful vesicular eruption in a dermatomal distribution. HZ is caused by the reactivation of varicella zoster virus (VZV) in someone with a known history of varicella. PHN is pain and/or dysesthesia that persist for 3 or more months at the site of resolved HZ.

ICD-10CM CODE

B02.29 Other postherpetic nervous system involvement

EPIDEMIOLOGY & DEMOGRAPHICS

INCIDENCE: PHN occurs in approximately 9% to 34% of HZ patients. It is the most frequent chronic complication of herpes zoster and the most common neuropathic pain disorder resulting from infection. In one study, approximately 60% of patients with HZ developed PHN at age 60 yr, and 75% developed PHN at age 70 yr. In another study, the incidence of PHN at 9 yr post-HZ eruption was 21%.

PEAK INCIDENCE: Unknown

PREDOMINANT SEX AND AGE:

- PHN occurs equally in males and females.
- The likelihood of developing PHN significantly increases with advancing age.

GENETICS: Family history of HZ is considered a risk factor for HZ, with higher risk if multiple family members have had HZ.

RISK FACTORS:

- Advanced age
- Greater severity of HZ prodromal pain
- Greater severity of pain during acute HZ eruption
- Location—specifically ophthalmic (V1) location and brachial plexus
- Severe immunosuppression

PHYSICAL FINDINGS & CLINICAL PRESENTATION

- HZ typically presents as a painful vesicular eruption in a dermatomal distribution. Rarely, HZ can occur subclinically with dermatomal pain in the absence of a rash.
- PHN is pain that continues for 3 months at the dermatomal site of the resolved HZ. The pain may be described as burning, stabbing, shooting, or shock-like.
- Patients may note an amplified response to stimuli at the site of PHN, with increased pain response (hyperalgesia), pain to typically nonnoxious stimuli (allodynia), or focal changes in autonomic function (e.g., increased sweating).
- Physical examination should include a comparison of sensory function in the affected dermatome with that on the contralateral side.

ETIOLOGY

PHN is associated with damage and scarring to the dorsal root ganglion secondary to inflammation related to active herpes zoster infection.

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS

Zoster sine herpete (subclinical HZ without skin eruption)

TREATMENT

ACUTE GENERAL Rx

- Administration of acyclovir or valacyclovir within 72 hours of HZ onset is thought to help reduce the likelihood of developing PNH. However, one Cochrane review paper found no difference with acyclovir administration.
- A single published study supports the use of amitriptyline (25 mg daily) as an adjunct to an antiviral agent in acute HZ to decrease the incidence of PHN and the pain associated with subsequent PHN.
- A suggestive noncontrolled study with coadministration of valacyclovir and gabapentin during acute HZ reduced the incidence of PHN as well.
- Corticosteroids do NOT prevent PHN.

CHRONIC Rx

TOPICAL TREATMENTS:

- Lidocaine 5% patches may be used for mild pain.
- Capsaicin 0.075% cream (although little reported efficacy) 5 times per day.
- Capsaicin 8% patch has greater efficacy, but overall analgesia may be minimal at best, with one third of patients unable to tolerate the agent due to burning, stinging, and erythema. However, a single 60-minute treatment with high concentration capsaicin patch was found in one study to reduce PHN for up to 12 weeks regardless of concomitant systemic neuropathic pain medication use.

ORAL TREATMENTS: First line:

- Gabapentinoids (gabapentin, pregabalin) are the only FDA-approved oral therapy for PHN and are some of the most commonly used first-line therapies for chronic PHN pain. Gabapentin may be administered in the immediate-release or extended-release formulation. Dosing includes gabapentin 300 mg 3 times a day (titrating up to max 3600 mg/day) and pregabalin 75 mg nightly (titrating up to 300 mg twice daily).
- Tricyclic antidepressants such as amitriptyline (25 mg/day, increased by 25 mg every night to a maximum of 75 mg/night), desipramine (10-25 mg/day, increased by 25 mg/day every 3 days as needed to a maximum of 150 mg/day), and nortriptyline (10-25 mg/day, increased by 25 mg/day weekly as needed to maximum of 75 mg day) are other first-line treatments. These medications have a delayed onset of action and may not work as well in patients with certain types of pain, such as burning pain or allodynia. They have a considerable side effect profile. Their use in elderly patients should be carefully considered. A recent study showed the combination of gabapentin and nortriptyline was more efficacious than either drug as monotherapy for neuropathic pain.

Second line:

- Opiates (e.g., controlled-release oxycodone): Side effects, the possibility of misuse, and the potential for abuse must be weighed.

Other modalities:

- Dorsal root entry zone (DREZ) lesions have been used with an improvement rate of 20% in long-term studies.
- For recalcitrant cases, epidural corticosteroids and nerve blocks, botulinum toxin, and cryotherapy.
- Fig. 1 describes a treatment algorithm for HZ and PHN.

COMPLEMENTARY & ALTERNATIVE MEDICINE

- Acupuncture:
  1. Studies on acupuncture and PHN pain have had varying results; however, the only randomized, controlled study showed no significant difference in pain reduction between control and treatment groups.

REFERRAL

For complicated cases, dermatology, neurology, and/or pain management input can be helpful.

PEARLS & CONSIDERATIONS

COMMENTS

- Careful consideration of treatment side effects and drug interactions is needed.
- The natural history of PHN is slow resolution, and most individuals respond to medical therapy. However, a subtype of patients may develop severe, long-lasting pain that is recalcitrant to medical therapy.
- In a questionnaire study of 385 adults age >65 yr with persistent acute pain, the mean duration of PHN was 3.3 yr.

PREVENTION

- Vaccination:
  1. A nonlive VZV vaccine (Shingrix®) is approved by the FDA for individuals age 50 and older. It is administered as two shots spaced 2 months apart and is 97% effective against shingles in people ages 50 to 69, and 91% effective against PHN in people 50 and older. It is more effective than the live attenuated VZV vaccine (zostvax).
